Cerebral metastases (Figure 43.13) are the most common intracranial tumours, and affect about one-quarter of cancer sufferers. The tumours of origin and their contribution to the burden of cerebral metastases is detailed in Table 43.5. In general, patients with multiple cerebral metastases are not suitable for surgery. Occasionally, diagnostic biopsy may be warranted where the primary is unknown. In patients with good functional status and well-controlled systemic disease, craniotomy for resection of a single metastasis, and exceptionally up to three metastases, may be considered.

Glioma

These are tumours of glial cell origin, with subtypes including astrocytomas, oligodendrogliomas, ependymomas and mixed tumours. The diagnosis is histological, but imaging often predicts both a glial origin and the grade of tumour (Figure 43.14): MRI with and without contrast is the preferred modality. If the diagnosis is in doubt, a whole-body CT scan and liver function tests may be required to help exclude an extracranial primary. Initial management should generally include steroids to alleviate any mass effect, and anti-epileptics where seizures are a presenting feature, or are likely in view of temporal location. Definitive treatment depends on the likely tumour grade in view of presentation and imaging findings. Gliomas, except for the grade I pilocytic astrocytoma which typically occurs in children, are notable for their diffuse infiltration into surrounding brain, so that recurrence after even macroscopically complete resection is the rule.

Low grade glioma (WHO Grade II) has a peak incidence in the fourth decade of life. Historically a ‘watch-and-wait’ strategy, with or without initial biopsy to confirm the diagnosis, has been applied. This reflects the natural history of progression to high grade tumour over a variable period, usually several years. The alternative, now more generally favoured, approach is to pursue initial complete macroscopic resection where feasible. However, this is based on limited evidence that progression is delayed and survival prolonged by this approach. Where tumours encroach on eloquent cortex, especially the speech areas of the dominant hemisphere, awake craniotomy allows mapping of function with surface electrodes at operation, to limit resection and minimise postoperative deficit.

High grade gliomas include anaplastic astrocytomas (WHO grade III) and glioblastomas (WHO grade IV), the most common glial tumour (Figure 43.15).
They present de novo with peak incidence in the fifth and sixth decades of life respectively, or may represent transformation of previously diagnosed, or clinically silent, low grade gliomas. Active treatment consists of maximal resection, high-dose-focused radiation therapy, and chemotherapy administered locally as carmustine wafers at the time of resection, or systemically with oral temozolomide. Median survival for glioblastoma remains just over 12 months.

Solitary metastasis represents a differential diagnosis for many gliomas, so that a chest x-ray is an important component of the work-up, and if the diagnosis is in significant doubt a whole-body CT and liver function tests to exclude an extracranial primary are required.

### Meningioma

Meningiomas are usually benign lesions, although anaplastic variants do occur. They arise from the meninges, and typically present due to mass effect from the tumour, compounded by vasogenic oedema in the adjacent brain and obstructive hydrocephalus where CSF drainage is impaired. Imaging will demonstrate a contrast-enhancing mass distinct from the brain with a dural base (Figure 43.16).

These are generally slow-growing lesions: smaller lesions, perhaps detected incidentally in an elderly patient, may well warrant a 'watch-and-wait' approach. If the lesion is large or positioned so as to impinge on key structures, the patient may require steroids and early surgery. The degree of resection predicts recurrence, with rates of 10 per cent at ten years for total excision with a clear dural margin and 30 per cent at ten years for subtotal excision. Lesions which are difficult to approach surgically may be managed with radiotherapy or stereotactic radiosurgery (Summary box 43.9).

### Summary box 43.9

**Common brain tumours**
- Metastases and gliomas are common tumours arising within brain substance, appearing as ‘ring-enhancing’ lesions on contrast CT. Surgery is usually life-extending rather than curative.
- Meningiomas arise from the meninges around the brain and typically enhance uniformly on contrast CT. Most are benign and amenable to curative resection.
- MRI brain is optimal for evaluation of these lesions. Diffusion-weighted sequences help to exclude abscess when glioma or metastasis is suspected.
- Where metastasis is suspected, CT of the body may demonstrate the primary lesion and allow staging.
- Steroids are administered to control swelling and mass effect in the short term.

**Pituitary tumours**
Most tumours in this region are benign pituitary adenomas, although the differential includes malignant variants, craniopharyngioma, meningioma, aneurysm and Rathke’s cleft cyst (Figure 43.17).

Microadenomas are less than 10 mm in size and usually present incidentally or with endocrine effects. Macroadenomas

**Figure 43.13** T1 magnetic resonance imaging (MRI) with contrast – two right occipital lung metastases are demonstrated. They are well demarcated and enhance with gadolinium contrast.

**Figure 43.14** Computed tomography (CT) with contrast demonstrates a heterogeneous right frontoparietal lesion with mass effect and midline shift, almost certainly a glioblastoma multiforme. A magnetic resonance image with and without contrast will aid evaluation.
Brain tumours

are larger than 10 mm, and often present with visual field deficits (Figure 43.17). Thirty per cent of adenomas are prolactinomas, 20 per cent are non-functioning, 15 per cent secrete growth hormone and 10 per cent secrete adrenocorticotropic hormone (ACTH).

Features of note in the initial assessment include any history of galactorrhoea (suggestive of prolactinoma), and Cushingoid or acromegalic features pointing to ACTH- or growth hormone-secreting tumours, respectively. Baseline assessment of pituitary function should include serum prolactin, follicle-stimulating hormone and luteinising hormone together with testosterone in males or oestradiol in females, thyroid function tests, and fasting serum growth hormone and cortisol. Preoperative prolactin levels are crucial since prolactinomas may be managed without the need for surgery. The cortisol level is also important, since deficiency must be corrected especially in the perioperative period. Diagnosis of ACTH-secreting tumours can be difficult, and may require the use of specialised tests, such as petrosal sinus sampling and the dexamethasone suppression test.

Effective treatment requires close cooperation between the neurosurgical team and an endocrinologist.

Prolactinomas are managed initially with dopamine agonists, such as bromocryptine and cabergoline. Growth hormone-secreting tumours may also respond to dopamine agonists, or to somatostatin analogues, such as octreotide.

Surgical resection is usually performed by a trans-sphenoidal approach, using a microscope or endoscope. Sometimes large tumours also require a craniotomy. After operation, patients are at risk of CSF leak (3 per cent) and pituitary insufficiency. Diabetes insipidus resulting from manipulation of the pituitary stalk is common in the immediate postoperative period and usually resolves spontaneously. Where it is suspected, the patient will require hourly measurement of urine output, and blood and urine samples for calculation of sodium concentration and osmolality. If confirmed, the condition can be managed with DDAVP (desmopressin) in consultation with endocrinology.

Urgent intervention is generally reserved for patients with deteriorating vision.

Pituitary apoplexy is the syndrome associated with haemorrhagic infarction of a pituitary tumour. It presents with sudden headache, visual loss and ophthalmoplegia with or without impaired conscious level. Intravenous steroids and urgent surgical decompression are required.

Harvey Williams Cushing, 1869–1939, Professor of Surgery, Harvard University Medical School, Boston, MA, USA.
Vestibular schwannoma (acoustic neuroma)

These are nerve sheath tumours arising in the cerebellopontine angle, which present with hearing loss, tinnitus and balance problems. Facial numbness and weakness are less common, while large tumours may present with features of brainstem compression or hydrocephalus. The differential diagnosis includes meningioma, metastasis and epidermoid cyst (Figure 43.18).

Small intracanalicular tumours (within the internal auditory canal) may be managed with surveillance. For intermediate size tumours, radiosurgery is an alternative to operation. Large lesions (>4 cm), especially with brainstem compression, will require excision and consideration of ventriculoperitoneal shunt to relieve hydrocephalus. Translabyrinthine, retrosigmoid and middle fossa approaches are possible, the latter options offering potential preservation of hearing in smaller tumours with some intact function at presentation. In removing larger tumours, it is often impossible to preserve hearing, or indeed facial nerve function.

Brain tumours in children

Brain tumours are the most common solid tumours in children. Neonates develop predominantly neuroectodermal tumours in supratentorial locations, including subtypes detailed below (see also Summary box 43.10):
- teratoma;
- primitive neuroectodermal tumour (PNET);
- high grade astrocytoma;
- choroid plexus papilloma/carcinoma.

Older children tend to suffer infratentorial tumours, especially:
- medulloblastoma (an infratentorial PNET);
- ependymoma;
- pilocytic astrocytoma.

Cysts

A number of benign fluid-filled intracranial lesions typically present incidentally, or with mass effect or hydrocephalus. Treatment of symptomatic or enlarging lesions is usually surgical, involving excision, endoscopic fenestration into a cistern or ventricle, or shunting for hydrocephalus.

Cyst types
- Arachnoid cyst – typically middle fossa, CSF enclosed in an envelope of arachnoid mater.
- Colloid cyst – occurs in the roof of the third ventricle, believed to represent embryonic endodermal remnants.
- Dermoid and epidermoid cysts – epithelial lined structures arising from displaced ectodermal remnants, typically in the posterior fossa (midline) and cerebellopontine angle, respectively.
- Porencephalic cysts – brain cavities lined with gliotic white matter, containing CSF in communication with the ventricles or subarachnoid space.

Neural tube defects

Failure of closure of the neural tube is associated with folic acid deficiency, family history and some anticonvulsants. Prenatal screening, using serum alphafoetoprotein levels and ultrasound, and diagnostic testing, using amniocentesis, are possible. The spectrum of conditions associated with failed closure of the posterior neuropore includes:
- Spina bifida occulta: a congenital absence of a spinous process, without exposure of meninges or neural tissue, but presenting a characteristic shallow hair-covered hollow at the base of the spine. This is common and rarely clinically significant. Sometimes it may be associated with tethered cord syndrome,
which involves thickening of the filum terminale, resulting in traction on the cord. Presentation is with progressive deficits, spasticity, bladder dysfunction or scoliosis, and treatment involves surgical exploration and untethering of the cord.

- Meningocele: a sac of meninges, covered by skin and containing CSF alone, herniates through an anterior or posterior bony defect.
- Myelomeningocele: a herniating sac of meninges without covering skin contains spinal cord, nerves or both. This is always associated with Chiari II malformation (see below). Open myelomeningocele presents a high infection risk and requires early surgical repair.
- Lipomyelomeningocele: adipose tissue adherent to the spinal cord herniates through a bony defect to the sacrolumbar soft tissue. This may be associated with bladder dysfunction and requires surgical relief of the resultant cord tethering.

Failure of closure of the anterior neuropore produces anencephaly, which is uniformly fatal – the spectrum of spinal dysraphisms, however, is replicated in the skull. Cranium bifidum is a failure of fusion, often in the occipital region. This may be associated with herniation of meninges and CSF (meningocele), and potentially also brain substance (encephalocele) (Figure 43.19).

**Posterior fossa malformations**

Chiari malformations involve cerebellar herniation through the foramen magnum:

- Normal: Up to 5 mm of cerebellar tonsillar descent through the foramen magnum
- Chiari I: >5 mm of tonsillar descent: presents typically in young adults with headache and variable neurological disturbance
- Chiari II: descent of the tonsils and vermis: presents in infancy with poor feeding, stridor and apnoeic episodes.

They are often associated with syringomyelia, the presence of a fluid-filled cavity (syrinx) in the spinal cord. Compression of the brainstem and cerebellum, or development of a syrinx, may cause neurological deficits. Shunting and foramen magnum decompression are the mainstay of treatment. Chiari malformations may also present incidentally or with headaches exacerbated by valsalva.

Dandy Walker malformations present in infancy with macrocephaly, developmental delay and hydrocephalus; most patients have associated abnormalities in the CNS and other organ systems. Imaging demonstrates a hypoplastic cerebellar vermis, with the posterior fossa occupied by a large thin-walled cyst. Treatment usually involves shunt placement.

**Craniosynostosis**

Normal fusion of the coronal, lambdoidal, squamosal and sagittal sutures occurs between six and 12 months of age; others, such as the frontal suture fuse later. Craniosynostosis is the premature fusion of one (simple craniosynostosis) or more (complex craniosynostosis) cranial sutures, preventing growth perpendicular to the suture. This results in a range of skull deformities (see Table 43.6; Figures 43.20 and 43.21) and hydrocephalus. Syndromic craniosynostosis, often associated with abnormalities of the fibroblast growth factor receptor genes, is accompanied by developmental delay and other abnormalities. The surgical treatment aims to correct deformity and prevent development of raised ICP (Summary box 43.11).

**Summary box 43.11**

Paediatric neurosurgery

Children manifest a range of developmental pathologies requiring neurosurgical management including:

- cysts
- neural tube defects
- posterior fossa abnormalities
- craniosynostosis

In general, intracranial pathologies present with features including developmental delay, seizures, macrocephaly and hydrocephalus.

**FUNCTIONAL NEUROSURGERY**

Where neurosurgery normally seeks to avoid disturbing neural tissue as far as possible, functional procedures aim to relieve epilepsy, movement disorders or pain by ablation or stimulation.

**Epilepsy**

Up to 10 per cent of the population will suffer a seizure at some point in their lives, and epilepsy, a syndrome of recurrent unprovoked seizures, represents the most common neurological...
disorder. About 20–30 per cent of patients fail to achieve adequate seizure control with drugs, and many of these focal epilepsies may benefit from surgery. Where a primary lesion, such as a tumour, arteriovenous malformation (AVM) or cavernoma is present, lesionectomy alone may be appropriate. In other cases, the clinical picture including seizure type, focal features and investigation results can be used to identify the seizure focus. Dual pathology refers to the presence of an extrahippocampal lesion plus hippocampal atrophy, important because removal of both the lesion and the atrophic hippocampus is the best surgical approach and should be considered whenever possible.

**Investigation**

MRI imaging is a mainstay, demonstrating for example reduced hippocampal volume and distorted architecture in mesial tem-
poral sclerosis. Nuclear medicine modalities including single-photon emission computed tomography (SPECT) and positron emission tomography (PET) are sometimes used to demonstrate ictal and inter-ictal metabolic abnormalities.

Electroencephalography (EEG) entails recording from an array of scalp electrodes, and comparison between ictal and inter-ictal recordings. This is especially helpful in lateralisating the focus of complex partial seizures in temporal lobe epilepsy, and is combined with video monitoring of the seizure in a video-telemetry suite. A more detailed localisation may be achieved invasively by the preoperative placement of subdural or depth electrodes, preoperatively or by intraoperative electrocorticography (ECoG).

Neuropsychological evaluation is used to evaluate the patient’s preoperative function looking for concordant focal impairments, and, using the Wada test where sodium amytal is injected into each internal carotid artery in turn, with simultaneous speech and memory testing to localise function. The aim is to establish language laterality and to confirm that resection on the side of the lesion will not significantly impair verbal memory function.

**Surgical management**

The seizure focus may be resected, generally where it is in non-eloquent brain, or otherwise a disconnection can be performed. Awake craniotomy, allowing mapping particularly of speech centres, is increasingly employed.

Mesial temporal epilepsy is commonly medically refractory and can be addressed surgically by amygdalohippocampectomy or resection of the temporal lobe including the mesial structures. The extent of resection is limited by the potential for damage to the optic tracts, and to speech areas in the dominant hemisphere. With careful patient selection, cure rates of up to 70 per cent or greater can be achieved.

Functional, or rarely anatomical, hemispherectomy (Figure 43.22) may be performed for specific epilepsy syndromes associated with hemiplegia, such as infantile hemiplegia syndrome. This is usually considered in the early years of life when plasticity and potential for functional recovery is greatest.

Disconnection procedures include corpus callosotomy, used for patients suffering drop attacks, and subpial transections to isolate a seizure focus in eloquent brain from the surrounding cortex.

Vagal nerves stimulators are implanted in severe drug refractory epilepsy, usually in children, and can achieve some success in reducing seizure frequency, although the mechanism is unclear, and is never curative.

**Movement disorders**

Prior to the advent of levodopa, surgical ablation of the subthalamic nucleus or globus pallidus interna was a mainstay of management for Parkinson’s. Inhibition of the action of these centres remains a valuable tool later in the course of the disease as the therapeutic window using levodopa narrows, but this is now generally achieved using deep brain stimulation with electrodes. This offers the advantage of an adjustable and reversible effect, and can be performed bilaterally where equivalent lesioning surgery would likely result in deficits.

![Coronal T2-weighted magnetic resonance imaging scan image following an anatomical hemispherectomy.](image)

Deep brain stimulation is also an option for other movement disorders where less invasive approaches are ineffective. These include dystonias, which may be amenable to bilateral stimulation of the globus pallidus interna, and essential tremor where the ventral intermediate nucleus of the thalamus is the target.

**Pain syndromes**

Neurosurgical approaches to the relief of pain may address the underlying aetiology directly, or may seek to interrupt or modulate the transmission responsible for the pain. The contrasting approaches are demonstrated in the management of trigeminal neuralgia. This manifests, generally in middle age or later, with paroxysmal lancinating pain in the distribution of one or more divisions of the trigeminal nerve. The pain occurs without other neurological disturbance, and may be triggered by trivial stimuli such as eating or brushing the teeth. The pain was first attributed to stimulation of the nerve by an adjacent vascular structure, often the superior cerebellar artery, by Walter Dandy. Occasionally, another primary lesion is responsible; for example, bilateral trigeminal neuralgia in younger patients is suggestive of multiple sclerosis. Where medications, such as gabapentin and carbamazepine cannot achieve control, surgical options include:

- Craniotomy and microvascular decompression: this is designed to address the proposed origin of the neuropathic pain, by applying material between the nerve and adjacent vessel to prevent direct contact and stimulation. It achieves long-lasting relief of symptoms in about 80 per cent of patients,
but is associated with the standard risks of craniotomy (see below Risks of craniotomy, p. 19) and a significant incidence of cranial nerve deficit.

- Peripheral nerve injections, which can achieve good short-term relief of pain restricted to small areas supplied by terminal branches of the trigeminal.
- Percutaneous Gasserian rhizolysis: this involves needle placement under x-ray guidance at the Gasserian ganglion in Meckel’s cave. This permits lesioning of the ganglion by glycerol injection, radiofrequency thermocoagulation or balloon compression, with the aim of disrupting aberrant pain transmission. A similar effect can also be achieved using stereotactic radiosurgery. Facial numbness and late recurrence of pain are common after these procedures.

Treatment of pain elsewhere may also be based on lesioning of nerve tracts. For example, pain related to brachial plexus infiltration or injury may be treated by sectioning the spinothalamic tract (cordotomy), or the dorsal root entry zone (DREZ operation). These approaches are limited by the potential for producing deficits, and especially by the occurrence of deafferentation (‘phantom limb’) pain syndromes which are particularly unpleasant and difficult to treat.

Electrical stimulation is used to modulate pain transmission; for example, spinal cord stimulators can be applied to a range of pain syndromes, especially those associated with failed spinal surgery. Deep brain stimulation targeting the periaqueductal grey and sensory thalamic nuclei has a role in chronic pain arising in the context of thalamic stroke. Implanted devices may also be used for intrathecal delivery of opiates for pain control, or baclofen to alleviate spasticity (Summary box 43.12).

Summary box 43.12

**Functional neurosurgery**

- Intractable epilepsy can be treated surgically by implantation of a vagal nerve stimulator or by resection of one or more seizure foci
- Deep brain stimulation using implanted electrodes has largely replaced lesioning of these structures for management of drug-refractory Parkinson’s disease
- Microvascular decompression is offered for trigeminal neuralgia, and other neuropathic pain syndromes may respond to lesioning of nerve tracts

**OCCLUSIVE VASCULAR DISEASE**

There is class 1 evidence for the role of carotid endarterectomy in reducing the risk of stroke in patients with symptomatic carotid stenosis, and a debatable role for the procedure in patients with no previous transient ischaemic episodes.

In a subgroup of otherwise fit patients with completed posterior fossa or non-dominant middle cerebral artery territory infarcts, there is a role for decompressive craniectomy in the acute setting to manage the brain swelling and raised ICP associated with the infarct.

Moya moya disease is the progressive obliteration of one or both internal carotid arteries, thought to represent an autoimmune process. The development of external carotid circulation collaterals produces the angiographic ‘puff of smoke’ appearance responsible for this Japanese-derived name. It presents in youth or early middle age with ischaemia or haemorrhage. Untreated, the majority of patients suffer major deficit or die within two years. Ischaemia may be addressed by a variety of bypass techniques, for example by anastomosing the superficial temporal artery (arising from the external carotid) to the middle cerebral artery.

**COMPRESSIVE NEUROPATHIES**

Carpal tunnel syndrome is a compression neuropathy resulting from entrapment of the median nerve under the flexor retinaculum at the wrist. Risk factors include diabetes, obesity, thyroid disorders and acromegaly. The presentation is usually with paraesthesia in the hand, worse at night. Examination will reveal sensory disturbance in the median nerve distribution – the palmar aspect of the thumb, index and middle fingers, and the radial aspect of the ring finger. The palm itself is relatively spared, reflecting supply by the palmar cutaneous branch passing superficial to the retinaculum. Wasting of the thenar eminence, and weakness of abductor pollicis brevis may also be apparent, and tapping over the carpal tunnel (Tinel’s test) or wrist flexion (Phalen’s test) may reproduce symptoms. Nerve conduction studies confirm the diagnosis, and management includes wrist splints, steroid injections, and carpal tunnel decompression by division and release of the flexor retinaculum.

A range of related peripheral mononeuropathies, characterised by sensory disturbance, wasting and weakness in the nerve distribution, are investigated using nerve conduction studies, and are typically amenable to surgical decompression. Common examples include:

- **Ulnar nerve entrapment at the elbow:** the sensory disturbance affects the little finger and ulnar aspect of the ring finger, and wasting of the hypothenar eminence may be evident. Froment’s sign is elicited by asking the patient to hold a piece of paper in the first web space while the examiner attempts to slide it away; the distal phalanx of the thumb is seen to flex, reflecting the use of flexor pollicis longus (anterior interosseous innervated) instead of adductor pollicis (ulnar innervated, so weak).
- **Meralgia paraesthetica:** the lateral cutaneous nerve of the thigh is compressed under the inguinal ligament, producing sensory disturbance in the lateral thigh.

**PRACTICAL AND ETHICAL ISSUES**

**Creutzfeldt–Jakob disease**

CJD is a rare transmissible spongiform encephalopathy producing a rapidly progressive dementia, and is uniformly fatal. The causative agent seems to be a mis-folded protein, a prion, which is not destroyed by conventional sterilisation techniques. UK practice involves undertaking preoperative checks to exclude any risk factors for CJD infection. These include family history,

George S Phalen, contemporary, orthopaedic surgeon and Chief of Hand Surgery, The Cleveland Clinic, Cleveland, OH, USA. He helped to establish the American Society for Surgery of the Hand.

Jules Froment, 1878–1946, Professor of Clinical Medicine, Lyons, France.
receipt of pituitary-derived human growth hormone, cadaveric dura mater grafts, and previous brain or spinal surgery prior to 1997. Where risk factors are present, instruments must be quarantined or destroyed postoperatively.

**Risks of craniotomy**
The risks associated with craniotomy are important to appreciate in discussing operations with patients and family, and in evaluating patients who deteriorate postoperatively. The figures quoted in brackets will vary significantly between individual procedures and even between centres:
- infection (5 per cent) and wound breakdown;
- intracerebral haemorrhage;
- seizures;
- CSF leak;
- permanent neurological deficit;
- death (1 per cent).

**Brainstem death**
This is defined as the irreversible loss of cerebral and brainstem function. Brainstem death is legally equivalent to death, and is a pre-condition for the harvesting of organs for transplant from heart-beating donors.

Diagnosis requires:
- identification of the cause of irreversible coma;
- exclusion of reversible causes of coma;
- clinical demonstration of the absence of brainstem function.

In the UK, this entails testing twice, by two clinicians, to demonstrate the absence of:
- response to pain;
- respiratory drive (apnoea despite a pCO2 >6.7 kPa);
- pupillary light reflex;
- corneal reflex;
- vestibulo-ocular reflex;
- oculocephalic reflex;
- gag reflex.

**FURTHER READING**
**OCULAR ANATOMY**

**Adnexae**
The lids comprise skin, connective tissue, the orbicularis oculi (VIIth cranial nerve) and the tarsal plate, with multiple meibomian glands opening posterior to the lashes and lined with conjunctiva, which is reflected onto the sclera. The upper lid is elevated by the levator muscle (IIIrd cranial nerve) and has a horizontal strip of sympathetically innervated Müller’s muscle, giving rise to 2 mm of ptosis in Horner’s syndrome. Both lids are attached to the orbital rim by the medial and lateral canthal tendons. Both have a rich vascular supply and are innervated by the V1 division of the trigeminal nerve (Vth cranial nerve) above and the V2 division below.

**Lacrimal system**
The almond-shaped lacrimal gland lies under the upper outer orbital rim and opens into the upper conjunctival fornix through 10–15 ducts. Tears are swept across the globe by the lids and evaporate or pass into the upper and lower lid puncta, and then into the canaliculi to join the common canaliculus, which passes into the lacrimal sac under the medial canthal tendon. The sac is drained by the nasolacrimal duct into the nose, opening in the inferior meatus under the inferior turbinate.

**The globe**
The cornea is the 12-mm diameter window of the eye, 0.5 mm thick centrally; its clarity is due to the regular arrangement of collagen bundles and relative dehydration. It merges into the sclera at the corneoscleral junction (the limbus), the insertion of the bulbar conjunctiva. The sclera, which is 1 mm thick, comprises four-fifths of the wall of the eye, and gives attachment to the extraocular muscles. It is perforated by the long and short posterior ciliary arteries and the vortex veins and is contiguous with the optic nerve sheath. The uvea comprises iris, ciliary body and vascular choroid. The optic nerve is continuous with the retina and retinal pigment epithelium. The most sensitive part of the retina, the macula, lies at the posterior pole within the vascular arcade. The biconvex lens and capsule are suspended by the suspensory ligament, over 300 tiny fibres attached to the ciliary muscle. Aqueous humour arises from the ciliary processes, hydrates the vitreous gel, passes through the pupil into the anterior chamber between the iris and the cornea and then drains out through the trabecular meshwork into Schlemm’s canal in the drainage angle. The inner retina is supplied by the central retinal artery and drained by the central retinal vein (Figure 44.1).

**Orbit**
The orbit is four-sided and pyramidal in structure, housing the globe, optic nerve, the four rectus and two oblique muscles, the lacrimal gland, orbital fat, the IIIrd, IVth, Vth and VIth cranial

---

**LEARNING OBJECTIVES**

To understand and appreciate:
- The common ocular disorders and recognise ophthalmic symptoms and specific signs

- The value of special investigations
- When specialist referral is appropriate
nerves, the ophthalmic artery with its tributaries and the ophthalmic veins, which anastomose anteriorly with the face and posteriorly with the cranial cavity. Above is the frontal lobe of the brain, temporally the temporal fossa, inferiorly the maxillary sinus and nasally the lacrimal sac and ethmoidal and sphenoidal air sinuses. The optic nerve passes through the optic canal to the chiasm, with other nerves and vessels passing through the superior ophthalmic fissure.

**PERIORBITAL AND ORBITAL SWELLINGS**

**Swellings related to the supraorbital margin**

**Dermoid cysts**

Dermoid cysts are usually external angular cysts although they may occur medially (Figure 44.2). They often cause a bony depression by their pressure and they may have a dumbbell extension into the orbit. They can also erode the orbital plate of the frontal bone to become attached to dura and for this reason it is important to image the area by computed tomography (CT) before excision.

**Neurofibromatosis**

Neurofibromatosis may also produce swellings above the eye. The diagnosis can usually be confirmed by an examination of the whole body, as there are often multiple lesions. Proptosis can also result (Figure 44.3). Other ophthalmic features may be present.

**Swellings of the lids**

**Meibomian cysts (chalazion)**

These are the most common lid swellings (Figure 44.4). A meibomian cyst is a chronic granulomatous inflammation of a meibomian gland. It may occur on either upper or lower lids and presents as a smooth, painless swelling. It can be felt by rolling the cyst on the tarsal plate. It can be distinguished from a stye (hordeolum), which is an infection of a hair follicle and is usually painful. Persistent meibomian cysts are treated by incision and curettage from the conjunctival surface. Styes are treated by antibiotics and local heat.

**Basal cell carcinomas (rodent ulcers)**

This is the most common malignant tumour of the eyelids (Figure 44.5). It is locally malignant, is more common on the lower lids and usually starts as a small pimple that ulcerates and has raised edges (‘rodent ulcer’). It is easily excised in the early stages. Histological confirmation that the excision is complete is required. More extensive lesions may require specialist techniques, such as Mohs’ micrographic surgical excision controlled by frozen section. Local radiotherapy or cryotherapy can be carried out; however, recurrence is more common, more aggressive and more difficult to detect (Summary box 44.1).

---

Heinrich Meibom (Meibomius), 1638–1700, Professor of Medicine, History and Poetry, Helmstadt, Germany, described these glands in 1666.
Summary box 44.1

Basal cell carcinomas
- Basal cell carcinomas are the most common malignant eye tumour
- Treatment is by excision with care with histopathological margin control
- All unusual lesions (especially in the elderly) should be biopsied

Other lid swellings
Other types of lid swelling can occur but they are less common. They include sebaceous cysts, papillomas, keratoacanthomas, cysts of Moll (sweat glands) (Figure 44.6) or Zeis (sebaceous glands) and molluscum contagiosum. When molluscum contagiosum occurs on the lid margin, it can give rise to a mild viral chronic keratoconjunctivitis and should be curetted or excised.

Carcinoma of the meibomian glands and rhabdomyosarcomas are rare lesions; they need to be treated by radical excision. Atypical or meibomian cysts that recur should be biopsied.

Swellings of the lacrimal system

Lacrimal sac mucocele
This occurs from obstruction of the lacrimal duct beyond the sac and results in a fluctuant swelling that bulges just below the medial canthus. It can become infected to give rise to a painful tense swelling (acute dacryocystitis). If untreated it may give rise to a fistula. Treatment is by performing a bypass operation between the lacrimal sac and the nose (a dacryocystorhinostomy (DCR)). Watering of the eye can occur due to eversion of the lower lid (ectropion), which causes loss of contact between the lower punctum and the tear film, or from reflex hypersecretion as a result of irritation of inturned lashes in entropion, and these must be distinguished from a mucocoele.

Lacrimal gland tumours
These are swellings of the lacrimal glands, which lie in the upper lateral aspect of the orbit. Eventually, they lead to impairment of ocular movements and displacement of the globe forwards, downwards and inwards. Pathologically the tumours resemble parotid tumours and they can be pleomorphic adenomas with or without malignant change, carcinomas or mucoepidermoid tumours.

Orbital swellings
Orbital swellings result in displacement of the globe and limitation of movement. A full description of orbital swellings is outside the realm of this text but some of the most common causes include the following:
- Pseudoproptosis. This results from a large eyeball, as seen in congenital glaucoma or high myopia.
- Orbital inflammatory conditions that result in orbital cellulitis (Figure 44.7).
- Haemorrhage after trauma or retrobulbar injection.
- Neoplasia affecting the lacrimal gland, the optic nerve, the orbital walls or the nasal sinuses, e.g. glioma (neurofibromatosis) (see Figure 44.3), meningioma and osteoma (Figure 44.8).
- Dysthyroid exophthalmos (Figures 44.9, 44.10 and 44.11). This may be unrelated to active thyroid disease but can start after thyroidec- tomy and may need urgent tarsorrhaphy, large doses of steroids or even orbital lateral wall decompression if the eyeball is threatened by exposure or optic nerve compression. CT and magnetic resonance imaging (MRI) scans are useful in diagnosis.
Intraocular tumours

- Pseudotumour, or malignant lymphoma.
- Haemangiomas of the orbit (Figure 44.12).
- Tumour metastases. These are rare. In children they usually arise from neuroblastomas of the adrenal gland, whereas in adults the oesophagus, stomach, breast and prostate can be sites of primary lesions.

Diagnostic aids
Diagnostic aids include radiography, CT, MRI, ultrasonography and, less commonly, tomography and orbital venography.

Treatment
Treatment is directed to the cause of the lesion if at all possible, taking care to prevent exposure of the eye, diplopia or visual impairment from optic nerve compression.

INTRAOCULAR TUMOURS

Children
Retinoblastoma is a multicentric malignant tumour of the retina, which can be bilateral. Some are sporadic, but many are hereditary. Children with a family history should be carefully monitored from birth. It is often not spotted until the tumour fills the globe and presents as a white reflex in the pupil or as a squint (Figure 44.13). The differential diagnosis includes retinopathy of prematurity, primary hyperplastic vitreous and intraocular infections. If the tumour is large, enucleation may be required, but radiotherapy, cryotherapy, chemotherapy or laser treatment can cure small lesions. Liaison with a paediatric oncologist is essential (Summary box 44.2).
626  THE EYE AND ORBIT

Summary box 44.2

Intraocular tumours
- All children with a squint should have a fundal examination to exclude a retinoblastoma
- A blind painful eye may hide a melanoma

Adults

Malignant melanoma is the most common tumour and it originates in the pigment cells of the choroid (Figure 44.14), ciliary body or iris. It can present with a reduction in vision, a vitreous haemorrhage or by the chance finding of an elevated pigmented lesion in the eye. Tumour growth is variable but, as a general rule, the more posterior the lesion, the more rapidly progressive it is likely to be. Spread may be delayed for many years; however, the liver is frequently involved, hence the advice ‘beware of the patient with a glass eye and an enlarged liver’. Treatment is by light or laser coagulation, radioactive plaque, radiotherapy, enucleation and, in selected cases, local excision using hypotensive anaesthesia. Diagnosis is made by direct observation and/or ultrasound, which shows a solid tumour (Figure 44.15).

INJURIES INVOLVING THE EYE AND ADJACENT STRUCTURES

Corneal abrasions and ulceration

The cornea is frequently damaged by direct trauma or by foreign bodies (Figure 44.16). Ulceration can occur with infection or after damage to the facial nerve. Post-herpetic ulceration is common and serious if not treated. Fluorescein instillation illuminated by blue light shows up corneal ulceration at an early stage (Summary box 44.3).

Summary box 44.3

Corneal abrasions
- A drop of fluorescein dye illuminated by a blue light reveals even the smallest corneal abrasion

Treatment is by protection (eye pads, tarsorrhaphy or a bandage contact lens) and antibiotics topically and rarely systemically: 0.5 per cent chloramphenicol or ofloxacin eye drops.
drops are commonly used. The eye is made more comfortable by the use of mydriatics, such as homatropine or cyclopentolate. Herpes simplex dendritic ulcers are treated with aciclovir ointment. In countries in the Far and Middle East, chronic infection with trachoma can cause corneal opacification and blindness. Corneal grafting is the only cure for an opaque cornea. Until recently, full thickness penetrating keratoplasty was the only corneal graft technique. This has largely been replaced by lamellar or partial thickness graft surgery, in a technique termed DSEK or ‘Descamets stripping endothelial keratoplasty’. Rarely, osteo-odonto keratoprosthesis can be attempted in very severe cases of opaque corneas that are not suitable for grafting. Acanthamoeba is a rare serious cause of corneal infection. This infection usually follows the use of contact lenses. Specialist management and treatment is recommended.

### Blunt injuries to the eye and orbit

The floor of the orbit is its weakest wall and in blunt trauma, such as a blow from a fist, it is often fractured without fractures of the other walls. This is called a blow-out fracture. Clinical signs are enophthalmos, bruising around the orbit, maxillary hypoaesthesia, limitation of upward gaze due to entrapment of the inferior rectus muscle leading to vertical diplopia. This occurs when the extraocular muscles or orbital septa become trapped in the fracture and can be identified as a soft-tissue mass in the antrum on a radiograph (Figure 44.17), although CT scans or tomograms may be necessary. Surgical repair of the orbital floor with freeing of the trapped contents may be necessary if troublesome diplopia persists or enophthalmos is marked. A child with an orbital floor fracture requires urgent assessment as a ‘greenstick’ fracture can result in ischaemia of a trapped inferior rectus muscle and may require urgent surgery. If an orbital haemorrhage is too extensive to examine the eye, it may be necessary to examine the eye under anaesthesia because there may be a hidden perforation of the globe. Injuries to the lids and lid margins must be repaired, and if the lacrimal canaliculi are damaged they should be repaired if possible, especially the lower canaliculus as 75 per cent of tear drainage goes through it.

Blunt injuries can also cause damage to the optic nerve, which can result in blindness and a total afferent pupillary defect (Figures 44.18 and 44.19).

### Concussion injuries

Concussion injuries of the eye can give rise to several problems, which include the following:
- **Iritis**. Inflammation, treated with topical steroids.
- **Hyphaema** (blood in the anterior chamber) (Figure 44.20). Rest and sedation, particularly in children, are advised because the main danger in this condition is secondary bleeding, resulting in an acute rise in intraocular pressure and blood staining of the cornea. The use of antifibrinolytic agents (e-aminocaproic acid) has been advocated and, if the pressure rises, surgery to wash out the blood may be necessary.
Subluxation of the lens. This is suspected if the iris, or part of the iris, ‘wobbles’ on movement (iridodonesis).

Secondary glaucoma. This is often associated with recession of the drainage angle.

Retinal and macular haemorrhages and choroidal tears (Figure 44.21).

Retinal dialysis. This may lead to a retinal detachment and permanent damage to vision (Figure 44.22).

Penetrating eye injuries

These occur when the globe is penetrated, often in road traffic and other major accidents (Figure 44.23), and also in injuries from sharp instruments. The compulsory wearing of seatbelts in motor vehicles has substantially reduced the incidence of this type of eye injury, by up to 73 per cent in the UK. The presence of an irregular pupil suggests prolapse of the iris and should arouse the suspicion of a penetrating injury. Treatment is prompt primary repair to restore the integrity of the globe. If a perforation is suspected, extensive eye examination should not be attempted before anaesthesia because this may lead to further extrusion of the intraocular contents. If the fundal view is poor, ultrasonography and orbital imaging are indicated. Secondary corneal grafting, lensectomy and vitrectomy have considerably improved the visual prognosis; these must be done by an experienced eye surgeon. Injuries to the optic nerves must also be excluded in severe accidents.

Intraocular foreign bodies

Intraocular foreign bodies must always be excluded when patients attend the accident and emergency department with an eye injury and a history of working with a hammer and chisel or a history of a potentially high-velocity injury. Radiography of the orbits should always be performed, and ferrous and copper foreign bodies should always be removed, sometimes requiring the use of a magnet. B-scan ultrasonography can also assist in localising foreign bodies when a vitreous haemorrhage or cataract is present. CT can be used, but MRI is contraindicated (Summary box 44.4).

Summary box 44.4

Penetrating eye injuries

- A distorted and irregular pupil warrants the careful exclusion of a penetrating eye injury

Burns

Radiation burns

These occur following exposure to ultraviolet radiation after arc welding or excessive sunlight (snow blindness) and sun lamps. Such burns cause intense gritty burning pain and photophobia as a result of keratitis (corneal inflammation), which starts some hours after exposure. Mydriatic and local steroids with anti-biotic drops ease the condition, and healing usually occurs after 24 hours.

Thermal burns

If these involve the full thickness of the lids, corneal scarring may occur from exposure, and immediate corneal protection is necessary. A splash of molten metal may cause marked local necrosis and may lead to permanent corneal scarring. Treatment...
is to remove any debris by irrigation and to instill local atropine, antibiotics and steroids to prevent superadded infection and scarring. Lid reconstruction may be necessary.

Chemical burns
Chemical burns, and especially alkali burns, can be serious because ocular penetration occurs quickly and ischaemic necrosis can result (Figure 44.24). Immediate copious irrigation until the pH is neutral will ensure that the chemical is diluted as much as possible, and all particles should be removed from the fornices. Treatment can then be continued as with thermal burns. Well-fitting goggles should prevent such injuries.

DIFFERENTIAL DIAGNOSIS OF THE ACUTE RED EYE
This is important in the management of minor ocular complaints and the recognition of conditions that require expert attention. Possible causes of the acute red eye include:

- subconjunctival haemorrhage
- conjunctivitis
- keratitis
- uveitis
- episcleritis and scleritis
- acute glaucoma.

Any condition with pain, visual impairment or a pupil abnormality suggests a more serious diagnosis.

Subconjunctival haemorrhage
This presents as a bright-red eye, often noticed incidentally, with only minimal discomfort and normal vision. Causes include coughing, sneezing, minor trauma, hypertension and, rarely, a bleeding disorder. Reassurance and treatment of the underlying cause are required. Most settle within a week, but can recur.

Conjunctivitis
Symptoms are grittiness, redness and discharge. Causes are infective, chemical, allergic or traumatic. In the newborn, it can be serious; gonococcal and chlamydial infection must be excluded. Bacterial conjunctivitis is purulent, usually self-limiting and treated with topical broad-spectrum antibiotics. Chlamydia and adenovirus infections must be considered. Adenoviral infections are common and usually affect one eye much more in severity and onset, tending to be more watery than sticky, and are often associated with a palpable preauricular gland.

Vernal conjunctivitis (Figure 44.25) is a form of allergic conjunctivitis, characterised by itchy eyes, usually worse in the spring and early summer and often associated with other allergic problems such as hay fever. Clinically, most signs are under the upper lid, which may have a cobblestone appearance instead of a smooth surface.

Giant pupillary conjunctivitis with large papillae under the upper lid may be seen in soft contact lens wearers. This is usually caused by an allergy to the sterilising solutions and lens protein and may be helped by either using a preservative-free solution or using daily-wear disposable lenses.

Kaposi’s sarcoma can rarely present like a subconjunctival haemorrhage (Figure 44.26).

Considerable conjunctival and corneal irritation can be caused by the lids turning in (entropion) (Figure 44.27) or turning out (ectropion) (Figures 44.28 and 44.29), and by ingrowing lashes. The lids should be repaired surgically to their normal position.
Vision is not commonly affected in conjunctivitis but, with some viral infections, a keratitis may be present and result in visual impairment and pain. All of the other conditions described below are painful and usually affect vision.

**Keratitis (inflammation of the cornea)**

Herpes simplex infection presents as a dendritic (branching) ulcer, shown easily by staining with fluorescein or Bengal Rose. It is treated with aciclovir ointment five times per day. The use of steroid drops must be avoided as this can make the condition much worse (Figure 44.30).

Corneal ulceration may occur as a result of ingrowing lashes or corneal foreign bodies, marginal ulceration and infected abrasions. Infected ulcers can occur in patients wearing soft contact lenses or elderly immunocompromised individuals. Herpes zoster (shingles) may affect the ophthalmic division of the Vth nerve and can give rise to a keratitis and uveitis. It is important to avoid the use of steroid drops until a diagnosis has been made. Local anaesthetic drops should also not be given on a regular basis.

**Uveitis**

This can be anterior (iritis) or, more rarely, posterior. In anterior uveitis, the pupil will be small, sometimes irregular, there is circumcorneal injection and there may be keratic precipitates present on the posterior surface of the cornea. Pain, photophobia and some visual loss are usually present. Posterior uveitis can present with a white eye and blurred vision. It usually takes a chronic course. Granulomatous diseases, Behçet’s disease, Reiter’s syndrome, toxoplasmosis and cytomegalovirus infection should be excluded. Topical systemic steroids and, sometimes, immunosuppressive drugs are useful in treating these conditions.

**Episcleritis and scleritis**

Episcleritis or inflammation of the episcleral tissue often occurs as an idiopathic condition (Figure 44.31).

Scleritis is a less common, more serious, condition in which the deeper sclera is involved. There is often an associated uveitis...
and severe pain. Thinning of the sclera may result. Systemic non-steroidal anti-inflammatory drugs (NSAIDs) or steroids may be required to treat the condition adequately.

Scleritis is often associated with severe rheumatoid conditions. The presence of scleritis suggests that there is active systemic disease and it requires systemic work-up including renal function tests.

**Acute glaucoma**
This usually occurs in older, often hypermetropic, patients. The cornea becomes hazy, the pupil oval, dilated and non-reacting, the vision poor and the eye feels hard. In severe cases, pain may be accompanied by vomiting and the condition can be mistaken for an acute abdominal problem. Tonometry (intraocular pressure measurement) is diagnostic. Urgent treatment to reduce the pressure with pilocarpine, acetazolamide and, if refractory, mannitol should be started, followed by YAG laser iridotomy or surgical iridectomy. The condition is usually bilateral and the second eye usually needs a prophylactic iridotomy at the same time.

Except for a simple conjunctivitis and subconjunctival haemorrhage, which are self-limiting, the management of an acute red eye requires expert treatment and a specialist opinion should be sought. A painful eye with a IIIrd nerve palsy (ptosis, dilated pupil, globe down and out) often signifies an intracranial aneurysm and should be investigated immediately.

**Painless Loss of Vision**
This may occur in one or both eyes, and the visual loss may be transient or permanent. Possible causes are:

- **Acute:**
  - obstruction of the central retinal artery (Figure 44.32);
  - obstruction of the central retinal vein (Figure 44.33);
  - ischaemic optic neuropathy;
  - migraine and other vascular causes;
  - vitreous and retinal haemorrhages;
  - retinal detachment (Figure 44.34);
  - macular hole, cyst or haemorrhage;
  - cystoid macular oedema, often after surgery;
  - hysterical blindness.

- **Chronic:**
  - cataract;
  - glaucoma;
  - macular degeneration;
  - diabetic retinopathy;

Specialist help should be sought in any case of loss of vision. The erythrocyte sedimentation rate and C-reactive protein should be measured immediately if cranial arteritis is suspected, and the carotid system should be examined for bruits and other signs of arteriosclerosis in cases of ischaemic optic neuropathy and central retinal artery occlusion. Glaucoma, hypertension, hyperviscosity syndromes and diabetes should be looked for in cases of central vein thrombosis.

**Recent Developments in Eye Surgery**
In the last three decades, eye surgery has become a microsurgical specialty. Cataract surgery has been transformed by changes in local anaesthesia, implants, phacoemulsification and small-incision surgery, which allow compressible/foldable silicone or acrylic implants to be inserted through a 2-mm incision. The implant power can be more accurately measured by new formulae and the use of A-scan ultrasonography or laser wavefront...
biometry, and multifocal and accommodative lenses are now available.

There are new treatments for eye disorders that involve abnormal growth of blood vessels in the back of the eye, such as the wet form of age-related macular degeneration. Monoclonal anti-vascular endothelial growth factor (VEGF) antibodies, such as the drug ranibizumab, may be injected directly into the vitreous cavity to reduce new vessel proliferation. Intravitreal steroid injections help to treat cystoid macular oedema.

Developments in vitreous surgery have enabled membranes to be peeled off the retina and macular holes to be repaired. They have also increased the success rate in retinal detachment surgery with the additional use of gases and silicone oil or heavy liquid inserted into the vitreous cavity tamponading the retina.

Some paralytic squints can be helped by the use of adjustable sutures or injections of botulinum toxin into the overacting muscles.

Refractive errors can be treated by the excimer laser. These can be combined with laser in situ keratomileusis (LASIK) surgery, which involves cutting a corneal flap (by femtosecond laser or surgery) and performing the laser surgery at a deeper level. There have been some concerns about defective contrast sensitivity and problems with night vision after laser correction of myopia. Phakic implants have also been used to correct high refractive errors. Corneal topography aids the accuracy of corneal and refractive surgery and the increased use and quality of CT and MRI scans has revolutionised the diagnosis of orbital and intracranial lesions involving the optic pathways (Figures 44.35, 44.36 and 44.37).

Fluorescein angiography, and ocular coherence tomography (OCT) are invaluable in the diagnosis and treatment of macular conditions. The glaucoma detection (GDx) retinal nerve fibre analyser and Heidelberg retinal tomography (HRT) are increasingly used in the diagnosis and management of glaucoma.

**LASERS IN OPHTHALMOLOGY**

Argon blue–green or diode laser is used to treat the retina in diabetic retinopathy (pan-retinal photocoagulation from proliferative disease or focal treatment for leaky microaneurysms),
and is also used to close retinal tears or breaks that might lead to retinal detachment.

Argon laser or selective laser trabeculoplasty can be used to open the drainage angle to control elevated intraocular pressure in open angle glaucoma. Trans-scleral diode photocoagulation of the ciliary body is used to treat refractory secondary glaucoma with uncontrolled ocular pressure.

Laser iridotomy with the Nd:YAG laser is used to treat both the affected and fellow eye in acute angle closure glaucoma. The Nd:YAG laser is also used to photodisrupt and clean an opaque posterior capsule which occurs in 5–10 per cent of cases following cataract surgery.

### SURGICAL PROCEDURES

**Excision of an eyeball/enucleation**

Indications include a blind, painful eye, a blind, cosmetically poor eye/intraocular neoplasm and, in cadavers, for use in corneal grafting.

*The operation*

The speculum is introduced between the lids and opened. The conjunctiva is picked up with toothed forceps and divided completely all round as near as possible to the cornea. Tenon’s capsule is entered and each of the four rectus and two oblique muscle tendons is hooked up on a strabismus hook and divided close to the sclera. The speculum is now pressed backwards and the eyeball projects forwards. Blunt scissors, curved on the flat, are insinuated on the inner side of the globe, and these are used to sever the optic nerve. The eyeball can now be drawn forwards with the forceps, and the oblique muscles, together with any other strands of tissue that are still attaching the globe to the orbit, are divided. A swab, moistened with hot water and pressed into the orbit, will control the haemorrhage. If an orbital implant is inserted to give better eye movement, the muscles are sutured to the implant at the appropriate sites. The subconjunctival tissues and conjunctiva are closed in layers.

**Evisceration of an eyeball**

Evisceration is preferred to excision in endophthalmitis, minimising the risk of orbital and intracranial spread with meningitis. The sclera is transfixed with a pointed knife a little behind the corneosclerotic junction, and the cornea is removed entirely by completing the encircling incision in the sclera. The contents of the globe are then removed with a curette, care being exercised to remove all of the uveal tract. At the end of the operation the interior must appear perfectly white. A ball orbital implant made of acrylic or hydroxyapatite is placed within the orbit behind the sclera to improve the appearance when the artificial eye is fitted.

**Incision and curettage of chalazion (meibomian cyst)**

The lid margin is everted to allow the application of a meibomian clamp. The ring of the clamp is placed on the palpebral conjunctiva with the granuloma in the centre. An incision is made with a small blade in the axis of the gland. The herniating granulomatous tissue is removed with a curette and the cavity is scraped clean. Recurrent cysts may have to have the cyst wall dissected away with scissors. A biopsy may be necessary in atypical or recurrent cysts to exclude malignant change.

### FURTHER READING

Cleft lip and palate: developmental abnormalities of the face, mouth and jaws

LEARNING OBJECTIVES

To understand:
- The aetiology and classification of cleft lip and palate
- The principles of reconstruction of cleft lip and palate
- The key features of the perioperative care of the child with cleft lip and palate
- The associated complications of cleft lip and palate and their management

INTRODUCTION

Clefts of the lip, alveolus and hard and soft palate are the most common congenital abnormalities of the orofacial structures. They frequently occur as isolated deformities, but can be associated with other medical conditions, particularly congenital heart disease. They are also an associated feature in over 300 recognised syndromes.

All children born with a cleft lip and palate need a thorough paediatric assessment to exclude other congenital abnormalities. In certain circumstances, genetic counselling must be sought if a syndrome is suspected.

INCI DENCE

The incidence of cleft lip and palate is 1:600 live births and of isolated cleft palate is 1:1000 live births. The incidence increases in Oriental groups (1:500) and decreases in the black population (1:2000). The highest incidence reported for cleft lip and palate occurs in the Indian tribes of Montana, USA (1:276).

Although cleft lip and palate is an extremely diverse and variable congenital abnormality, several distinct subgroups exist, namely cleft lip with/without cleft palate (CL/P), cleft palate (CP) alone and submucous cleft palate (SMCP).

The typical distribution of cleft types is:
- cleft lip alone: 15 per cent;
- cleft lip and palate: 45 per cent;
- isolated cleft palate: 40 per cent.

Cleft lip/palate predominates in males, whereas cleft palate alone appears to be more common in females. In unilateral cleft lip, the deformity affects the left side in 60 per cent of cases.

AETIOLOGY

Contemporary opinion on the aetiology of cleft lip and palate is that cleft lip and palate and isolated cleft palate have a genetic predisposition and a contributory environmental component. A family history of cleft lip and palate in which the first-degree relative is affected increases the risk to 1:25 live births. Genetic influence is more significant in cleft lip/palate than cleft palate alone, in which environmental factors exert a greater influence.

Environmental factors implicated in clefting include maternal epilepsy and drugs, e.g. steroids, diazepam and phenytoin. The role of antenatal folic acid supplements in preventing cleft lip and palate remains equivocal.

Although most clefts of the lip and palate occur as an isolated deformity, Pierre Robin sequence remains the most common syndrome. This syndrome comprises isolated cleft palate, retrognathia and a posteriorly displaced tongue (glossoptosis), which is associated with early respiratory and feeding difficulties.

Isolated cleft palate is more commonly associated with a syndrome than cleft lip/palate and cleft lip alone. Over 150 syndromes are associated with cleft lip and palate, although Stickler’s (ophthalmic and musculoskeletal abnormalities), Shprintzen’s (cardiac anomalies), Down’s, Apert’s and Treacher Collins’ syndromes are most frequently encountered (Summary box 45.1).

Summary box 45.1

Cleft lip and palate
- Associated with other congenital abnormalities
- Incidence varies between races from 1:300 to 1:2000 live births
- Aetiology is both genetic and environmental
**ANATOMY OF CLEFT LIP AND PALATE**

**Cleft lip**
The abnormalities in cleft lip are the direct consequence of disruption of the muscles of the upper lip and nasolabial region. The facial muscles (Figure 45.1) can be divided into three muscular rings of Delaire: the nasolabial muscle ring surrounds the nasal aperture; the bilabial muscle ring surrounds the oral aperture; and the labiomental muscle ring envelops the lower lip and chin regions.

**Unilateral cleft lip**
In the unilateral cleft lip, the nasolabial and bilabial muscle rings are disrupted on one side resulting in an asymmetrical deformity involving the external nasal cartilages, nasal septum and anterior maxilla (premaxilla) (Figure 45.2a and b). These deformities influence the mucocutaneous tissues causing a displacement of nasal skin onto the lip and a retraction of labial skin, as well as changes to the vermillion and lip mucosa. All these changes need to be considered in planning the surgical repair of the unilateral cleft lip.

**Bilateral cleft lip**
In the bilateral cleft lip, the deformity is more profound but symmetrical. The two superior muscular rings are disrupted on both sides producing a flaring of the nose (caused by lack of nasolabial muscle continuity), a protrusive premaxilla and an area of skin in front of the premaxilla devoid of muscle, known as the prolabium (Figure 45.3a and b). As in the unilateral cleft lip, the muscular, cartilaginous and skeletal deformities influence the mucocutaneous tissues, which must be respected in planning the repair of the bilateral cleft lip.

**Cleft palate**
Embryologically, the primary palate consists of all anatomical structures anterior to the incisive foramen, namely the alveolus and upper lip. The secondary palate is defined as the remainder of the palate behind the incisive foramen, divided into the hard palate and, more posteriorly, the soft palate.

Cleft palate results in failure of fusion of the two palatine shelves. This failure may be confined to the soft palate alone or involve both hard and soft palate. When the cleft of the hard palate remains attached to the nasal septum and vomer, the cleft is termed *incomplete*. When the nasal septum and vomer are completely separated from the palatine processes, the cleft palate is termed *complete* (Summary box 45.2).

**Summary box 45.2**

**Types of cleft palate**
- May involve the soft palate or the soft and hard palate
- It is complete when nasal septum and vomer are separated from the palatine process

---

*Figure 45.1* The muscle chains of the face: frontal view. The nasal cartilages are represented in blue. A, nasolabial (muscles 1–3); B, bilabial (muscles 4–6); C, labiomental (muscles 7–9); 1, transverse nasalis; 2, levator labii superioris alaeque nasi; 3, levator labii superioris; 4, orbicularis oris (oblique head) – upper lip; 5, orbicularis oris (horizontal head) – upper lip; 6, orbicularis oris – lower lip; 7, depressor anguli oris; 8, depressor labii inferioris; 9, mentalis.

*Figure 45.2* (a) Schematic representation of disruption of the nasolabial and bilabial muscle chains in unilateral (left) cleft lip. A, nasolabial; B, bilabial; C, labiomental. (b) Unilateral cleft lip before muscular reconstruction.
**Soft palate**

In the normal soft palate, closure of the velopharynx, which is essential for normal speech, is achieved by five different muscles functioning in a complete but coordinated fashion. In general, the muscle fibres of the soft palate are orientated transversely with no significant attachment to the hard palate.

In a cleft of the soft palate (Figure 45.4a) the muscle fibres are orientated in an anteroposterior direction, inserting into the posterior edge of the hard palate (Figure 45.4b).

**Hard palate**

The normal hard palate can be divided into three anatomical and physiological zones (Figure 45.5). The central palatal fibromucosa is very thin and lies directly below the floor of nose. The maxillary fibromucosa is thick and contains the greater palatine neurovascular bundle. The gingival fibromucosa lies more lateral and adjacent to the teeth.
In performing surgical closure of cleft palate the changes associated with the cleft must be understood to obtain an anatomical and functional repair. In complete cleft palate, the median part of the palatal vault is absent and the palatal fibromucosa is reduced in size. The maxillary and gingival fibromucosa are not modified in thickness, width or position.

CLASSIFICATION
Any classification for such a diverse and varied condition as cleft lip and palate needs to be simple, concise, flexible and exact but graphic. It must be suitable for computerisation but descriptive and morphological. An example of such a classification is the LAHSHAL system, which is able to describe site, size and extent, as well as type of cleft (Figure 45.6).

Complete clefts of the lip, alveolus and hard and soft palate are designated as capitals L, A, H and S, respectively. Incomplete clefts are recorded in lower case letters whereas microform clefts are documented with asterisks. Hence, LAHSHAL is the anatomical paraphrase of a complete bilateral cleft lip and palate. Another example, labSh, represents an incomplete right unilateral cleft lip and alveolus with a complete cleft of soft palate extending partly onto the hard palate.

PRIMARY MANAGEMENT
Antenatal diagnosis
An antenatal diagnosis of cleft lip, whether unilateral or bilateral, is possible by ultrasound scan after 18 weeks of gestation. Isolated cleft palate cannot be diagnosed by antenatal scan. When an antenatal diagnosis is confirmed, referral to a cleft surgeon is appropriate for counselling to allay fears. Photographs of cleft lip shown to parents 'before and after' surgery are invaluable. Introduction to a parent support group and meeting parents of a child with a similar cleft who has undergone surgery may also be extremely helpful (Summary box 45.3).

Summary box 45.3
Antenatal diagnosis and counselling
- All but isolated cleft palate can be diagnosed by ultrasound scan after 18 weeks’ gestation
- Parents will need counselling and support

Feeding
Most babies born with cleft lip and palate feed well and thrive, provided that appropriate advice is given and support is available. Some mothers are successful in breastfeeding, particularly when the cleft is incomplete and confined to the lip. Good feeding patterns can be established with soft bottles (e.g. Mead Johnson) and modified teats (orthodontic, Nuyk). Simple measures, such as enlarging the hole in the teat, often suffice. Feeding plates, constructed from a dental impression of the upper jaw, are rarely necessary to improve feeding. Some babies are provided with an active plate that aims not only to improve feeding but also reduce the width of the cleft lip and palate prior to surgery. The long-term benefit of such a regime remains unproven.

Airway
Major respiratory obstruction is uncommon and occurs exclusively in babies with Pierre Robin sequence. Hypoxic episodes during sleep and feeding can be life-threatening. Intermittent airway obstruction is more frequent and is managed by nursing the baby prone. More severe and persistent airway compromise can be managed by ‘retained nasopharyngeal intubation’ to maintain the airway. Surgical adhesion of the tongue to the lower lip (labioglossopexy) in the first few days after birth is an alternative but less commonly practised method of management (Summary box 45.4).

Summary box 45.4
Problems immediately after birth
- Some babies are able to feed normally but some will need assistance
- Breathing problems in Pierre Robin sequence may be life-threatening

PRINCIPLES OF CLEFT SURGERY
The ultimate goal in cleft lip and palate management is a patient with a normal appearance of lip, nose and face, whose speech is normal and whose dentition and facial growth fall within the range of normal development.

Surgical techniques are aimed at restoring normal anatomy. With the exception of rare conditions such as holoprosencephaly, there is no true hypoplasia of the tissues involved on either side of the cleft. There is, however, displacement, deformation and underdevelopment of the muscles and facial skeleton. Emphasis is placed on muscular reconstruction of the lip, nose and face, as well as muscles of the soft palate. Normal
or near-normal anatomy promotes normal function, thereby encouraging normal growth and development of lip, nose, palate and facial skeleton. An in-depth understanding of the anatomy of the cleft is invaluable if the surgeon is to achieve normal, or near-normal, anatomical reconstruction (Summary box 45.5).

Surgical techniques

There have been many different surgical techniques and sequences advocated in cleft lip and palate management. Cleft lip repair is commonly performed between three and six months of age, whereas cleft palate repair is frequently performed between six and 18 months.

The Delaire technique and sequence (Table 45.1) is one of many regimes currently practised.

Cleft lip surgery

Skin incisions (Figures 45.7 and 45.8) are developed to restore displaced tissues, including skin and cartilage, to their normal position, while gaining access to the facial, nasal and lip musculature.

Muscular continuity is achieved by subperiosteal undermining over the anterior maxilla. Nasolabial muscles are anchored to the premaxilla with non-resorbable sutures. Oblique muscles of orbicularis oris are sutured to the base of the anterior nasal spine and cartilaginous nasal septum. Closure of the cleft lip is completed by suturing the horizontal fibres of orbicularis oris to achieve a functioning oral sphincter (Figures 45.9 and 45.10).

When the cleft lip is incomplete (Figures 45.11a and 45.12a), meticulous assessment of the cleft deformity is of paramount importance, as complete muscle disruption may be present leading to nasal and skeletal deformity. Full muscular exposure and reconstruction is imperative in many incomplete clefts if facial symmetry is to be achieved (Figures 45.11b and 45.12b).

Cleft palate surgery

Cleft palate closure can be achieved by one- or two-stage palatoplasty. The surgical principle is mobilisation and re-construct the aberrant soft palate musculature (Figure 45.13a and b), together with closure of the residual hard palate cleft by minimal dissection and subsequent scar formation (Figure 45.14a and b). Excess scar formation in the palate adversely affects growth and development of the maxilla. The philosophy of two-stage closure encourages a physiological narrowing of the hard palate cleft to minimise surgical dissection at the time of the second procedure (Summary box 45.6).

Summary box 45.6

**Principles of surgery**

- Cleft lip surgery attaches and reconnects the muscles around the oral sphincter
- Cleft palate surgery aims to bring together mucosa and muscles with minimal scarring
- Two-stage procedures attempt to minimise dissection
Following primary surgery, regular review by a multidisciplinary team is essential. Many aspects of cleft care require long-term review:

- hearing
- speech
- dental development
- facial growth.

**Hearing**

Eustachian tube dysfunction plays a central role in the pathogenesis of otitis media with effusion in babies and children born with a cleft palate. Children with a cleft lip alone exhibit
the same frequency of otitis media as their age-matched non-
cleft counterparts. It has been recently recognised that a child 
with a craniofacial anomaly including cleft lip and palate is at 
increased risk of a sensorineural hearing deficit. All children 
born with a cleft lip and palate should undergo assessment 
before 12 months of age for sensorineural and conductive hear-
ing loss by auditory brainstem responses (ABR) and tympanom-
etry, respectively.

Sensorineural hearing loss is managed with a hearing aid 
whereas the management of secretory otitis media remains 
more controversial. Early (6–12 months) prophylactic myrin-
gotomy and grommet insertion temporarily eliminates middle 
ear effusion. Regular audiological testing may be as appropri-
ate, reserving surgery for established secretory otitis media with 
infection. No firm evidence is available to support the interven-
tional approach over the conservative regime. Nevertheless, the 
relationship between hearing loss and potential speech prob-
lems remains important. Regular audiological assessment during 
childhood is of utmost importance.

Speech
Initial speech assessment should be performed early (18 months) 
and repeated regularly to ensure that problems are identified 
early and managed appropriately.

Common speech problems associated with cleft lip and palate are:

- **Velopharyngeal incompetence.** This is associated with 
  increased nasal airflow and resonance, producing a nasal 
or ‘hypernasal’ quality to speech. It frequently reflects poor 
function of the soft palate associated with inadequate muscle 
repair.

- **Articulation problems.** These arise either as a compensatory 
  mechanism to overcome velopharyngeal incompetence 
or, less commonly, are caused by jaw/dental and occlusal 
abnormalities. Videofluoroscopy, nasal airflow studies 
(aerophonoscopy) and nasendoscopy are helpful in defining 
the exact mechanism of the problem, aiding management.

- **Speech problems.** These are managed by speech and language 
  therapy; secondary palatal surgery, either intravelar veloplasty 
  (muscular reconstruction of soft palate) or pharyngoplasty; 
  and speech training devices (Summary box 45.7).

### Summary box 45.7

**Associated hearing and speech problems**
- Higher incidence of sensorineural and conductive hearing loss
- Regular hearing tests are important if speech is to develop normally
- Speech problems may result from airflow problems

**Dental**

Dental anomalies are common findings in children with cleft 
lip and/or palate. Various phenomena including delayed tooth 
development, delayed eruption of teeth and morphological
abnormalities are well documented. The number of teeth may be reduced (hypodontia) or increased (hyperdontia), occurring most commonly in the region of the cleft alveolus involving the maxillary lateral incisor tooth. These abnormalities can occur in both primary and secondary dentition.

All children with cleft lip and palate should undergo regular dental examination. Dental management should also include preventative measures, such as dietary advice, fluoride supplements and fissure sealants.

A well-maintained and disease-free dentition in childhood is an absolute prerequisite for orthodontic treatment (Summary box 45.8).

**Summary box 45.8**

**Dental problems**
- Too many/too few teeth or problems with eruption of teeth are common
- Good dentition is essential for successful reconstructive surgery

**Figure 45.13** (a and b) Method of repair of cleft palate. First-stage palatoplasty to reconstruct muscles of the soft palate. Red lines represent incisions, and orange areas raw surfaces.

**Figure 45.14** (a and b) Schematic representation of closure of the hard palate. Second-stage palatoplasty achieved with two-layered closure. Red lines represent incisions, and orange areas raw surfaces.
Orthodontic management

Many children with cleft lip and palate require orthodontic treatment. Orthodontic treatment is commonly carried out in two phases:

1. Mixed dentition (8–10 years) – to expand the maxillary arches as a prelude to alveolar bone graft.
2. Permanent dentition (14–18 years) – to align the dentition and provide a normal functioning occlusion. This phase of treatment may also include surgical correction of a malpositioned/retrusive maxilla by maxillary osteotomy (Figure 45.15a and b).

Secondary surgery for cleft lip and palate

Good outcome in cleft lip and palate is directly attributable to the quality of the primary surgery. Secondary cleft procedures include:

- cleft lip revision (unilateral and bilateral);
- alveolar bone graft;
- simultaneous lip revision and alveolar bone graft;
- secondary palate procedures, e.g. veloplasty and pharyngoplasty, closure of a palatal fistula;
- dentosseous procedures, including transplantation of teeth/insertion of osseointegrated dental implants;
- orthognathic surgery;
- rhinoplasty.

Cleft lip revision

Indications for revisional surgery to the previously repaired cleft lip are dependent on the site and severity of the residual deformity.

Revisional surgery should be delayed for two years after primary lip closure unless the surgeon is of the opinion that the initial procedure was inadequate, particularly with respect to muscular reconstruction.

Indications for revision include:

- lip deformity:
  - malaligned vermillion;
  - asymmetrical Cupid’s bow;
  - muscle discontinuity or malalignment;
- nasal deformity:
  - lateral drift of alar base;
  - poor nasal tip projection;
  - deviation of cartilaginous nasal septum into the non-cleft nostril.

Residual nasal deformity is an external manifestation of incomplete reconstruction of the nasolabial muscle ring.

Examples of lip revision are shown in Figures 45.16, 45.17, 45.18 and 45.19 (Summary box 45.9).

Summary box 45.9

Cleft lip revision surgery

- Should be delayed for at least two years after primary surgery
- Aims to improve incomplete primary reconstruction

Cupid’s Bow: Cupid, the Roman god of love, is often depicted holding a double-curved bow which he uses to shoot arrows into his victims.

Figure 45.15 Correction of midface retrusion by maxillary advancement osteotomy, before (a) and after (b) surgery.

Alveolar bone grafting

Alveolar bone grafting in a mixed dentition is a well-established procedure for patients with a residual alveolar cleft associated with cleft lip and palate. The rationale for performing alveolar bone grafting includes:
- stabilisation of maxillary segments;
- to promote eruption of the canine tooth into the cleft site;
- to enhance bony support of the teeth adjacent to the cleft alveolus;
- to promote closure of the oronasal fistula;
- to close residual fistula of the anterior palate;

- to provide adequate bone stock to receive an osseointegrated dental implant where a tooth is congenitally absent.

Normally, but not universally, patients undergo a period of orthodontic treatment prior to bone grafting. The collapsed maxillary segment is expanded orthodontically to widen the

Figure 45.16 (a) Revision of unilateral complete cleft lip, seen from below. (b) Skin incisions. (c) Wide exposure of nasolabial and orbicularis oris muscle. (d) Lip closure highlighting improved nasal symmetry.
cleft alveolus. The surgery is best performed before the canine tooth erupts (between 8 and 11 years of age). There is a consensus that earlier bone grafting may be beneficial not only for the unerupted canine tooth but also to promote eruption and bony support to the adjacent central and lateral incisor when present. Alveolar bone grafting can also be performed simultaneously with secondary lip revision (Figure 45.20).

Cancellous bone is harvested from either the iliac crest or tibial plateau. This is achieved either through an open approach or preferably through a small incision utilising a trephine. When the defect is very small, alternative bone sites, e.g. mental symphysis, are sometimes advocated. Bone grafting is a highly successful procedure when carried out in experienced hands, with over 90 per cent of patients achieving acceptable interdental alveolar bone height, but it does require the interaction of surgeon and orthodontist. When the lateral incisor is absent and the canine tooth fails to erupt, surgical exposure of the canine

tooth may be required to aid its eruption. It is a fundamental principle that, following alveolar bone grafting, efforts should be made to ensure that a tooth erupts into the alveolar bone graft site. Failure to provide a tooth in the alveolar bone graft site usually results in bony resorption in the long term. This can be overcome by the insertion of an osseointegrated implant into the grafted site, thereby preserving bone stock (Figure 45.21) (Summary box 45.10).

**Summary box 45.10**

**Alveolar bone grafting**
- Aimed at stabilising orthodontic treatment
- Promotes normal eruption of canine and other teeth

**Orthognathic surgery**
Impaired growth of the midface (maxilla) is now attributed to poor and traumatic primary surgery. Surgical techniques must endeavour to minimise scarring, although in many cases patients have a genetic predisposition to poor midfacial growth. Elective maxillary advancement or bimaxillary surgery is often indicated to restore aesthetics and dental occlusal harmony. Orthognathic
surgery is usually performed when facial growth is complete (16 years in female patients, 19 years in male patients).

The principal dentofacial deformity associated with cleft lip and palate is underdevelopment in both the horizontal and vertical direction of the maxilla. This leads to a pseudoprognathism in late adolescence, which is not correctable by orthodontic fixed-appliance therapy alone. Patients needing orthognathic surgery can be identified as early as ten years old, although planning and treatment does not commence until 14–15 years of age. Treatment with fixed appliances to align teeth in each dental arch is carried out over a period of 18–24 months as a prelude to orthognathic surgery. Orthognathic surgery may require maxillary osteotomy advancement alone (Figure 45.15a and b) or bimaxillary osteotomy and genioplasty (Figure 45.22). Rigid fixation, with or without bone grafting of the maxilla, is essential as cleft lip and palate patients undergoing orthognathic surgery have a high risk of a skeletal relapse as a result of the scarring associated with primary cleft lip and palate surgery.

Open septorhinoplasty

Following revisional cleft lip and palate surgery, orthognathic surgery and alveolar bone grafting, many patients still require definitive surgical nasal correction. In patients with cleft lip and palate, open rhinoplasty is preferred to gain access to the external cartilaginous framework, which is frequently deformed (Figure 45.23). The principal deformity is a collapse of the lower lateral cartilage on the cleft side, together with a dislocation of the cartilaginous septum into the non-cleft nostril. The open method ensures adequate access and repositioning of the cartilaginous framework as a tertiary procedure to improve nasal tip projection, correct septal deformity and relocate alar cartilages. A postauricular onlay graft to the middle crus of the cleft nostril lower lateral cartilage may be required to enhance good nasal tip projection and symmetry (Summary box 45.11).

Summary box 45.11

Deformities requiring nasal reconstruction
- Collapse of the lower lateral cartilage on the cleft side
- Dislocation of cartilaginous septum into the non-cleft nostril

Summary

The management of children with cleft lip and palate is complex, requiring the skill of a multidisciplinary team. Each team should include professionals who are appropriately qualified with specialist training, treating an adequate number of patients per year in centralised units. Meticulous record keeping of
Figure 45.23  (a) Characteristic nasal deformity of a non-functional unilateral cleft lip repair. (b) Incisions for open rhinoplasty. (c) Exposure of the cartilaginous skeleton of the external nose. (d) Repositioning of external nasal cartilages to improve nasal tip projection.
photography, radiology, dental casts and speech recordings are indispensable to permit regular audits and improve outcomes.

**DEVELOPMENTAL ABNORMALITIES OF THE TEETH AND JAWS**

**Teeth**

Developmental abnormalities of the teeth can be divided into:
- abnormality in number;
- defects of structure and size;
- disorders of eruption of teeth.

**Number**

**Anodontia** is the term that is strictly applied to congenital absence of all teeth, which may involve both deciduous and permanent dentition. This is a rare condition that is often hereditary.

Partial anodontia is a much more common disorder in which there is a failure of development of the primary or, more commonly, the secondary dentition. Teeth that are most frequently absent are the third molars (wisdom teeth), second premolars and maxillary lateral incisor teeth.

Partial anodontia is associated with certain congenital disorders:
- ectodermal dysplasia;
- Down's syndrome;
- cleft lip and palate.

Management of partial anodontia involves prosthetic replacement of the teeth, usually in combination with orthodontic treatment. Congenitally missing teeth can be replaced with removable prostheses, fixed prostheses or, more recently, the use of osseointegrated dental implants.

Additional teeth (**hyperdontia**) can occur alone or in association with other syndromes. Additional teeth are termed **supernumerary** teeth and are often impacted in the jaw with abnormal morphology. The most common site for supernumerary teeth is the maxillary incisor region, particularly in the midline (mesiodens). When additional teeth are of a similar morphology to the normal dentition, the term supplemental is appropriate. Supplemental teeth are common in the maxillary incisor and premolar regions, and less common in the wisdom tooth region when they are termed the fourth molars. Most supernumerary teeth are removed to encourage the eruption of the permanent dentition (Summary box 45.12).

---

**Summary box 45.12**

**Problems with numbers of teeth**
- Absent teeth can be replaced with prosthetic teeth, which may involve osseointegrated implants
- Supernumerary teeth are often impacted and are removed to allow eruption of secondary dentition

**Defects of the structure of teeth**

Structural changes of the teeth can occur as a consequence of genetic disorders or environmental factors.

Genetic disorders frequently include **amelogenesis imperfecta** and **dentinogenesis imperfecta**, which affect the enamel and dentine of the teeth, respectively. Both of these conditions are characterised by defects in both dentitions, in which all teeth are affected. In amelogenesis imperfecta, the defects are variable and may involve changes in structure (hypoplasia) or in mineralisation (hypocalcification). The loss of enamel leads to rapid attrition of the teeth to gum level in early adolescence. Dentinogenesis imperfecta results in soft dentine associated with short roots. Dentinogenesis imperfecta is strongly associated with osteogenesis imperfecta.

Acquired conditions producing changes in the structure of the teeth may be either local or systemic. Local causes are usually the consequence of trauma to the deciduous predecessor tooth, which interferes with enamel formation (amelogenesis). Common examples of systemic causes that produce tooth structure disruption are:
- measles
- rickets
- hypoparathyroidism
- tetracycline
- fluoride (Summary box 45.13).

---

**Summary box 45.13**

**Causes of defects of the structure of teeth**

**Congenital**
- Amelogenesis imperfecta
- Dentinogenesis imperfecta

**Acquired local**
- Trauma

**Acquired systemic**
- Disease – measles, rickets
- Drugs – fluoride, tetracycline

**Disorders of eruption**

Both primary and secondary dentition erupt in a specific sequence, although the timing of eruption does vary from child to child. Delayed eruption of teeth may involve a single tooth or may involve the entire dentition.

**Local factors**

There are numerous factors that impair the eruption of a single tooth. These include:
- loss of space/overcrowding
- additional teeth
- dentigerous cysts
- retention of deciduous tooth.

**Systemic factors**

These can prevent the eruption of multiple teeth. Examples of such conditions include:
- metabolic diseases – cretinism and rickets
- osteodystrophies – cleidocranial dysostosis and fibrous dysplasia
- hereditary gingival fibromatosis.

Management of unerupted teeth involves the removal of the obstruction to eruption, including supernumerary teeth, as well
as the relief of crowding. Patients with cleidocranial dysostosis should undergo long-term follow up with regular radiographic assessment. Supernumerary teeth, as and when they appear, should be removed to encourage the eruption of permanent dentition in adolescence. Many patients with cleidocranial dysostosis require multiple operations to expose teeth and encourage eruption (Summary box 45.14).

Summary box 45.14
Management of unerupted teeth
- Remove obstruction to eruption
- Surgical exposure if eruption delayed

Jaws
Disproportionate growth between the maxilla and mandible can occur, which results in derangement of the dental occlusion. The occlusion can be classified into three different subtypes:
- class I: a normal relationship of upper and lower incisors and molar dentition;
- class II: the mandibular teeth are placed posterior to the maxillary teeth;
- class III: the mandibular teeth are placed anterior to the maxillary teeth.

This classification is usually, but not invariably, the consequence of aberrant skeletal development of the maxilla and mandible, such that in a class II condition there is usually an underdevelopment of the mandible (mandibular retrognathia), whereas in a class III condition there may be simultaneous overgrowth of the mandible (mandibular prognathism) and underdevelopment of the maxilla (maxillary hypoplasia).

In the Caucasian population, the most common deformity of the facial skeleton is an underdevelopment of the mandible (retrognathia), producing a skeletal class II relationship often associated with excessive vertical growth of the maxilla. Bimaxillary protrusion is rare but is a characteristic of African races.

Condylar hyperplasia is an idiopathic condition seen in patients between 15 and 30 years of age, more common in women than men, in which there is hyperplasia or overgrowth of the neck of the mandibular condyle. This gives an asymmetrical growth to the jaw in both a vertical and horizontal plane.

Facial disproportionate growth is also a characteristic of many syndromes. Examples include:
- Treacher Collins’ syndrome
- Crouzon’s syndrome
- Apert’s syndrome
- Pierre Robin sequence.

Figure 45.24 (a) Profile of class II relationship with vertical growth of maxilla and mandibular retrognathia. (b) Preoperative occlusion with anterior open bite. (c) Postoperative view following superior repositioning of maxilla, mandibular advancement and genioplasty. (d) Postoperative occlusion.

Octave Crouzon, 1874–1938, physician, la Salpêtrière, Paris, France, described this condition in 1912.

Figure 45.26 (a) Condylar hyperplasia with mandibular asymmetry. (b) Bone scan revealing increased bone activity in the right mandibular condyle. (c) Postoperative appearance following bimaxillary osteotomy to correct facial asymmetry.
Orthognathic surgery

Orthognathic surgery is the term given to the surgical correction of deformities of the jaw. It is usually undertaken in close cooperation between orthodontic and maxillofacial surgeons. Surgery is directed at simultaneously changing the position of both maxilla and mandible at the end of the growth period. This is termed bimaxillary osteotomy. Treatment planning usually commences at the age of 12–13 years, in which the orthodontist aligns the dental arches in correct relation for each jaw. This frequently results in an accentuation of the facial deformity at the end of the orthodontic phase of treatment. Treatment normally takes two years, in which orthognathic surgery is performed towards the end of orthodontic treatment, although orthodontic treatment in the form of fixed appliances usually continues postoperatively for up to six months after surgery. Surgical planning should be meticulous and involves clinical examination and cephalometric assessment in the form of radiograph analysis, as well as study model analysis, working in close cooperation with maxillofacial technologists.

Orthognathic surgery is generally carried out through intraoral incisions, in which the upper and lower jaws are mobilised by achieving osteotomy cuts with saws and drills (Figure 45.24). Following mobilisation of the mandible and maxilla, the jaws are repositioned and held with titanium plates and screws placed through an intraoral approach. This frequently avoids the use of intermaxillary fixation and allows earlier function of the jaws, as well as improved early dietary intake. Examples of orthognathic surgery are shown in Figures 45.25 and 45.26.

Patients with syndromic conditions, such as hemifacial microsomia and Crouzon’s and Treacher Collins’ syndromes, require the services of a craniofacial surgeon. As these syndromes are extremely rare, management and surgery should only be carried out in designated centres. The principal treatment is to correct the deformity from the cranium downwards, with correction of the cranial deformity within the first three years of life and correction of the residual midfacial and lower facial deformity in childhood and adolescence.

The use of distraction osteogenesis in the management of craniofacial deformity has reduced the requirements for major orthognathic surgery in patients with severe facial deformity (Summary box 45.15).

Summary box 45.15

**Principles of orthognathic surgery**
- Orthodontist aligns the dental arches
- Surgery then corrects the jaw deformity

**FURTHER READING**

CHAPTER 46
The nose and sinuses

LEARNING OBJECTIVES
To be familiar with:
- The basic anatomy of the nose and paranasal sinuses
- The principles of managing post-traumatic nasal and septal deformity
- The causes and management of epistaxis
- The diagnosis and management of nasal polyposis
- The clinical features of sinus infection and its treatment and potential complications
- The common sinonasal tumours, their presentation, investigation and principles of treatment

BASIC ANATOMY OF THE NOSE AND PARANASAL SINUSES
The supporting structures of the nose are shown in Figure 46.1. The septum consists of the anterior quadrilateral cartilage, the perpendicular plate of the ethmoid and the vomer (Figure 46.2). The lateral wall of the nasal cavity contains the superior, middle and inferior turbinates (Figure 46.3). Opening onto the lateral nasal wall are the ostia of all of the nasal sinuses, except the sphenoid sinus (Figures 46.4 and 46.5).

Figure 46.1 The nasal skeleton.

Figure 46.2 The left side of the nasal septum.

Figure 46.3 The right lateral nasal wall.

Figure 46.4 The right lateral nasal wall with turbinates removed to show the sinus ostia. A, insertion of superior turbinate; B, insertion of middle turbinate; C, insertion of inferior turbinate; SM, superior meatus; MM, middle meatus; IM, inferior meatus.
TRAUMA TO THE NOSE AND PARANASAL SINUSES

Fracture of the nasal bones

Blunt injury to the nose may fracture the nasal bones (Figure 46.7). The fracture line can extend into the lacrimal bone and tear the anterior ethmoidal artery producing catastrophic haemorrhage. This may be delayed, occurring only as the soft tissue swelling subsides, reducing the tamponade effect on the torn vessel.

Violent trauma to the frontal area of the nose can result in a fracture of the frontal and ethmoid sinuses with potential extension into the anterior cranial fossa. Dural tears and brain injuries, either open or closed, are then at risk from sinonasal ascending infection which may progress to meningitis or brain abscess. Cerebrospinal fluid (CSF) rhinorrhoea is a certain sign of a dural tear.

Management of fractured nasal bones

Fractured nasal bones are often accompanied by extensive overlying soft tissue swelling and bruising, which may hinder the assessment of any underlying bony deformity. Reviewing after 4–5 days when the soft tissue swelling has diminished will allow a better assessment of any deformity. If there is a significant degree of nasal deformity then this can be corrected by manipulation of the nasal bones under local or general anaesthesia. This should be carried out within 10–20 days of the injury while the bony fragments are still mobile.

Septal injury

A blunt injury of moderate force may lead to lateral displacement or deformity of the septal cartilage, restricting the nasal airway. Unlike the nasal bones, the nasal septum cannot be manipulated back into position and requires a formal septoplasty.
procedure to restore the anatomy and the patency of the nasal airways.

Bleeding under the mucoperichondrium of the septum will cause a septal haematoma and nasal obstruction. Untreated, a septal haematoma will progress to abscess formation and ultimately result in necrosis of the septal cartilage and nasal collapse. A septal haematoma should be treated by incision and evacuation of the blood clot, insertion of a small silicone drain and packing of the nasal fossa. A broad-spectrum prophylactic antibiotic should be prescribed (Summary box 46.1).

### Summary box 46.1

**Nasal trauma**

- Do not overlook a septal haematoma
- Displaced nasal bone fractures should be reduced within 10–20 days of injury
- Severe persistent epistaxis after trauma suggests lacrimal bone fracture and injury to the anterior ethmoid artery
- Cerebrospinal fluid rhinorrhoea indicates a fracture involving the frontal or ethmoid sinuses with a dural tear

---

**THE NASAL SEPTUM**

**Septal deformity**

Deviation of the nasal septum may occur naturally or arise as a result of nasal trauma and is readily apparent on anterior rhinoscopy (Figure 46.8). Surgical correction can be achieved by a submucous resection (SMR) of the septum, where the deformed septal cartilage is excised while preserving a dorsal strut. The alternative is a septoplasty procedure during which the septal cartilage is preserved, but the anatomical abnormalities giving rise to its deformity, such as a twisted maxillary crest or inclination of the bony septum, are corrected.

Complications of septal surgery include septal perforation. If too much cartilage is excised in the SMR procedure, loss of support to the dorsum of the nose may result in a supratip depression or drooping of the tip of the nose.

**Septal perforation**

A hole in the nasal septum causes a turbulent airflow through the nose and a resulting sensation of nasal blockage and extensive nasal crusting. The causes of septal perforation are listed in Summary box 46.2.

Septal perforations seldom heal spontaneously. A great variety of operations have been described to close septal perforations, but none has met with universal success. A more certain option is to occlude the perforation by inserting a Silastic biflanged prosthesis (Figures 46.9 and 46.10).

Wegener’s granulomatosis is a systemic idiopathic autoimmune disease affecting the nose, lungs and kidneys. Mucosal granulations on the nasal septum destroy cartilage, producing a septal perforation with saddle deformity of the nose. Laboratory findings include a high erythrocyte sedimentation rate, impaired creatinine clearance and antineutrophil cytoplasmic antibodies (ANCA) in most cases.

---

**Summary box 46.2**

**Causes of septal perforations**

- Trauma
- Iatrogenic following septal surgery
- Nose picking
- Infection
  - Syphilis
  - Tuberculosis
- Vasculitis
  - Wegener’s granulomatosis
- Tumours
- Toxins
  - Chrome salts
  - Cocaine
- Idiopathic

**Figure 46.10** Silastic prosthesis for septal perforation.

_Friedrich Wegener, 1907–1990, Professor of Pathology, Lübeck, Germany, described this form of granulomatosis in 1939._
EPISTAXIS

The causes of epistaxis are listed in Table 46.1. The most common site of bleeding is from Kiesselbach’s plexus in Little’s area of the anterior portion of the septum (see Figure 46.6). Anterior bleeding is common in children and young adults as a result of nose blowing or picking. In the elderly, arteriosclerosis and hypertension are the underlying causes of arterial bleeding from the posterior part of the nose.

Table 46.1 Causes of epistaxis.

<table>

</tr>
</tbody>
</table>

Hereditary haemorrhagic telangiectasia (Osler’s disease) gives rise to recurrent multifocal bleeding from thin-walled vessels deficient in muscle and elastic tissue (Figure 46.11). Juvenile angiofibroma is an uncommon condition that affects adolescent boys and may lead to massive life-threatening episodes of bleeding. Diagnosis is made with contrast CT scanning or magnetic resonance imaging (MRI). Anterior bowing or indentation of the posterior antral wall (Holman–Miller or antral sign) is the classical finding but may be seen in other expansive lesions in this area. It is a very vascular tumour, which should not be biopsied because of the risk of uncontrollable haemorrhage. Excision is best carried out by a surgeon experienced in the management of the condition. Preoperative embolisation of the feeding blood vessels may help to reduce blood loss during surgery. Sometimes the tumour is managed with radiotherapy.

Management of epistaxis

Bleeding from Kiesselbach’s plexus may be controlled by silver nitrate cautery under local anaesthesia. Posterior bleeding, as seen in the elderly, may require anterior nasal packing either with Vaseline-impregnated ribbon gauze or absorbable sponge. An alternative to anterior packing is the use of an inflatable epistaxis balloon catheter (Figure 46.12). The catheter is passed into the nose and the distal balloon is inflated in the nasopharynx to secure it. The proximal balloon, which is sausage shaped, is then inflated within the nasal fossa to compress the bleeding point. Although usually effective, they can be uncomfortable.

Post-nasal packing may be required in refractory cases whereby a gauze pack is positioned in the nasopharynx under general anaesthesia. Endoscopic-assisted cautery or clipping of a posterior bleeding point can be an effective alternative to nasal packing.

For uncontrolled life-threatening epistaxis in which the above methods have proved ineffective, haemostasis is secured by vascular ligation. Depending on the origin of bleeding, it may be necessary to ligate the internal maxillary artery in the pterygopalatine fossa and the anterior and posterior ethmoidal...
arteries. An alternative measure is external carotid artery ligation above the origin of the lingual artery.

In Osler’s disease, anterior nasal packing is best avoided, if at all possible, because it is most likely to lead to further mucosal trauma and bleeding. High-dose oestrogen induces squamous metaplasia of the nasal mucosa and has been used effectively in treating this condition (Summary box 46.3).

### Summary box 46.3

**Epistaxis**

- The most common causes are nose picking, hypertension and anticoagulant therapy
- Young people bleed from the anterior septum – Kiesselbach’s plexus
- Elderly people bleed from the posterior part of the nose
- Silver nitrate cautery is used to control anterior bleeding
- Moderate bleeding may require anterior nasal packing
- Severe bleeding may require anterior and posterior nasal packing
- Persistent bleeding may require endoscopic cautery/clipping or arterial ligation

### NASAL POLYPS

**Pathology**

Nasal polyps are benign swellings of the ethmoid sinus mucosa of unknown origin. Histologically, the polyps contain a waterlogged stroma infiltrated with inflammatory cells and eosinophils. The majority of nasal polyps arise from the ethmoid sinuses, with each individual ethmoid air cell giving rise to a single polyp as its swollen mucosal lining prolapses out of the air cell to hang down inside the nasal cavity. Polyps can arise from the other nasal sinuses and a single large polyp arising from the maxillary antrum is referred to as an antrochoanal polyp (Figure 46.13). This usually fills the nose and eventually prolapses posteriorly down into the nasopharynx.

**Clinical features**

Patients present with nasal obstruction, watery rhinorrhoea, sinus infection and often anosmia. Polyps are easily identifiable within the nose as pale semitransparent grey masses, which are mobile and insensitive when palpated with a fine probe. This allows them to be distinguished from hypertrophied turbinates (Figure 46.14).

Malignancy should be considered in adults with unilateral nasal polyps, whereas in children such polyps must be distinguished from a meningocoele or encephalocoele by high-resolution CT scanning of the anterior cranial fossa. Nasal polyps are unusual in children. However, they do occur in conjunction with cystic fibrosis in 10 per cent of cases.

**Management of nasal polyps**

Medical treatment with systemic steroids will often reduce the size of nasal polyps and give short-term relief of nasal blockage. Unfortunately, the polyps tend to recur when the treatment stops. Surgical treatment is required in patients with severe nasal obstruction and pansinusitis that is refractory to medical treatment. Polyps may be removed either by avulsion with a nasal snare or endoscopically with a powered nasal microresector (Figure 46.15). After multiple recurrences, ethmoidectomy should be considered (Summary box 46.4).

---

**Figure 46.13** Antrochoanal polyp.

**Figure 46.14** Nasal polyp in right nasal vestibule.

**Figure 46.15** Powered nasal microresector.
MAXILLARY SINUSITIS

Clinical features
Local disorders, such as nasal polyps, deviated nasal septum or upper dental sepsis, may predispose to sinus infection. Patients with persistent maxillary sinusitis have a mucopurulent post-nasal discharge, headache, which is variable in severity and location, facial pain and nasal obstruction. Irritation of the superior alveolar nerve may give rise to referred upper toothache. The nasal mucosa is swollen and bathed in mucopurulent secretions. Plain sinus radiographs may show a fluid level in the antrum or complete opacity (Figure 46.16). About 10 per cent of infections of the maxillary antrum are caused by dental sepsis from anaerobic organisms. The resultant mucopurulent nasal secretion has a foul taste and smell. Complications of maxillary sinusitis include acute orbital cellulitis or osteitis.

Treatment
Adequate penetration of antibiotics into chronically inflamed sinus mucosa is doubtful and, therefore, treatment may need to be prolonged. Topical nasal decongestants, such as ephedrine nasal drops, will often encourage the sinus to drain.

Antral lavage under local or general anaesthesia allows confirmation of the diagnosis and provides the opportunity to obtain samples for bacteriology. The antrum is entered through the inferior meatus below the inferior turbinate where the bone separating the antrum from the nasal fossa is extremely thin and can be easily penetrated by a trocar and cannula (Figure 46.17). If infection has caused a significant degree of inflammation and fibrosis of the lining of the antrum, intranasal endoscopic techniques may be employed to create a middle meatal antrostomy or enlarge the natural ostium. Endoscopic nasal surgery allows a more functional approach to diseases of the paranasal sinuses and, as a result, the indications for radical antrostomy are decreasing (Summary box 46.5).

FRONTOETHMOIDAL SINUSITIS

Chronic frontoethmoiditis gives rise to mucopurulent catarrh, frontal headache or a feeling of pressure between the eyes, nasal obstruction and hyposmia. Nasal endoscopy will confirm pus issuing from the middle meatus. The ethmoid sinuses can only be properly assessed radiologically by CT scanning, including coronal as well as axial sections.

Complications include periorbital cellulitis (Figure 46.18). This may progress to cavernous sinus thrombosis and septicaemia. Spread of infection by direct bone penetration or via the diploic vein can give rise to extradural, subdural or frontal lobe abscess formation (Summary box 46.6).
Summary box 46.6

**Frontoethmoiditis**

- Assessment is best achieved by CT scanning
- It may require open surgical drainage
- Chronic infection may require an obliterator osteoplastic flap procedure
- Orbital infections may threaten sight
- Intracranial infections may cause meningitis, cerebral abscess or cavernous sinus thrombosis

### TUMOURS OF THE NOSE AND SINUSES

Tumours arising in the nasal fossa may present with unilateral nasal obstruction, persistent unilateral anterior rhinorrhea, post-nasal catarrh, epistaxis, unilateral blood-stained rhinorrhea, facial swelling or proptosis.

#### Benign tumours

Simple papillomas or viral warts can grow inside the nasal vestibule. They can be confused with carcinomas and are best excised for histological diagnosis.

Osteomas of the nasal skeleton are not uncommon and are usually detected on radiography as an incidental finding (Figure 46.19). In symptomatic individuals, the osteoma can be removed via the frontal sinus or an external ethmoidectomy.

Transitional cell papillomas can occur both in the nasal cavity and the nasal sinuses. They are sometimes referred to as inverted papillomas because histologically the hyperplastic epithelium inverts into the underlying stroma. The papillomas are covered with transitional epithelium. Calcification within the tumour may be seen on CT scanning along with sclerosis of bone at the margins of the growth (Figure 46.20). Transitional cell papillomas can undergo malignant change.

#### Malignant tumours

The most common malignant tumours to occur within the nasal cavity and paranasal sinuses are squamous cell carcinoma (Figure 46.21), adenoid cystic carcinoma and adenocarcinoma. Adenocarcinoma has been linked to exposure to hardwood dust in the furniture industry. Adenoid cystic carcinomas arise from minor salivary glands, which can be found in the nose. Suspicious signs of invasion of neighbouring tissues include diplopia, proptosis, loosening of the teeth (Figure 46.22), trismus, cranial nerve palsies and regional lymphadenopathy (Figure 46.23).

Patients with sinus or intranasal malignancy are best managed in a combined clinic where the expertise of ear, nose and throat (ENT) surgeons, maxillofacial surgeons and radiotherapists can be employed (Summary box 46.7).

Summary box 46.7

**Tumours of the nose and sinuses**

- Unilateral nasal obstruction, discharge and bleeding are often presenting symptoms in nasal or sinus tumours
- Osteomas are often asymptomatic
- Transitional cell papilloma is the most common benign tumour – this tumour may undergo malignant change
- Squamous cell carcinoma is the most common malignant tumour
- Almost 50 per cent of sinonasal cancers arise on the lateral nasal wall and 33 per cent in the maxillary antrum
- Multidisciplinary management of malignant sinonasal tumours requires input from ENT surgeons, maxillofacial surgeons and radiotherapists

**FURTHER READING**

To be familiar with:
- The anatomy of the ear
- The conditions of the outer, middle and inner ear
- The examination of the ear including hearing tests

To understand that:
- The outer layer of the tympanic membrane migrates outwards
- The facial nerve can be damaged by trauma and ear disease
- Chronic ear disease can lead to intracranial sepsis
- There are two types of hearing loss: conductive and sensorineural

INTRODUCTION

The mammalian ear is an evolutionary masterpiece. Its highly complex ‘three-dimensional anatomy’ is best learnt by dissecting cadaver temporal bones.

SURGICAL ANATOMY OF THE EAR

The external ear

The external and middle ear develop from the first two branchial arches. The external ear canal is 3 cm in length; the outer two-thirds is cartilage and the inner third is bony. The skin on the lateral surface of the tympanic membrane is highly specialised and migrates outwards along the ear canal. As a result of this migration most people’s ears are self-cleaning. The external canal is richly innervated and the skin is tightly bound down to the perichondrium so that swelling in this region results in severe pain.

The lymphatics of the external ear drain to the retroauricular, parotid, retropharyngeal and deep upper cervical lymph nodes.

The tympanic membrane and middle ear

The anatomy of the tympanic membrane and ossicles is shown in Figure 47.1. The relations of the middle ear are important (Figure 47.2).

The tympanic membrane and ossicles act as a transformer system converting vibrations in the air to vibrations within the fluid-filled inner ear.

The inner ear

The inner ear comprises the cochlea and vestibular labyrinth (saccule, utricle and semicircular canals). These structures are embedded in dense bone called the otic capsule.

The cochlea is a minute spiral of two and three-quarter turns. Within this spiral, perilymph and endolymph are partitioned by the thin Reissner’s membrane. The endolymph has a high concentration of potassium, similar to intracellular fluid, and the perilymph has a high sodium concentration and communicates with the cerebrospinal fluid (CSF). Maintenance of the ionic gradients is an active process and is essential for neuronal activity.

There are approximately 15,000 hair cells in the human cochlea. They are arranged in rows of inner and outer hair cells. The inner hair cells act as mechanoelectric transducers, converting the acoustic signal into an electric impulse. The outer hair cells contain contractile proteins and serve to tune the basilar membrane on which they are positioned.

Each inner hair cell responds to a particular frequency of vibration. When stimulated, it depolarises and passes an impulse to the cochlear nuclei in the brainstem.

The vestibular labyrinth consists of the semicircular canals, utricle and saccule and their central connections. The three semicircular canals are arranged in the three planes of space at right angles to each other. Like the auditory system, hair cells are present. In the lateral canals, the hair cells are embedded in a gelatinous cupula. Shearing forces, caused by angular movements of the head, produce hair cell movements and generate action potentials. In the utricle and saccule, the hair cells are embedded in an otoconial membrane that contains particles of calcium carbonate. These respond to changes in linear acceleration and the pull of gravity.

Impulses are carried centrally by the vestibular nerve and connections are made to the spinal cord, cerebellum and external ocular muscles. Its function is to record the position and movements of the head.

The sensory nerve supply

The external ear is supplied by the auriculotemporal branch.
Friedrich Heinrich Adolf Rinne, 1819–1868, otologist, Göttingen, Germany, described his test in 1855.

Friedrich Eugen Weber-Liel, 1832–1891, otologist, University of Berlin and Jena, Germany. He described the operation of tenotomy of the tensor tympani used for certain forms of partial deafness.

The skin on the outer surface of the eardrum migrates outwards so that the ear canal is ‘self-cleaning’.

The facial nerve pursues a tortuous course through the middle ear.

The ear has a rich sensory innervation so that ‘referred otalgia’ is common.

Cancer of the larynx can present with otalgia.

Taking a thorough history is the most important part of the assessment; the symptoms that need to be enquired after are listed in Table 47.1.

Table 47.1 History-taking.

**EXAMINATION OF THE EAR**

The tools of the trade are shown in Figure 47.3. Examination of the ear is part of the general ear, nose and throat (ENT) examination. The Rinne and Weber tuning fork tests are used to distinguish between a conductive and a sensorineural hearing loss.

In Weber’s test, the base of a 256 Hz vibrating tuning fork is placed on the centre of the patient’s forehead so that the sound is conducted through the bones of the skull (not air). If the patient hears the sound more clearly in one ear than the other, then there is either a conductive loss in that ear or neurological loss in the opposite ear. Rinne’s test then distinguishes between these two possibilities. A 512-Hz tuning fork is placed on the mastoid bone until the patient can no longer ‘hear’ it vibrating. It is then moved so that its tips are just outside the ear. The patient should now ‘hear’ the sound again if conduction is normal.

The cranial nerves and especially the function of the facial nerve should be examined.
Although conversational testing can give a useful guide to the level of hearing, pure tone audiometry in a soundproof booth is the best way of establishing the air and bone hearing levels (Figure 47.4). Other common audiological tests include speech audiometry, tympanometry, stapedial reflexes, electric response audiometry, otoacoustic emissions, caloric testing and electroneystagmography (see Further reading).

Radiological investigation
Computed tomography (CT) scanning of the temporal bones is routinely used preoperatively to show detailed individual anatomy, as well as alerting the surgeon to anatomical variants. Pus, bone and air are shown well on high-resolution CT (Figure 47.5).

Magnetic resonance imaging (MRI) is better than CT at imaging soft tissue (e.g. facial and auditory nerve) and is the best method for imaging tumours of the acoustic nerves (Figure 47.6).

CONDITIONS OF THE EXTERNAL EAR

Congenital anomalies
See Table 47.2.

</tr>
</tbody>
</table>

Trauma
A haematoma of the pinna occurs when blood collects under the perichondrium. The cartilage receives its blood supply from the perichondrial layer and will die if the haematoma is not evacuated, resulting in a cauliflower ear. A generous incision under general anaesthetic, with a pressure dressing or compressive sutures and antibiotic cover, is recommended (Figure 47.7).

Inflammation and infection
Otitis externa is common and consists of generalised inflammation of the skin of the external auditory meatus. The cause is
often multifactorial but includes general skin disorders, such as psoriasis and eczema, and trauma. Common pathogens are *Pseudomonas* and *Staphylococcus* bacteria, *Candida* and *Aspergillus*. Once the skin of the ear canal becomes oedematous, skin migration stops and debris collects in the ear canal. This acts as a substrate for the pathogens. The hallmark of acute otitis externa is severe pain. Movement of the pinna elicits pain, which distinguishes it from otitis media.

The initial treatment is with topical antibiotics and steroid ear drops, together with analgesia. If this fails, meticulous removal of the debris with the aid of an operating microscope is required. Fungal infection can be recognised by the presence of hyphae within the canal (Figure 47.9). Fungal infection causes irritation and itch. The treatment is meticulous removal of the fungus and any debris, as well as stopping any concurrent antibiotics. Systemic antibiotics are rarely required for otitis externa but should be used if cellulitis of the pinna occurs (Figure 47.10).

**Necrotising otitis externa** is a rare but important condition. It presents as a severe, persistent, unilateral otitis externa in an immunocompromised individual. It is important to think of the diagnosis in an elderly diabetic patient. Usually the infecting organism is *Pseudomonas aeruginosa*. Osteomyelitis of the skull base occurs and several cranial nerves (VII, IX, X) may be destroyed by the progressing infection. Intensive systemic antibiotics are required and the disease process should be monitored by high-resolution imaging (Summary box 47.3).
Summary box 47.3

Types of otitis externa

- Acute bacterial otitis externa is very common and extremely painful; treat with topical steroids and topical antibiotics
- Systemic antibiotics should be reserved for cellulitis of the pinna
- Chronic otitis externa needs the underlying dermatitis to be treated; application of topical steroid in spirit is recommended
- Fungal otitis externa itches and can be diagnosed by the presence of hyphae and spores; treat with meticulous cleaning and stop antibiotics
- Necrotising otitis externa is a progressive skull base infection that occurs in immunocompromised individuals and can be life-threatening; intensive long-term antibiotic treatment is required

Neoplasms

Benign osteomas arise from the bone of the ear canal in individuals who swim in cold water (Figure 47.11). No treatment is required unless the osteomas obstruct the canal. Other benign tumours include papillomas and adenomas.

Malignant primary tumours of the external ear are either basal cell or squamous cell carcinomas (Figure 47.12). Both may present as ulcerating or crusting lesions that grow slowly and may be ignored by elderly patients. Squamous cell carcinomas metastasise to the parotid and/or neck nodes. The ear canal may be invaded by tumours from the parotid gland and post-nasal space carcinomas, which ‘creep’ up the Eustachian tube. All resectable malignant tumours of the ear are treated primarily with surgery, with or without the addition of radiation therapy.

CONDITIONS OF THE MIDDLE EAR

Congenital anomalies

Congenital anomalies of the middle ear may be associated with other general congenital deformities. There are a number of branchial arch syndromes, e.g. Pierre Robin’s, craniofacial dysostosis, Down’s and Treacher Collins’ syndromes.

Trauma

Trauma to the middle ear can result in a perforated tympanic membrane (Figure 47.13a). Such perforations usually heal spontaneously (Figure 47.13b). Trauma can also result in ossicular discontinuity and it is usually the incus that is displaced. Tympanoplasty operations are available to reconstruct the
damaged ossicular chain and repair the tympanic membrane (Summary box 47.4).

**Summary box 47.4**

*Congenital anomalies and trauma of the middle ear*

- Congenital anomalies may be isolated or associated with general congenital deformities
- CT can identify middle ear abnormalities that may be corrected by surgery
- Traumatic perforations of the tympanic membrane usually heal spontaneously, but explosive and welding injuries do not
- A myringoplasty is an operation that repairs the tympanic membrane
- With severe head trauma, the incus can be displaced, which leads to a conductive hearing loss

**Suppurative otitis media**

Suppurative otitis media is extremely common in childhood and is characterised by purulent fluid in the middle ear. Mastoiditis may be associated with otitis media because the mastoid air cells connect freely with the middle ear space. The tympanic membrane bulges because of pressure from the pus in the middle ear (Figure 47.14). The child suffers extreme pain until the tympanic membrane bursts. The most common infecting organisms are *Streptococcus pneumoniae* and *Haemophilus influenzae*. Appropriate systemic antibiotics should be given for 10 days.

Mastoiditis (Figure 47.15) requires hospital admission and intravenous antibiotics. If the infection does not resolve quickly, a cortical mastoidectomy is required, together with a myringotomy. Mastoiditis can lead to intracranial infection.

**Otitis media with effusion (glue ear)**

The majority of children experience at least one episode of glue ear. It is primarily thought to be caused by poor Eustachian tube function. Initially, the negative middle ear pressure results in transudation of fluid into the middle ear space (Figure 47.16). If hypoxia continues, a mucoid exudate is produced by the glands within the middle ear mucosa. This sticky exudate is referred to as ‘glue ear’.

The following symptoms may be associated with glue ear:

- hearing impairment, which often fluctuates;
- delayed speech;
- behavioural problems;
- recurrent ear infections, which occur because the exudate is an ideal culture medium for micro-organisms;
- reading and learning difficulties at school.

**The otoscopic findings with glue ear**

The otoscopic findings of exudative glue ear are of a dull drum that is immobile on pneumatic otoscopy. The tympanic membrane is retracted and radial blood vessels may be present (Figure 47.17).

In children first presenting with bilateral glue ear, 50 per cent will be better within 6 weeks. Initially, a ‘wait and watch’ policy is therefore appropriate. If a bilateral conductive hearing loss persists, the child will miss out on educational opportunities...
and may not fulfil his or her academic potential; in these circumstances, treatment is required.

Medical treatment is of limited value. The Otovent® device may improve Eustachian tube function and is worth trying. Insertion of ventilation tubes (grommets) (Figure 47.18) and adenoidectomy are effective. The controversy is not whether surgery works, but when to intervene.

A middle ear effusion in adults is relatively rare and, when it occurs, it does not usually last long. The condition is often associated with an upper respiratory tract infection. A persistent unilateral effusion in an adult should always be viewed with suspicion. A nasopharyngeal carcinoma may cause the effusion by blocking the opening of the Eustachian tube in the post-nasal space. This is the most common carcinoma in men in southern China (Summary box 47.5).

Summary box 47.5

Acute suppurative otitis media and glue ear

- Acute suppurative otitis media can progress to mastoiditis
- Glue ear is very common in children and usually resolves without treatment
- Persistent hearing loss and/or recurrent acute otitis media is best treated with grommets and/or an adenoidectomy
- A persistent middle ear effusion in an adult is rare and may be caused by a cancer of the post-nasal space, especially in Chinese and Asian races
Chronic suppurative otitis media

Chronic suppurative otitis media (CSOM) may involve the pars tensa and the middle ear and is referred to as tubotympanic disease; it results from trauma or infection. When perforated, the tympanic membrane usually repairs itself, but if the outer layer of the tympanic membrane fuses with inner mucosa a chronic perforation results (Figure 47.19). The patient’s main symptoms are of an intermittent mucoid discharge associated with a mild conductive hearing loss. It is rare for this type of disease to be associated with intracranial complications.

A diagnosis is made on otoscopy and the tuning forks usually suggest a conductive hearing impairment. The first-line treatment is topical antibiotics and steroid drops and, on occasion, microsuction. If medical treatment fails, it may be necessary to graft the tympanic membrane.

Atticoantral CSOM (often associated with cholesteatoma) is important because of the complications associated with it. A retraction pocket develops in the pars flaccida and, if the squamous epithelium cannot migrate out of this pocket, a cholesteatoma results. A low-grade osteomyelitis gives the discharge its characteristic faecal smell. Invariably, the discharge is accompanied by hearing loss and mild discomfort. The patient may simply put up with these symptoms until a severe complication occurs.

The hearing loss that is caused by cholesteatoma may be conductive as a result of ossicular erosion or sensorineural as a result of cochlea damage. Vestibular symptoms may occur because of erosion of the semicircular canals or the migration of toxins into the vestibule. Erosion of the facial nerve is relatively unusual.

The close proximity of the middle ear and mastoid to the middle and posterior cranial fossae means that intracranial sepsis can result from chronic ear disease. The infection spreads to the dura via emissary veins, which connect the middle ear mucosa to the dura, or by direct extension of the disease through the bone. Meningitis, extradural, subdural or intracerebral abscess, or a combination of these may occur. Diagnosis should be suspected on otoscopy (Figure 47.20). Pus, crusts, granulations or a whitish debris in the attic are hallmarks of the disease. Examination under the microscope, audiometry and, sometimes, CT scanning are indicated.

The treatment is surgical and follows the principle of exposing the disease, excising the disease and then exteriorising the affected area. Three commonly applied operations for this disease are an atticotomy, modified radical mastoidectomy or combined approach tympanoplasty (Summary box 47.6).

Summary box 47.6

**Chronic suppurative middle ear disease**
- Tubotympanic CSOM, in which there is a hole in the eardrum and frequently a mucoid discharge; this is seldom serious
- Atticoantral CSOM (cholesteatoma). In this condition, squamous epithelium has invaded a retraction pocket in the attic part of the eardrum and is known as a cholesteatoma. Presents with hearing loss and faecal smell from the ear. It is a common cause of intracranial sepsis

**Tuberculous otitis media**

This is an important cause of suppuration in many countries. The diagnosis should always be considered in any ear that fails to respond to standard therapy.

**Otosclerosis**

This is a condition in which new abnormal spongy bone is laid down in the temporal bone. Of particular importance is the bone that is laid down around the footplate of the stapes, which
impedes the mobility of the stapes and results in a conductive hearing loss (Figure 47.21). A diagnosis should be suspected in any patient with a conductive hearing loss and a normal tympanic membrane.

A similar type of stapes fixation occurs in osteogenesis imperfecta and is known as van der Hoeve’s syndrome. Otosclerosis is often bilateral.

The treatment options are simple reassurance, a hearing aid or a stapedotomy operation (Figure 47.22).

**Neoplasms**

Middle ear tumours are rare with the most common being a glomus tumour (Figure 47.23). Glomus tumours arise from non-chromaffin paraganglionic tissue. The carotid body tumour arising in the neck is an example of this type of tumour. In the temporal bone, three types of glomus tumour are recognised and classification depends on the location: glomus tympanicum (arising in the middle ear), glomus jugulare (arising next to the jugular bulb) and glomus vagale (skull base).

Pulsatile tinnitus is a classic symptom and the hearing loss that occurs may be either conductive or sensorineural. Palsies of the VIIth, IXth, Xth, XIth and/or XIIth nerves may occur. The classic sign is a cherry-red mass lying behind the tympanic membrane. An audible bruit may be heard with a stethoscope over the temporal bone. The treatment of choice is preoperative embolisation followed by surgical excision. Radiotherapy is also effective.

Squamous cell carcinoma may also occur within the middle ear. It usually presents with deep-seated pain and a blood-stained discharge. Facial paralysis often occurs. Squamous carcinomas usually arise in a chronically discharging ear and can arise in a chronically infected mastoid cavity. Radical surgical excision, with or without radiotherapy, provides the only chance of cure (Summary box 47.7).

**Figure 47.21** Section of normal stapes (a) and section of stapes affected by otosclerosis (b).
CONGENITAL ANOMALIES

Congenital inner ear disorders may be associated with external or middle ear abnormalities or exist on their own. The most common anomaly is dysplasia of the membranous labyrinth, although dysplasia of the bony labyrinth and even total aplasia of the ear may occur. Intrauterine infections, including rubella, toxoplasmosis and cytomegalovirus infection, can cause inner ear damage. Perinatal hypoxia, jaundice and prematurity are also risk factors for a hearing loss. After birth, meningitis may cause profound sensorineural hearing loss.

If a child’s parents suspect a hearing impairment, it is important to believe them, especially when glue ear has been excluded. In children in whom there is a suspicion of sensorineural hearing loss, brainstem-evoked audiometry is used to establish hearing thresholds (Figure 47.24). If some hearing is present, the early fitting of hearing aids can maximise the neural plasticity that is present in the developing brain. If a child has a profound hearing loss, early intervention with a cochlear implant is the ideal solution (Figure 47.25). Most cases of profound sensorineural hearing loss are due to loss of cochlear hair cells, so that an implant inserted through the round window can selectively stimulate the cochlear neurones, which usually remain intact. The results of cochlear implantation are miraculous but it is expensive technology.
Presbycusis

Presbycusis is characterised by a gradual loss of hearing in both ears, with or without tinnitus. The hearing loss usually affects the higher frequencies and a classical audiogram is shown in Figure 47.26. The consonants of speech lie within the high-frequency range, which makes speech discrimination difficult.

Many patients with presbycusis are concerned that they may lose their hearing completely and they need reassurance. Hearing aid technology has improved dramatically and most patients can benefit.

Tinnitus

Tinnitus is an abnormal noise that appears to come from the ear or within the head. It may have an extrinsic cause, for example the pulsatile tinnitus of a glomus tumour. Usually, however, the tinnitus is generated within the cochlea. Most people will experience tinnitus at some time in their lives. Tinnitus frequently accompanies presbycusis, as well as any other condition that damages the inner ear structures. Most individuals adapt to the presence of tinnitus, but in some patients it proves intrusive. Reassurance and relaxation therapy are highly effective as are hearing aids for patients who also have presbycusis. An ENT surgeon who was a keen fisherman found that he could not hear his tinnitus when fishing next to a waterfall. From this observation, tinnitus maskers were developed (Figure 47.27). A masker provides a similar noise to the tinnitus and ‘blanks it out’.

Trauma

Noise exposure

Hair cells within the cochlea are damaged by sudden acoustic trauma (blast injury or gunfire) or prolonged exposure to excessive noise. The sensorineural hearing loss that results is greatest at high frequencies (particularly 4000 Hz) and is often accompanied by tinnitus (Figure 47.28). The law in the UK requires that workers are protected from noise, but in a disco an individual relies on common sense!

Head injury

The otic capsule is the hardest bone in the body but, if trauma to the head is severe, temporal bone fractures may occur. These tend to be either longitudinal (80 per cent) or transverse (20 per cent). Transverse fractures usually involve the labyrinth and lead to a sensorineural hearing loss that is permanent. Profound vertigo occurs initially, followed by gradual compensation. In about 50 per cent of cases, there is an associated facial nerve paralysis.

Drug ototoxicity

Certain drugs differentially affect the cochlea, causing hearing loss and tinnitus, whereas others affect the vestibular system, causing vertigo. Aminoglycosides are well known to be ototoxic, as is cis-platinum. Recognition of risk factors, such as poor renal function in patients being treated with aminoglycosides, is most important. Although many topical ear drops contain aminoglycosides, there is little evidence that such topical treatment causes sensorineural hearing loss if used for short periods.
Prosper Menière, 1799–1862, physician, Institute for Deaf Mutes, Paris, France, described this condition in 1861. Sir Charles Bell, 1774–1842, surgeon, The Middlesex Hospital, London, UK (1812–1835), and later Professor of Surgery, the University of Edinburgh, Scotland, UK (1836–1842).

John W Epley, contemporary, Director, Portland Otology Clinic, Portland, Oregon, USA, established his clinic in 1975; he developed the Epley manoeuvre for treating benign paroxysmal positional vertigo.

Benign paroxysmal positional vertigo (BPPV) may follow head or neck trauma. Vertigo is an illusion of movement and BPPV is characterised by intermittent attacks of vertigo that occur when the head is moved in a certain position. Typically, the vertigo only lasts for a few seconds and is not associated with other otological symptoms. Positional testing can evoke nystagmus and helps in the diagnosis of this condition. The condition is usually self-limiting, and special manoeuvres described by Epley help the majority of patients.

Reduction in cochlear blood flow

This is the most likely cause for most cases of sudden onset of severe sensorineural hearing loss. Five per cent of patients with an acoustic neuroma present with sudden sensorineural hearing loss and, therefore, radiological investigation is required to exclude this diagnosis.

Inflammation

Viral infections are thought to account for acute vestibular failure. This condition is characterised by a sudden onset of vertigo. The vertigo is so severe that the patient goes to bed for 5 days. Central compensation then occurs, although recurring episodes of vertigo can occur for up to 18 months.

Menière’s disease

The aetiology is not known but the pathology is well documented. There is an excessive accumulation of endolymphatic fluid (hydrops) and it is thought that the distension of the endolymphatic compartment may rupture Reissner’s membrane, which leads to mixing of endolymph and perilymph. The condition is characterised by a triad of symptoms: intermittent attacks of vertigo, a fluctuating sensorineural hearing loss and tinnitus. The patient often has a sensation of pressure in the affected ear before an attack. The hearing loss typically affects the lower frequencies. The vertigo characteristically lasts between 30 minutes and 6 hours and is often accompanied by nausea and vomiting. The investigations include pure tone audiometry, electrocochleography and an MRI scan to exclude an acoustic neuroma. Medical treatment with betahistadine and diuretics is effective, with selective destruction of the vestibular labyrinth by percolating gentamicin through a grommet being reserved for resistant cases.

Facial paralysis

Viral infections that involve the facial nerve are one of the most common causes of facial weakness (80 per cent). Bell’s palsy results from a viral infection of the facial nerve. The nerve swells and is compressed within the temporal bone. Early treatment with high-dose steroids is appropriate. Not all facial nerve palsies are due to viral infection and a thorough otoneurological examination is required. The facial nerve can be damaged at the cerebellopontine angle, within the internal auditory meatus, within the middle ear, at the skull base and within the parotid gland. It is essential to consider these potential sites of facial nerve damage in any patient with VIIth nerve paralysis (Summary box 47.8).

Summary box 47.8

Facial paralysis

- The facial nerve passes through the middle ear and mastoid
- When considering a paralysis, think ‘complete’ or ‘partial’
- Protect the eye: carry out a full otoneurological examination to find the cause
- If acute, consider steroids and antiviral agents
Ramsay Hunt syndrome
This is caused by herpes zoster and is characterised by facial paralysis, pain and the appearance of vesicles on the tympanic membrane, ear canal and pinna (Figure 47.29). It is accompanied by vertigo and sensorineural hearing loss (VIIIth nerve). Treatment with aciclovir is effective if given early.

The metabolic causes of inner ear damage
These include diabetes mellitus and thyroid disease, both of which may cause sensorineural hearing loss.

Neoplasms
These are uncommon but can present with sensorineural hearing loss, tinnitus and vertigo. Acoustic neuromas, which are actually schwannomas of the vestibular division of the VIIIth nerve, are the most common, followed by meningiomas. Acoustic neuromas grow slowly and somewhat unpredictably and as they expand can cause cranial nerve palsies, brainstem compression and raised intracranial pressure. The early symptoms are a unilateral sensorineural hearing loss or unilateral tinnitus, or both. It is important to diagnose these tumours early and remove them when they are small. The morbidity and mortality from surgery is directly related to tumour size. If the tumour is removed when it is small, there is an extremely good chance of preserving facial nerve function.

The investigation of choice for detecting acoustic neuromas is MRI. The treatment options include a ‘wait and see’ policy, which may be appropriate for an elderly patient with minimal symptoms. MRI can be used to monitor the tumour (Summary box 47.9).

Summary box 47.9

- Presbycusis is the bilateral high-frequency loss associated with ageing
- Unilateral tinnitus or sensorineural hearing loss needs to be investigated to exclude acoustic neuroma
- Sudden sensorineural hearing loss needs immediate treatment, and radiological investigation in the case of acoustic neuroma
- Menière’s disease presents with the triad of sensorineural hearing loss, tinnitus and vertigo

FURTHER READING
CLINICAL ANATOMY AND PHYSIOLOGY

The pharynx
The pharynx is a fibromuscular tube forming the upper part of the respiratory and digestive passages. It extends from the base of the skull to the level of the sixth cervical vertebra at the lower border of the cricoid cartilage where it becomes continuous with the oesophagus. It is divided into three parts: the nasopharynx, oropharynx and hypopharynx (Figure 48.1).

Nasopharynx
The nasopharynx lies anterior to the first cervical vertebra and has the openings of the Eustachian tubes in its lateral wall, behind which lie the pharyngeal recesses, the fossae of Rosenmüller. The adenoids are situated submucosally at the junction of the roof and posterior wall of the nasopharynx.

Oropharynx
This is bounded above by the soft palate, below by the upper surface of the epiglottis and anteriorly by the anterior faucial pillars. The oropharynx contains the palatine tonsils situated in the lateral wall between the anterior and posterior pillars of the fauces. They are part of the complete ring of lymphoid tissue (Waldeyer’s ring) together with the adenoids and lingual tonsils on the posterior third of the tongue. This ring of lymphoid tissue occupying the entry to the air and food passages is constantly exposed to new antigenic stimuli and is an important part of the mucosa-associated lymphoid tissues (MALT), which process antigen and present it to T helper cells and B cells (Figure 48.2).

The tissue of Waldeyer’s ring undergoes physiological hypertrophy during early childhood as the child is exposed to...
increasing amounts of antigenic stimuli, and there is often a similar hypertrophy of the cervical lymph nodes.

It also has an exceptionally good blood supply from the facial artery, which may be closely related to the lower pole, and laterally a plexus of paratonsillar veins, which may be the source of serious venous bleeding following tonsillectomy.

**Hypopharynx**

The hypopharynx is bounded above and anteriorly by the sloping laryngeal inlet. Its inferior border is the lower border of the cricoid cartilage where it continues into the oesophagus. The hypopharynx is commonly divided into three areas: the pyriform fossae, the posterior pharyngeal wall and the post-cricoid area. The mucosa of these areas is, however, continuous so disease processes, such as squamous carcinoma, can easily involve more than one area and may also spread submucosally. The motor nerve supply of the pharynx and larynx is the vagus nerve.

Understanding of the physiology of normal swallowing and the problems caused by disease has been enhanced in the last two decades by the use of videofluoroscopy in which the passage of a bolus of radio-opaque liquid or solid from the point at which it enters the oral cavity down to its passage within the stomach is examined radiologically. It is considerably more accurate than a barium swallow.

Swallowing is mediated via efferent fibres passing to the medulla oblongata through the second division of the trigeminal nerve (V), glossopharyngeal nerve (IX) and vagus nerve (X) (Figure 48.3). The afferent pathway is from the nucleus ambiguous and is mediated via the glossopharyngeal (IX), vagus (X) and hypoglossal (XII) nerves. Damage to these major cranial nerves at any point along their pathway, by trauma or disease, may cause dysphagia with or without aspiration.

The main function of the larynx is not the production of voice but the protection of the tracheobronchial airway and lungs; it closes completely during swallowing.

**RELATIONS OF THE PHARYNX**

Some of these are illustrated in Figure 48.4.

**Parapharyngeal space**

This potential space lies lateral to the pharynx and extends from the base of the skull above to the superior mediastinum below. It is occupied by the carotid vessels, internal jugular vein, deep cervical lymph nodes, the last four cranial nerves and the cervical sympathetic trunk.

Infection and suppuration of the cervical lymph node in the parapharyngeal space most commonly occurs from infections of the tonsils or teeth (particularly the third lower molar tooth). It may then spread up to the skull base or down to the paraoesophageal region and superior mediastinum.

**Retropharyngeal space**

This potential space lies posterior to the pharynx, bounded anteriorly by the posterior pharyngeal wall and its covering buccopharyngeal fascia and posteriorly by the cervical vertebrae and their covering muscles and fascia. It contains the retropharyngeal lymph nodes, which are usually paired lateral nodes but which are separated by a tough median partition that connects the prevertebral with the buccopharyngeal fascia.

These nodes are more developed in infancy and young children, and it is at this age that they are most likely to be involved in inflammatory processes, which, if severe, may affect swallowing and respiration as a consequence of gross swelling and suppuration of the retropharyngeal space.
**Larynx**

The larynx is the protective sphincter that closes off the airway during swallowing and, in humans and some other mammals, is responsible for the production of sound. The larynx has a mainly cartilaginous framework that may ossify in later life, and which consists of the hyoid bone above, the thyroid and cricoid cartilages and the intricate arytenoid cartilages posteriorly.

The cricoid cartilage is the only complete ring in the entire airway and bounds the subglottis, which is the narrowest point of the airway. This is the most common site for damage from an endotracheal tube used for intensive care unit ventilation in seriously ill patients.

An anatomical description of the larynx divides it into the supraglottis, glottis and subglottis (Figure 48.5). The true vocal folds (often incorrectly called the vocal cords) are normally white in contrast to the pink mucosa of the rest of the larynx and airway. The true vocal folds meet anteriorly at the midlevel of the thyroid cartilage, whereas posteriorly they are separate and attached to an arytenoid cartilage. This arrangement produces the 'V' shape of the glottis (Figure 48.6).

**Nerve supply**

The sensory nerve supply to the larynx above the vocal folds is from the superior laryngeal nerve and below the vocal folds is from the recurrent laryngeal nerve. Both these nerves are branches of the vagus nerve (X). The motor nerve supply to the larynx is from the recurrent laryngeal nerve, which is a branch of the vagus nerve and which supplies all intrinsic muscles. Only one of these intrinsic muscles, the posterior cricoarytenoid, abducts the vocal folds during respiration. All other intrinsic muscles adduct the cords. As all of the intrinsic muscles of the larynx are supplied by the recurrent laryngeal nerve, damage to this nerve or to the vagus nerve will cause paralysis of the vocal fold on the side of the damage.
**Phonation/speech**

The larynx functions by closing the vocal fold against the air being exhaled from the lungs, but the rise in subglottic pressure forces the vocal folds apart slightly for an instant of time with accompanying vibration of the vocal fold epithelium. The opening and closing occurs in rapid sequence to produce a vibrating column of air, which is the source of sound.

Paralysis or disease of the vocal folds or closely associated laryngeal structures will give rise to disturbance of the sound, producing hoarseness.

The functions of the larynx are given in Summary box 48.1.

**The neck**

The neck is divided into anterior and posterior triangles by the sternocleidomastoid muscle. The anterior triangle extends from the inferior border of the mandible to the sternum below, and is bounded by the midline and the sternocleidomastoid muscle. The posterior triangle extends backwards to the anterior border of the trapezius muscle and inferiorly to the clavicle. The upper part of the anterior triangle is commonly subdivided into the submandibular triangle above the digastic muscle and the submental triangle below. The lymphatic drainage of the head and neck is of considerable clinical importance (Figure 48.7). The most important chain of nodes are the jugular nodes (also called cervical), which run adjacent to the internal jugular vein. The other main groups are the submental, submandibular, pre- and post-auricular, occipital and posterior triangle nodes.

A system of levels is used to describe the location of these neck nodes (Figure 48.8). The upper jugular nodes, level II, which contain the large jugulodigastric node, drain the naso- and oropharynx, including the tonsils, postero lateral aspects of the oral cavity, and the superior aspects of the larynx and pyriform fossae. They are the most common site of enlargement and may be palpated along the anterior border of the sternocleidomastoid muscle.

Metastatic spread of squamous cell carcinoma (80 per cent of head and neck cancer) most commonly occurs with tumours of the nasopharynx, tongue base, tonsil, pyriform fossae and supraglottic larynx. When an enlarged neck node is detected and malignant disease is suspected, these five primary sites must be carefully examined.

**CLINICAL EXAMINATION**

**Pharynx and larynx**

Before examination of the pharynx, the oral cavity should be examined with the aid of a good light and tongue depressors. A reflecting mirror on the head or a headband-mounted fibreoptic light source permits use of both hands to hold instruments. Inspection should include the buccal mucosa and lips, the palate, the tongue and floor of the mouth, all surfaces of the teeth and gums, opening and closing of the mouth and dental occlusion. Patients should be asked to elevate the tongue to the roof of the mouth and protrude the tongue to both the right and the left. Palpation may be required using one or two fingers gently intraorally to feel any swellings and this may be combined with extraoral palpation of the submental and submandibular lymph nodes and salivary glands.

Following examination of the oral cavity, the oropharynx is
then inspected with the tongue depressor placed firmly onto the tongue base to depress it inferiorly. The anterior and posterior faucial pillars, the tonsil, retromolar trigone and posterior pharyngeal wall should all be inspected for colour changes, ulceration, pus, foreign bodies and swellings. Even with an experienced examiner, approximately one-third of patients cannot tolerate the depression of the posterior base of tongue without gagging. Pain and trismus as a consequence of pharyngolaryngeal or neck pathology may additionally add to the difficulty of the examination.

Fibreoptic endoscopes passed through the nose or through the mouth, with or without topical anaesthesia, allow high-quality examination of the entire nasopharynx, oropharynx and larynx in almost every patient.

The neck

The patient should be examined sitting with the whole neck exposed so that both clavicles are clearly seen. The neck is inspected from in front and the patient asked to swallow, preferably with the aid of a sip of water. Movements of the larynx and any swelling in the neck are noted. The patient should be asked to protrude the tongue if there is a midline neck swelling. A thyroglossal cyst will move upwards with the tongue protrusion. The patient is then examined from behind with the chin flexed slightly downwards to remove any undue tension in the strap muscles, platysma and sternocleidomastoids. The neck is palpated bilaterally in a sequential manner comparing the two sides of the neck.

On examining for a lump in the neck, it is often helpful to ask the patient to point to the lump first. Ask if the lump is tender. A swelling beneath the sternomastoid muscle may be considerably larger than thought on palpation. If malignancy is suspected (hard, irregular or fixed to overlying skin or to deep structures), inspection of the nasopharynx, tonsils, tongue base, pyriform fossae and supraglottic larynx is essential (Summary box 48.2).

INVESTIGATIONS OF THE PHARYNX, LARYNX AND NECK

Plain lateral radiographs

Plain lateral radiographs of the neck and cervical spine may show soft tissue abnormalities; of particular importance is the depth and outline of the prevertebral soft tissue shadow. The outline of the laryngotracheal airway may be a useful guide to the presence of disease in the pharynx and larynx (Figure 48.9).

There should be no air within the upper oesophagus. If air is seen, endoscopy is advised. Radio-opaque foreign bodies may be seen impacted in the pharynx, larynx or upper oesophagus on these radiographs.

Barium swallow

Barium liquid video fluoroscopic studies record the movement of a small quantity of radio-opaque liquid and allow detailed evaluation of the oral and pharyngeal phases of swallowing (Figure 48.10).

Computed tomography scanning

Computed tomography (CT) scanning provides much improved demonstration of disease in the pharynx, larynx and neck. Intravenous contrast given at the same time as the CT scan

Figure 48.9 Plain lateral radiograph showing normal anatomy.
Investigations of the pharynx, larynx and neck

PART 7 | HEAD AND NECK

(dynamic scanning) further improves the demonstration of disease in these areas (Figure 48.11).

**Other imaging**
Magnetic resonance imaging (MRI) may be used to give better soft tissue definition of some diseases, however, bony and cartilaginous structures are less well defined (Figure 48.12). MRI is more vulnerable to movement artefact. Ultrasound scanning can be useful in differentiating solid lesions, e.g. malignant lymph nodes from cystic lesions such as a branchial cyst.

**Fine-needle aspiration cytology**
This technique can be performed under local anaesthesia. It is useful particularly if a neck lump is thought to be malignant. Increasingly high rates of accurate histological diagnosis are reported and there is no evidence of spread of tumour through the skin track caused by the fine hypodermic needle used with this technique. Flow cytometry should be undertaken if haematological malignancy, such as lymphoma, is suspected. Fine-needle aspiration is considerably aided by ultrasound or CT guidance.

**Angiography or digital subtraction vascular imaging**
These may be indicated if a vascular lesion, such as a carotid body tumour, is suspected. Angiography may have a therapeutic role to play by facilitating embolisation of the lesion.

**Direct pharyngoscopy and laryngoscopy**
Examination of the pharynx, larynx and neck under general anaesthesia may be required if there are problems with the routine examination of patients, such as an inadequate view as a result of trismus from pain, poor patient compliance or large obstructive pharyngeal or laryngeal pathology. These examinations may be further aided by the use of an operating microscope or rigid endoscope (Hopkins’ rod) (Figure 48.13).

Harold Horace Hopkins, 1918–1994, Professor of Applied Optics, University of Reading, Reading, UK. He invented the rigid rod endoscope (Hopkins’ rod, 1954), and contributed to the development of the fibres for flexible endoscopes.

The advantages and disadvantages of laryngeal examination techniques are given in Summary box 48.3.
Summary box 48.3

Advantages and disadvantages of larynx and pharynx examination techniques

Flexible nasendoscopy
- Well-tolerated examination
- Can also examine nasal passages and post-nasal space
- Need fibreoptic light source

Rigid endoscopy
- Can be used with stroboscope for evaluation of voice
- High definition view
- Needs fibreoptic light source
- Bulky and difficult if prominent gag reflex present

Laryngeal mirror
- Does not need fibreoptic light source
- No record of exam, small image

DISEASES OF THE PHARYNX

Nasopharynx

Enlarged adenoid

The most common cause of an enlarged adenoid (there is only one nasopharyngeal adenoid, despite the common use of the term ‘adenoids’) is physiological hypertrophy. The size of the adenoid alone is not an indication for removal. It is often associated with hypertrophy of the other lymphoid tissues of Waldeyer’s ring. If excessive hypertrophy causes blockage of the nasopharynx in association with tonsil hypertrophy, the upper airway may become compromised during sleep causing obstructive sleep apnoea.

Obstructive sleep apnoea

This condition is becoming increasingly diagnosed and is important because it can cause sleep deprivation and secondary cardiac complications. It has been implicated in some cases of sudden infant death syndrome. The most common symptom is snoring, which is typically irregular, with the child actually ceasing respiration (apnoea) and then restarting with a loud inspiratory snort. The child is often restless and may take up strange sleep positions as he or she tries to improve the pharyngeal airway. Surgical removal of the tonsils and adenoid is curative, but it is important to avoid sedative premedications and opiates postoperatively because they may further depress the child’s respiratory drive.

Obstructive sleep apnoea (OSA) may also occur in adults, where the obstruction may result from nasal deformity, a hypertrophic soft palate associated with an altered nasopharyngeal isthmus, obesity and general narrowing of the pharyngeal airway, or supraglottic laryngeal pathology. Initial investigation may include a sleep study, during which measurement of the patient’s sleep pattern and arterial oxygenation are undertaken. Continuous positive airways pressure (CPAP) devices may ameliorate OSA by splinting the obstruction open. Surgery may also be indicated, depending on the level(s) of the obstruction.

Hypertrophy of adenoid tissue most commonly occurs between the ages of four and ten, but the adenoid tissue usually undergoes spontaneous atrophy during puberty, although some remnants may persist into adult life (Figure 48.14). The relationship of adenoid enlargement to recurrent secretory otitis media or recurrent acute otitis media is not entirely clear.

Adenoidectomy

Adenoid tissue can be removed alone or in conjunction with a tonsillectomy. The indications for adenoidectomy are:
- obstructive sleep apnoea associated with post-nasal obstruction;
- post-nasal discharge;
- recurrent acute otitis media or prolonged serous otitis media, usually longer than three months’ duration;
- recurrent rhinosinusitis.

Removal of the adenoid

Operative technique. The adenoid tissue is removed with a guarded curette pressed against the roof of the nasopharynx and then carried downwards in a moderately firm sweeping movement bringing the excised adenoid into the oropharynx (Figures 48.15 and 48.16). The guard on the curette secures the adenoid and prevents it from dropping inferiorly into the airway. A
post-nasal swab is placed into the nasopharynx until all haemorrhage has ceased. A mirror can be used to guide the direction of the adenoid curette. Alternatively, suction monopolar diathermy may be used to remove adenoid tissue.

Reactive or secondary haemorrhage during the recovery period may require a nasopharyngeal pack under a further anaesthetic. This can occasionally cause respiratory depression in children and adults, and strict observation is required while the pack is in place.

**TUMOURS OF THE NASOPHARYNX**

**Benign**

There are two main types of benign tumour of the nasopharynx: the angiofibroma and the antrochoanal polyp. Both are rare.

**Angiofibroma**

This tumour is confined to young male patients, most commonly between the ages of 8 and 20 years. It usually causes progressive nasal obstruction, recurrent severe epistaxis, purulent rhinorrhea and, occasionally, loss of vision because of compression of the optic nerve. Although the tumour is rare, these symptoms in a young male patient should always arouse suspicion. The tumour is most common in northern India, although the reasons for this are unknown. Clinical examination often shows a tumour in the nasal cavity or nasopharynx, but CT scanning best demonstrates the extent of the tumour and its accompanying bony erosion. MRI scanning defines the soft tissue extent and, with these two modern investigations, angiography is rarely indicated. Biopsy should be avoided unless clinical and radiological examinations are not diagnostic because of the risk of bleeding.

Surgical resection requires adequate exposure either through a midfacial approach or lateral rhinotomy (Figures 48.17 and 48.18). Both allow ligation of the feeding maxillary artery. More recently, endoscopic resection has been used for smaller lesions.

**Antrochoanal polyp**

This relatively uncommon lesion is a benign mucosal polyp that arises in the maxillary antrum and prolapses into the nasal cavity where it expands backwards into the nasopharynx and occasionally into the oropharynx (Figures 48.19 and 48.20). It may mimic an angiofibroma from which it is distinguished by its avascularity and pale colour, and its site of origin on endoscopic examination and imaging. It requires complete removal via an endoscopic approach through the middle meatus or, occasionally, a Caldwell–Luc procedure.

**Malignant**

**Nasopharyngeal carcinoma**

Nasopharyngeal carcinomas are usually squamous cell carcinomas and have a very variable incidence. In most parts of the world, the tumour is rare with an annual incidence of one case per 100,000 population; however, among southern Chinese populations the rate is 30–50 cases per 100,000 population.
The aetiology of nasopharyngeal carcinoma is multifactorial. Genetic susceptibility, early infection by the Epstein–Barr virus and consumption of traditional diets, particularly salted fish, are known to contribute (Summary box 48.4).

**Summary box 48.4**

Aetiological factors in nasopharyngeal carcinoma

- Genetic, e.g. Cantonese
- Infective, e.g. Epstein–Barr virus
- Environmental, e.g. salted fish

The majority of tumours are undifferentiated with a characteristic morphology, comprising over 90 per cent of nasopharyngeal malignancy in endemic areas. Rare epithelial tumours are adenocarcinoma and adenoid cystic carcinoma. B- and T-cell lymphomas also occur in this region and should not be confused with the more common undifferentiated carcinoma. Nasopharyngeal carcinoma has a bimodal distribution with an increased incidence in teenagers and young adults and then again in the 50–60 age group.

**Clinical features**

Symptoms are closely related to the position of the tumour in the nasopharynx and the degree of distant spread if any. Early symptoms are often minimal and may be ignored by both patient and doctor. Approximately 50 per cent of patients will present with a mass of malignant nodes in the neck, indicating an advanced tumour. This percentage is even higher in patients under 21 years of age. Fine-needle aspiration or a biopsy of a neck node showing undifferentiated carcinoma requires immediate thorough examination of the nasopharynx. In about 5 per cent of patients, the nasopharynx may look normal or minimally asymmetrical but contains submucosal nasopharyngeal carcinoma. A biopsy of the nasopharynx is essential if there is suspicion of nasopharyngeal malignancy. Nasal complaints occur in one-third of patients and aural symptoms of unilateral deafness as a consequence of Eustachian tube obstruction and secretory otitis media occur in approximately 20 per cent. Neurological complications with cranial nerve palsies as a result of disease in the skull base occur relatively late in the disease, but are a poor prognostic factor (Summary box 48.5).

**Summary box 48.5**

Nasopharyngeal carcinoma: main presenting complaints

**Systemic**
- Cervical lymphadenopathy

**Local**
- Unilateral serous otitis media, otalgia
- Nasal obstruction, bloody discharge, epistaxis
- Cranial nerve palsies, especially III–VI then IX–XII

Investigation is by direct inspection with a flexible or rigid nasendoscope and biopsy under topical or general anaesthesia. Serological investigation for Epstein–Barr virus-associated antigenic markers in combination with the clinical and historical examination is valuable for the early detection of disease. Highly sensitive assays for antiviral antibodies together with virus-associated serological markers are useful in early detection. Immunoglobulin (Ig)A antiviral capsid antigen antibody and early antigen antibody have been evaluated in mass surveys in southern China and have been found to be an excellent screening method for the early detection of nasopharyngeal carcinoma in high-risk groups.

**Imaging**

Imaging is essential for staging and to determine the extent of disease. The investigation of choice is MRI with gadolinium and fat suppression. This allows for assessment of brain parenchyma, cavernous sinus and the closely associated cranial foramina. CT or positron emission tomography (PET) CT of the head, neck and chest has a major role in planning radiotherapy and assessing the response to treatment, diagnosing recurrence and detecting complications.

**Treatment**

The primary treatment of nasopharyngeal carcinoma is external beam or intensity modulated radiotherapy as the majority of the tumours are radiosensitive undifferentiated squamous cell carcinomas. Elective bilateral external radiotherapy is given to the skull base and neck in all patients, even when no neck nodes are apparent. Chemotherapy in both the adjuvant and neoadjuvant setting remains controversial. Surgery is usually reserved for regional recurrence in the neck. For early disease, three-year disease-free survival rates of more than 75 per cent are common;
however, in advanced disease the results are less good, with three-year disease-free survival rates of 30–50 per cent.

**OROPHARYNX**

**Acute tonsillitis**
This common condition is characterised by a sore throat, fever, general malaise, dysphagia, enlarged upper cervical nodes and sometimes referred otalgia. Approximately half the cases are bacterial, the most common cause being a pyogenic group A streptococcus. The remainder are viral and a wide variety of viruses have been implicated, in particular infectious mononucleosis, which may be mistaken for bacterial tonsillitis.

On examination, the tonsils are swollen and erythematous, and yellow or white pustules may be seen on the palatine tonsils, hence the name ‘follicular tonsillitis’ (Figure 48.21). A throat swab should be taken at the time of examination as well as blood for Paul–Bunnell testing.

**Treatment**
Paracetamol or similar analgesia may be administered to relieve pain and gargles of glycerol–thymol are soothing. The condition is frequently sensitive to benzyl- or phenoxyethylpenicillin (penicillin V) and these are given until antibiotic sensitivities are established. Ampicillin is avoided as it may precipitate a rash in patients with infectious mononucleosis. Most cases resolve in a few days.

**Quinsy**
This is an abscess in the peritonsillar region that causes severe pain and trismus (Figure 48.22). The trismus caused by spasm induced in the pterygoid muscles may make examination difficult but may be overcome by instillation of local anaesthesia into the posterior nasal cavity (anaesthetising the sphenopalatine ganglion) and the oropharynx. Inspection reveals a diffuse swelling of the soft palate just superior to the involved tonsil, displacing the uvula medially. In more advanced cases, pus may be seen pointing underneath the thin mucosa.

**Treatment**
In the early stages, intravenous broad-spectrum antibiotics may produce resolution. However, if there is frank abscess formation, incision and drainage of the pus can be carried out under local anaesthesia. A small scalpel is best modified by winding a strip of adhesive tape around the blade so that only 1 cm of the blade projects. In teenagers and young adults, the patient sits upright and an incision is made approximately midway between the base of the uvula and the third upper molar tooth (Figure 48.23). This may produce immediate release of pus, but, if not, a dressing forceps is pushed firmly through the incision and, on opening, pus may then be encountered. In small children, general anaesthesia is required.

**Chronic tonsillitis**
Chronic tonsillitis usually results from repeated attacks of acute tonsillitis in which the tonsils become progressively damaged and provide a reservoir for infective organisms.

**Tonsillectomy**
Recurrent acute tonsillitis is the most common relative indication for tonsillectomy in children and adolescents, although it is important that these attacks are well documented, frequent and do not simply constitute a minor viral sore throat. Chronic tonsillitis more frequently affects young adults, in whom it is important to establish that chronic mouth breathing secondary to nasal obstruction is not the main problem rather than the tonsils themselves. Absolute indications for tonsillectomy are when the size of the tonsils is contributing to airway obstruction or a malignancy of the tonsils is suspected (Table 48.1).
Table 48.1 Indications for tonsillectomy.

Ideally, the procedure should be undertaken when the tonsils are not acutely infected, and it is important to discuss factors that may increase the tendency to bleed. Blood transfusion is rarely required, but it is normal practice to type and screen blood for cross-match in children under 15 kg in weight.

Dissection tonsillectomy is carried out under general anaesthesia. The mucosa of the anterior faucial pillar is incised and the tonsil capsule identified. Using blunt dissection, the tonsil is separated from its bed until only a small inferior pedicle is left (Figure 48.24). It is then separated from the lingual tonsil. A tonsil swab is placed in the tonsillar bed and pressure applied for some minutes, following which bleeding points may be controlled by ligature or by bipolar diathermy.

Following surgery, the patient is kept under close observation for any systemic or local evidence of bleeding, with regular pulse and blood pressure measurements and observation to see whether the patient is swallowing excessively (Figure 48.25). Postoperatively, patients are encouraged to eat normally. Paracetamol is preferred to non-steroidal analgesics. Patients are allowed home on the same or following day and are warned that they may experience otalgia as a result of referred pain from the glossopharyngeal nerve and that secondary haemorrhage may occur up to 10 days following the surgery.

Haemorrhage is the most common complication in the immediate postoperative period. Local pressure may help in mild cases, but reactionary haemorrhage usually requires return to theatre for definitive treatment, particularly in younger patients. Under general anaesthesia, it may be possible to identify a bleeding spot, but often a more generalised ooze is observed and suturing of the tonsil bed combined with the application of Surgicel and bipolar diathermy is often more successful than attempted placement of ligatures.

Late haemorrhage is generally secondary to infection and patients should be commenced on intravenous antibiotics with aerobic and anaerobic cover. Significant or persistent bleeding may require a further general anaesthetic and undersewing of the surgical bed, which by this time will often be covered with slough and granulation tissue. Postoperative tonsillar haemorrhage is still a serious and life-threatening complication and should not be underestimated, particularly in the younger patient (Summary box 48.6).

**Summary box 48.6**

**Complications of tonsillectomy**
- Haemorrhage (immediate or late)
- Infection
- Pain/otalgia
- Postoperative airway obstruction
- Velopharyngeal insufficiency
- Parapharyngeal abscess

Parapharyngeal abscess may be confused with a peritonsillar abscess, but the maximal swelling is behind the posterior faucial pillar and there may be little oedema of the soft palate. The patient is usually a young child and there may be a severe general malaise. In early cases, admission to hospital and the institution of fluid replacements coupled with intravenous antibiotics may produce resolution. In advanced cases, drainage and intravenous antibiotics are required. With an obvious abscess pointing into the oropharynx, drainage may be carried out with a blunt instrument or the glove finger, but general anaesthesia is frequently required and the expertise of a senior anaesthetist, good illumination and good suction are absolutely essential. A large parapharyngeal abscess may compromise both the airway and swallowing.
Acute retropharyngeal abscess
This is the result of suppuration of the retropharyngeal lymph nodes and, again, is most commonly seen in children, with most cases occurring under one year of age. It is associated with infection of the tonsils, nasopharynx or oropharynx, and is frequently accompanied by severe general malaise, neck rigidity, dysphagia, drooling, a croupy cough, an altered cry and marked dyspnœa.

Dyspnœa may be the prominent symptom and may also be accompanied by febrile convulsions and vomiting. These children should always be carefully examined. Inspection of the posterior wall of the pharynx may show gross swelling and an abscess pointing beneath the thinned mucosa.

In countries where diphtheria still occurs, an acute retropharyngeal abscess may be confused with this, but the presence of the greyish-green membrane aids differentiation. Occasionally, a foreign body, most commonly a fish bone which has perforated the posterior pharyngeal mucosa, will give rise to a retropharyngeal abscess in older children and young adults. Intravenous antibiotics are commenced immediately, but surgical drainage of the abscess is often necessary. It requires experienced anaesthesia because, on induction, care must be taken to avoid rupturing the abscess. The airway is protected by placing the child in a head-down position while a pair of dressing forceps guided by the finger may be thrust into an obvious abscess in the posterior wall and the contents evacuated. On other occasions, an approach anterior and medial to the carotid sheath via a cervical incision anterior to the sternocleidomastoid muscle with an extension of tuberculosis of the cervical spine, which has spread through the anterior longitudinal ligament to reach the retropharyngeal space. In addition to the retropharyngeal swelling seen intraorally, there may be fullness behind the sternocleidomastoid muscle on one side. In contrast to an acute retropharyngeal abscess, this condition occurs almost solely in adults. Radiology usually shows evidence of bone destruction and loss of the normal curvature of the cervical spine. The spine may be quite unstable and undue manipulation may precipitate a neurological event.

A chronic retropharyngeal abscess must not be opened into the mouth, as such a procedure may lead to secondary infection. Drainage of the abscess may not be necessary if suitable treatment of the underlying tuberculosis disease is instituted. If it is necessary, drainage should be carried out through a cervical incision anterior to the sternocleidomastoid muscle with an approach anterior and medial to the carotid sheath to enter the retropharyngeal space. The cavity is opened and suctioned dry after taking biopsy material. Occasionally, surgery is required to decompress the spinal cord if there is a progressive neurological deficit.

Glandular fever (infectious mononucleosis)
This systemic condition is usually caused by the Epstein–Barr virus, but similar features can be caused by cytomegalovirus or toxoplasmosis. The tonsils are typically erythematous with a creamy grey exudate and appear almost confluent, usually symmetrical in contrast to a quinsy. In addition to the discomfort and dysphagia, patients may drool saliva and have respiratory difficulty, particularly on inspiration. They commonly have a high temperature and gross general malaise with other notable cervical or generalised lymphadenopathy. Occasionally, an enlarged spleen or liver may be detected. The condition is most frequent in teenagers and young adults. The diagnosis can be confirmed by serological testing showing a positive Paul–Bunnell test, an absolute and relative lymphocytosis, and the presence of atypical monocytes in the peripheral blood.

Treatment
Analgesia and maintenance of fluid intake are important. A small number of patients require admission to hospital if the airway is compromised and a short course of steroids may be helpful. Antibiotics are of little value and ampicillin is contraindicated because of the frequent appearance of a widespread skin rash. Rarely if the airway is severely compromised, an unhurried elective tracheostomy under local anaesthesia is safer and less traumatic than an emergency intubation. Emergency tonsillectomy is contraindicated because of the generalised pharyngeal oedema and compromised airway.

Human immunodeficiency virus
Acquired immune deficiency syndrome (AIDS) can affect the ear, nose and throat (ENT) system at any point during the disease. The initial seroconversion may present with the symptoms of glandular fever, which is followed by an asymptomatic period of variable length. In the pre-AIDS period, before the full-blown symptoms of the AIDS-related complex, many patients have minor upper respiratory tract symptoms that are often overlooked, such as otitis externa, rhinosinusitis and a non-specific pharyngitis. As the patient moves into the full-blown AIDS-related complex, persistent, generalised lymphadenopathy is frequently found affecting the cervical nodes, which is usually due to follicular hyperplasia. However, patients may also develop tumours such as Kaposi’s sarcoma, sometimes seen in the oral cavity, and high-grade malignant B-cell lymphoma affecting the cervical lymph nodes and nasopharynx. In addition, multiple ulcers may be found in the oral cavity or pharynx associated with herpes infection. Severe candida may affect the oral cavity, pharynx, oesophagus or even larynx, and a hairy leukoplakia may affect the tongue (Figure 48.26).

The globus syndrome
A wide variety of patients experience the feeling of a lump in the throat (from the Latin globus = lump). The symptom most commonly affects adults between 30 and 60 years of age. This feeling is not true dysphagia as there is no difficulty in swallowing. Most commonly patients notice the symptom more if they swallow their own saliva, i.e. a forced, dry swallow, rather than when they eat or drink.

The aetiology of this common symptom is unknown, but some patients may have gastro-oesophageal reflux or spasm of their cricopharyngeus muscle.

The original name of ‘globus hystericus’ is unhelpful and although these patients may be anxious and at times introverted, they nonetheless require full examination to exclude local disease. Radiological and endoscopic investigation may be necessary to exclude an underlying cause.
Pharyngeal pouch

A pharyngeal pouch is a protrusion of mucosa through Killian’s dehiscence, a weak area of the posterior pharyngeal wall between the oblique fibres of the thyropharyngeus and the transverse fibres of cricopharyngeus at the lower end of the inferior constrictor muscle (Figure 48.27). These fibres, along with the circular fibres of the upper oesophagus, form the physiological upper oesophageal sphincter mechanism. Why the pouch forms is not yet clear, even with modern videofluoroscopic and manometric studies. Many patients with pharyngeal pouches have been demonstrated to have normal relaxation of the upper oesophageal sphincter mechanism in relation to swallowing, but others have been shown to have incomplete pharyngeal relaxation, early cricopharyngeal contraction and abnormalities of the pharyngeal contraction wave.

Clinical features

Patients suffering from this condition are commonly more than 60 years of age and it is more common in men than women. As the diverticulum enlarges, patients may experience regurgitation of undigested food, sometimes hours after a meal, particularly if they are bending down or turning over in bed at night. They sometimes wake at night with a feeling of tightness in the throat and a fit of coughing. Occasionally, they may present with recurrent, unexplained chest infections as a result of aspiration of the contents of the pouch. As the pouch increases in size, the patients may notice gurgling noises from the neck on swallowing and the pouch may become large enough to form a visible swelling in the neck.

Radiological examination

A thin emulsion of barium is given to the patient as a barium swallow (Figure 48.28) or, ideally, as part of a videofluoroscopic swallowing study. Care should be exercised in patients who cough on swallowing, indicating they may have aspiration. A small volume of barium is sufficient to outline the pharynx, pouch and upper oesophagus. The videofluoroscopic study gives additional information about the pharyngeal contraction waves and the performance of the upper oesophageal sphincter.

Treatment

Surgery is indicated when the pouch is associated with progressive symptoms and particularly when a prominent cricopharyngeal bar of muscle associated with abnormality of the upper oesophageal sphincter mechanism causes considerable dysphagia. In elderly patients, a decision to operate may be influenced by their general condition. Preoperative chest physiotherapy and attention to the respiratory, cardiovascular and nutritional aspects of the patient are important. Perioperative antibiotics are recommended.

The preferred surgical technique is with endoscopic stapling of the diverticular wall. A double-bladed rigid endoscope is passed, with one blade in the diverticulum and one blade positioned in the oesophagus. An endoscopic linear stapler is then passed. One jaw of the stapler is placed in the oesophagus, the other in the pouch. The stapler is fired dividing the wall separating the two. The process should be repeated until the bottom of the pouch is reached. This has the effect of opening the pouch, incorporating it as part of the oesophageal wall and dividing the cricopharyngeus muscle. If the patient is symptom free after the procedure they may start graded peroral intake and early discharge.

In the classic external operation, the opening to the pouch is first identified using a pharyngoscope and a nasogastric tube placed into the oesophageal lumen for postoperative nutrition.

Figure 48.26 Intraoral view showing hairy tongue in a human immunodeficiency virus-positive patient.

Figure 48.27 A pharyngeal pouch.

Figure 48.28 Barium swallow showing a pharyngeal pouch.
This initial endoscopy is often difficult because the normal oesophageal opening is small compared with the lumen of the pouch, but it may be better visualised using a Dohlmann’s rigid endoscope. The pouch may be packed with ribbon gauze soaked in proflavin solution to further aid identification of its neck.

A lower neck incision along the anterior border of the left sternocleidomastoid muscle, or a transverse crease incision, is used and the muscle and carotid sheath are retracted laterally and the trachea and larynx medially. The pouch is found medially behind the lower pharynx and is carefully isolated and dissected back to its origin at Killian’s dehiscence. It is then excised and the pharynx closed in two layers or, if it is small, the pouch may be invaginated into the pharyngeal lumen before closing the muscle layers. In all cases, a myotomy dividing the fibres of the cricopharyngeus muscle and the upper oesophageal circular muscle fibres must be performed. The wound is usually closed with drainage and the patient fed through a nasogastric tube for 3–7 days.

The average operating time with an endoscopic procedure is 20–30 minutes compared with 60–90 minutes with an external procedure. Inpatient stay is also decreased for patients undergoing an endoscopic procedure. The endoscopic technique is associated with a high symptomatic success rate and a low morbidity which is particularly important in the elderly.

Complications

The classic operation has been associated with wound infection, mediastinitis, pharyngeal fistula formation, recurrent laryngeal nerve palsy and stenosis of the upper oesophagus. Endoscopic division is associated with the same risks but at lower rates. The recurrence rates between the two procedures appear to be equal; longer-term follow up will establish this. Endoscopic stapling will also allow for safe reoperation if necessary.

Other approaches

Variations have been tried which include simply hitching up the pouch into a superior position without excising it, thus allowing the fundus and body to empty continuously into the oesophagus. This is unsatisfactory with larger pouches, and upper oesophageal myotomy is still required.

Carbon dioxide or argon laser division of the diverticular wall via a special pharyngoscope may also be used. These techniques are associated with a higher recurrence rate than both endoscopic and open repair.

Sideropenic dysphagia

Prolonged iron deficiency anaemia may lead to dysphagia, particularly in middle-aged women. In addition, they may have koilonychia, cheilosis, angular stomatitis together with lassitude and poor exercise tolerance. The dysphagia is caused by a postcricoid or upper oesophageal web and these patients have a higher incidence of postcricoid malignancy. The syndrome is associated with the names of Plummer and Vinson, Paterson and Brown Kelly.

TUMOURS OF THE OROPHARYNX

Benign

Benign tumours of the oropharynx are rare, papillomas being the most common. These are usually incidental findings and are rarely of any importance.

Malignant

The most important epithelial tumour is squamous cell carcinoma, which constitutes approximately 90 per cent of all epithelial tumours in the upper aerodigestive tract (Figures 48.29 and 48.30). In the oropharynx, the proportion is less (70 per cent) because of the higher incidence of lymphoma (25 per cent) and salivary gland tumours (5 per cent).

Aetiology

Squamous carcinomas of the oropharynx are strongly associated with cigarette smoking and consumption of alcohol. In countries where the consumption of tobacco and alcohol are associated with poor oral hygiene, these malignancies assume major importance. Because of the rich lymphatic drainage of the oropharynx, cervical node metastases are common. They may be the only presenting feature with an apparent occult primary
tumour often being unsuspected and missed in the tonsil or tongue base.

**Treatment**

Treatment varies with facilities around the world, but early tumours may be cured by chemoradiotherapy, laser excision or more conventional excision. Recurrent disease following radiotherapy is usually managed surgically and repair of the oropharynx may require regionally based myocutaneous flaps or free flaps with microvascular anastomosis. Neck dissection is required in a large proportion of cases of advanced disease. Postoperative dysphagia with aspiration as a result of interference in the complex neuromuscular control of the second phase of swallowing is a particular problem in these patients. This type of surgery is best carried out in a major centre undertaking this work on a regular basis.

**Lymphoma of the head and neck**

Lymphomas of the head and neck may arise in nodal or extranodal sites and both Hodgkin's disease and non-Hodgkin's lymphoma commonly present as lymph node enlargement in the neck. Hodgkin's disease is rare in the oropharynx, but non-Hodgkin's lymphoma accounts for 15–20 per cent of tumours at this site in some countries. Most are of the B-cell type and have features in common with other MALT tumours. Further evaluation with CT scanning of the thorax and abdomen, and bone marrow evaluation are essential. Fine-needle aspiration cytology of neck lymph nodes is now mandatory and flow cytometry of the aspirates have aided in diagnosis and classification of lymphomas.

Radiotherapy is the treatment of choice for localised non-Hodgkin's lymphoma and may give control rates as high as 75 per cent at five years. For disseminated non-Hodgkin's lymphoma, systemic chemotherapy is preferred.

**TUMOURS OF THE HYPOPHARYNX**

**Benign**

Benign tumours of the hypopharynx are very rare, the most common being the fibroma and the leiomyoma. They show a smooth, constant mass lying in the lumen of the hypopharynx or oesophagus.

**Malignant**

Malignant tumours of the hypopharynx are almost exclusively squamous cell carcinomas with a predominance of moderate and poor differentiation. The tumours are usually classified according to their probable anatomical site of origin from the piriform fossa, post-cricoid region or posterior pharyngeal wall. Marked differences in the incidence of these tumours occur globally because of factors such as iron-deficiency anaemia (see above under Sideropenic dysphagia). They may be associated with marked submucosal spread of 10 mm or more, which further complicates evaluation. Tumours arising from the piriform fossa and posterior pharyngeal wall may spread to upper or lower cervical nodes. Tumours arising in the post-cricoid area typically metastasise to paratracheal and paraoesophageal nodes, which may not be palpable. As with oropharyngeal tumours, alcohol and tobacco are two principal carcinogens. Post-cricoid carcinoma, though rare, is more common in women than men.

The diagnosis of hypopharyngeal carcinoma should be considered in all patients presenting with dysphagia, hoarseness or referred otalgia, particularly if they have a history of iron deficiency anaemia, smoking or significant alcohol consumption.

Fibreoptic endoscopic examination in clinic may show only subtle signs, such as oedema or pooling of saliva unilaterally in the piriform fossa. Note should also be made that this region is not well seen on flexible gastroscopy. Preferred investigation is with direct rigid pharyngoscopy and oesophagoscopy with biopsy under a general anaesthetic. All regions of the neck must be assessed in a systematic manner. Fine-needle aspirate is advocated for suspicious nodes.

**Radiological examination**

A suspected primary requires a neck and staging CT and/or MRI of the neck.

**Treatment**

Squamous carcinoma of the hypopharynx commonly presents late and carries a poor prognosis. Early lesions may be treated with chemoradiotherapy or transoral endoscopic carbon dioxide laser resection. Major open excisional surgery is generally used for recurrence after radiotherapy or as primary excision in advanced disease. Total pharyngolaryngectomy is commonly required (Figure 48.31) and for lesions extending into the upper oesophagus, oesophagectomy with gastric pull-up or free flap reconstruction may be needed. Myocutaneous flaps, transposed jejunum or stomach are used to reconstruct the pharynx. Swallowing and voice rehabilitation are necessary to support patients after this major surgery if they are to adjust and maintain some quality of life (Summary box 48.7).

![Figure 48.31](image.png)
Summary box 48.7

Tumours of the hypopharynx
- Variable symptoms – discomfort, pain, dysphagia, hoarseness
- Awareness increased by history of smoking and alcohol
- Expert examination with nasendoscopy
- Referral to expert for detailed assessment and treatment – radiotherapy, laser or extensive surgery

DISEASES OF THE LARYNX

Emergencies

Stridor

Stridor means noisy breathing. It may be inspiratory or expiratory, or occurring in both phases of respiration. Inspiratory stridor is usually due to an obstruction at or above the vocal folds and is most commonly the result of an inhaled foreign body or acute infections such as epiglottitis. Expiratory stridor is usually from the lower respiratory tract and gives rise to a prolonged expiratory wheeze. It is most commonly associated with acute asthma or acute infective tracheobronchitis. Biphasic stridor is usually due to obstruction or disease of the tracheobronchial airway and distal lungs (Summary box 48.8).

Summary box 48.8

Stridor

- Inspiratory
  - Foreign body or epiglottitis
- Expiratory
  - Acute asthma or infective tracheobronchitis
- Biphasic
  - Obstruction, disease of tracheobronchial airway or distal lungs

Stridor in children

Infants and children presenting with stridor need careful assessment with a full history and examination as appropriate. If, on presentation, a child is cyanosed and severely unwell, the airway must be secured as soon as possible, but a brief history with important pointers can often be obtained from the parents.

History

In infants in the first year of life, it is important to establish if the stridor is associated with particular activities such as swallowing, crying or movement. These may suggest congenital laryngomalacia or subglottic stenosis. If the stridor is exacerbated by feeding, particularly in the first 4 weeks of life, this suggests a vascular ring or tracheo-oesophageal fistula. If the cry is weak or abnormal, this suggests a vocal fold palsy. If the problem only occurs in association with an upper respiratory tract infection and, in particular, is biphasic, this would suggest congenital subglottic stenosis. In a young child, inspiratory stridor and drooling suggest acute epiglottitis, whereas biphasic stridor without drooling suggests laryngotracheobronchitis or croup (Summary box 48.9).

Summary box 48.9

Acute paediatric stridor

- Congenital
  - Laryngomalacia
  - Laryngeal web
  - Subglottic stenosis

- Acquired
  - Inflammatory
    - Angioneurotic oedema
  - Traumatic
    - Impacted foreign body, laryngeal fracture
  - Infective
    - Epiglottis, laryngotracheobronchitis
  - Neurological
    - Vocal fold palsy
  - Neoplasia
    - Benign laryngeal papillomatosis

Examination

It is important when possible to observe the child carefully at rest. Once a baby starts to cry, it may be impossible to study its resting respiratory pattern for some time. Ask the mother, not a nurse or a colleague, to move a baby or young child into different positions, such as face down and supine, and watch for changes in respiratory pattern and level of distress. Observe any drooling and, with neonates and infants, always try to watch the child being fed, listening to the trachea and chest with a stethoscope if possible. Always examine the whole child, looking for any evidence of congenital abnormalities before attempting any examination of the throat.

If a child is stridulous and drooling and sitting upright in its mother’s arms or a chair, do not attempt to lie it down and do not attempt to look inside the mouth. These manoeuvres are potentially life-threatening as the child may aspirate a large quantity of thick saliva contained within the oral cavity. The child does not wish to attempt swallowing in the case of a retropharyngeal abscess, parapharyngeal abscess or acute epiglottitis as these conditions are so painful. It is particularly important in acute epiglottitis as the aspiration of thick saliva may be associated with further laryngeal spasm and a respiratory arrest. Restlessness, increasing tachycardia and cyanosis are important signs of hypoxia. If the child is not distressed and drooling, and not markedly stridulous, he/she may be cooperative enough that it is possible to look inside the mouth and check the palate, tongue and oropharynx. In stridulous children, particularly neonates and infants, a transcutaneous oximeter is invaluable. A resuscitation trolley with the necessary equipment for emergency intubation or tracheostomy should be close at hand if at all possible before commencing examination.

Investigation

Plain lateral radiographs of the neck and a chest radiograph can be obtained but only if the child’s condition permits. If a child is severely stridulous, they should not be sent to a radiography department without access to medical staff or resuscitation equipment.
Examination under anaesthesia is essential in all children whose diagnosis remains in doubt. This requires a high level of skill and appropriate rigid laryngoscopes, bronchoscopes, endoscopic Hopkins’ rods and an operating microscope should be made available if possible. Equipment should be available at all times to undertake an urgent tracheostomy to establish or maintain an airway.

**Acute epiglottitis**

In children, acute epiglottitis is of rapid onset. It tends to occur in children of two years of age and over. Stridor is usually associated with drooling of saliva. The condition is caused by *Haemophilus influenzae* infection, which initially causes a severe pharyngitis at the junction of the oro- and hypopharynx before producing inflammation and oedema of the laryngeal inlet. As it progresses, it involves the whole of the supraglottic larynx, with severe oedema of the aryepiglottic folds and epiglottis being the most notable component, hence the commonly used term ‘acute epiglottitis’.

These children frequently require intensive management with emergency intubation or tracheostomy followed by oxygenation, humidification, continuous oximetry and antibiotics such as ampicillin or chloramphenicol. There may be associated septicemia so blood cultures should be obtained. Attempted examination with a spatula into the mouth may precipitate a respiratory arrest and should be avoided. The incidence of acute epiglottitis has plummeted where *Haemophilus influenzae* vaccination programmes have occurred.

**Laryngotracheobronchitis (croup)**

Croup is usually of slower onset than acute epiglottitis and occurs most commonly in children under two years of age. It is usually viral in origin and the cases often occur in clusters. The children have biphasic stridor, and are often hoarse with a typical barking cough. Airway intervention is required less often, but admission to hospital with oxygenation and humidification, coupled with antibiotics, may be necessary if there are signs of secondary infection.

**Foreign bodies**

Both children and adults may inhale foreign bodies. Young children will attempt to swallow a wide variety of objects, but coins, beads and parts of toys are particularly common. In adults, the aspiration is usually food, particularly inadequately chewed bones and meat. This is more common in elderly edentulous adults. Occasionally, portions of dentures may be inhaled, particularly in association with road traffic accidents.

**Clinical features**

The history is paramount and a history of foreign body ingestion or inhalation in a child, even though the pain, dysphagia, coughing, etc. may have settled, should always be taken seriously.

Adults usually have a clear recall, which facilitates diagnosis. Fish bones may lodge in the tonsils or base of tongue with minimal symptoms, but small fish bones may give rise to para- and retropharyngeal abscess formation.

**Examination**

Examination may be prevented by trismus, pain and anxiety, but the presence of a foreign body may be suspected by a salivary pool within the pyriform fossa or adjacent oedema and erythema of the pharyngolaryngeal mucosa.

**Radiology**

Radiology may be helpful but is not critical. Fish bones are often invisible on plain radiographs and a normal plain radiograph does not exclude a foreign body within the pharynx, larynx, oesophagus or lungs.

Specialised studies may help in cases of doubt, using a CT scan or a gastrografin swallow in the case of a suspected oesophageal foreign body.

**Treatment**

In the case of an inhaled foreign body causing severe stridor in a neonate or infant, it may be removed either by hooking it from the pharynx with a finger or by inverting the child carefully by the ankles and slapping his/her back. In a larger child, it may be more appropriate to bend them over your knee with their head hanging down and again strike them firmly between the shoulders. In the case of adults, an impacted laryngeal foreign body may be coughed out using a Heimlich manoeuvre. This involves standing behind the patient, clasping the arms around the lower thorax, such that the knuckles of the clasped hands come into contact with the patient’s xiphisternum, and then a brief, firm compression of the lower thorax may aid instant expiration of the foreign body. If none of these immediate emergency measures removes the foreign body and the patient is cyanosed and severely stridulous, an immediate cricothyroidotomy or tracheostomy may be necessary. In less urgent cases, and when a foreign body is strongly suspected, endoscopy under general anaesthesia may be indicated.

**Other causes of acute pharyngolaryngeal oedema**

Angioneurotic oedema, radiotherapy, laryngeal trauma associated with road traffic accidents, corrosives, scalds and smoke ingestion may all cause significant pharyngolaryngeal oedema, in addition to the acute infective conditions mentioned elsewhere. Hoarseness is the predominant symptom along with dysphagia prior to the increase in dyspnoea. If flexible laryngoscopic examination is possible, marked oedema of the supraglottis and pharynx can be seen. Humidified oxygen, adrenaline nebulisers, systemic antihistamines and steroids may be valuable. Morphine should not be given as it may cause respiratory depression and respiratory arrest. If the dyspnoea progresses, intubation or tracheostomy will be necessary.

**TRACHEOSTOMY AND OTHER EMERGENCY AIRWAY MEASURES**

This procedure relieves airway obstruction or protects the airway by fashioning a direct entrance into the trachea through the skin of the neck. Tracheostomy may be carried out as an emergency when the patient is in extremis and the larynx cannot be intubated, but it is not always an easy procedure, particularly in an obese patient. An easier alternative for the inexperienced is insertion of a large intravenous cannula or a small tube into the cricothyroid membrane, which lies in the midline immediately below the thyroid cartilage. Emergency intubation is a further option when the laryngotracheal airway is not obstructed and tracheostomy may be performed thereafter. The time to do a tracheostomy is when you first think it may be necessary.
If time allows, the following should be undertaken:

- inspection and palpation of the neck to assess the laryngotracheal anatomy in the individual patient;
- indirect or direct laryngoscopy;
- assessment of pulmonary function.

Whenever possible, the procedure should be adequately explained to the patient beforehand, with particular emphasis on the inability to speak immediately following the operation. Ample reassurance is required that they will not have ‘lost’ their voice permanently. The indications for tracheostomy are shown in Summary box 48.10.

### Summary box 48.10

#### Indications for tracheostomy

- **Acute upper airway obstruction**
  - For example, an inhaled foreign body, a large pharyngolaryngeal tumour, or acute pharyngolaryngeal infections in children

- **Potential upper airway obstruction**
  - For example, after major surgery involving the oral cavity, pharynx, larynx or neck

- **Protection of the lower airway**
  - For example, protection against aspiration of saliva in unconscious patients as a consequence of head injuries, faciomaxillary injuries, comas, bulbar poliomyelitis or tetanus

- **Patients requiring prolonged artificial respiration**
  - Best performed within 10 days of ventilation

---

**Emergency tracheostomy**

If a skilled anaesthetist is unavailable, local anaesthesia is employed, but in desperate cases when the patient is unconscious, none is required. In patients who have suffered severe head and neck trauma and who may have an unstable cervical spine fracture, cricothyroidotomy may be more suitable. If it is possible, the patient should be laid supine with padding placed under the shoulders and the extended neck kept as steady as possible in the midline. This aids palpation of the thyroid and cricoid cartilage between the thumb and index finger of the free hand. The movements of the fingers of the free hand are important in this technique. The operation is more difficult in small children and thick-necked adults as the landmarks are difficult to palpate (Figures 48.32 and 48.33).

A vertical midline incision is made from the inferior aspect of the thyroid cartilage to the suprasternal notch and continued down between the infrahyoid muscles. There may be heavy bleeding from the wound at this point, particularly if the neck is congested as a result of the patient’s efforts to breathe around an acute upper airway obstruction. No steps should be taken to control this haemorrhage, although an assistant and suction are valuable. The operator should feel carefully for the cricoid cartilage using the index finger of the free hand while retracting the skin edges by pressure applied by the thumb and middle finger. If the situation is one of extreme urgency, a further vertical incision straight into the trachea at the level of the second, third and fourth ring should be made immediately without regard to the presence of the thyroid isthmus. The knife blade is rotated through 90°, thus opening the trachea. At this point, the patient may cough violently as blood enters the airway. The operator should be aware of this possibility and avoid losing the position of the scalpel in the open trachea. Any form of available tube should be inserted into the trachea as soon as possible and blood and secretion sucked out. Once an airway has been established, haemostasis is then secured. With the emergency under control, the tracheostomy should be refashioned as soon as possible.

Should additional equipment and more time be available once the cricoid cartilage has been identified, blunt finger dissection inferiorly can be used to mobilise the thyroid isthmus, which should be divided between haemostats, clearing the trachea before making a vertical incision through the second to the fourth rings. A tracheal dilator is inserted through the tracheal incision and the edges of the tracheal wound are separated gently. In cases of suspected human immunodeficiency virus (HIV) infection or diphtheria, the surgeon places a swab over the wound so that the violent expiratory efforts which may follow do not contaminate the operator(s) with infected mucus and blood. When respiratory efforts have become less violent, a tracheostomy tube is inserted into the trachea and the dilator removed. It is important that the surgeon keeps a finger on the tube while the assistant ties the attached tapes around the patient’s neck. Return the neck to a neutral position before tying the tapes firmly.

**Elective tracheostomy**

The advantage of an elective surgical procedure is that there is complete airway control at all times, unhurried dissection and careful placement of an appropriate tube. Close cooperation between the surgeon, anaesthetist and scrub nurse is essential.
and attention to detail will markedly reduce possible complications and morbidity from the procedure.

Following induction of general anaesthesia and endotracheal intubation, the patient is positioned with a combination of head extension and placement of an appropriate sandbag under the shoulders (Figure 48.34). There should be no rotation of the head. Children’s heads should not be overextended as it is possible to enter the trachea in the fifth and sixth rings in these circumstances. Insertion of a bronchoscope in the trachea may help when performing tracheostomy in young children. A transverse incision may be used in the elective situation (Figure 48.35). The tracheal isthmus is divided carefully and oversewn and tension sutures placed either side of the tracheal fenestration in children (Figure 48.36). A Bjork flap may be used in adults (Figures 48.37 and 48.38).

The advantages of the Bjork method outweigh the potential disadvantages and it is useful for those surgeons who undertake occasional tracheostomy or when the level of skill and experience of the nursing staff is limited. It is generally avoided in experienced hands. Performed correctly, it is safe and allows reintroduction of a displaced tube with the minimum of difficulty.

The inferiorly based flap is begun at its apex with an incision on the superior aspects of the second ring and extends down either side through the second and third rings. The tip of the flap should be stitched to the inferior edge of the transverse skin incision using horizontal mattress sutures through the structure of the second ring. These sutures should be generous enough so that they will not cut out. The first tracheal ring should not be violated in any circumstances.

In a paediatric patient who requires a tracheostomy, failure to remain in the midline may result in pneumothorax, as pleural spaces extend into the root of the neck laterally. Prior to incision of the trachea vertical stay sutures are placed lateral to the midline through the tracheal rings and left in place. A vertical incision is made between the second and third tracheal rings. No tracheal tissue is removed. These can provide traction for the trachea and allow for rapid tracheostomy tube reinsertion if accidental decannulation occurs prior to the establishment of

Viking Olaf Bjork, born 1918, formerly cardiac surgeon, Karolinska Sjukset, Stockholm, Sweden.
Percutaneous tracheostomy

In many countries, tracheostomy may be performed percutaneously with bronchoscopic assistance. A transverse incision is made between the first and second tracheal rings, and blunt dissection of the midline is then performed. A 22-gauge needle is inserted between the second and third tracheal rings. When air is aspirated into the syringe, the guidewire is introduced. After the guidewire is protected, dilators are introduced. All dilators are inserted in a sequential manner from small to large diameter. The tracheotomy tube is then introduced along the dilator and guidewire. The guidewire and dilator are removed, the cuff of the tracheotomy tube is inflated, and the breathing circuit is connected. The endotracheal tube can then be removed.

Patients must have appropriate anatomy and no limitation of neck movement. If any doubt arises as to the suitability of a patient for percutaneous tracheostomy a surgical approach should be adopted. Percutaneous tracheostomy is rarely performed in children.

Tracheostomy tubes

These are basically made of two materials: silver or plastic. Both materials have been used to make tubes of various sizes with varying curves, angles, cuffs, inner tubes and speaking valves (Figures 48.39 and 48.40). A cuffed tube is used initially, which may be changed after 3–4 days to a non-cuffed plastic or silver tube. The pressure within the tube cuff should be carefully monitored and should be low enough so as not to occlude circulation in the mucosal capillaries. When in position, the tube should be retained by double tapes passed around the patient’s neck with a reef knot on either side. It is important that the patient’s head is flexed when the tapes are tied, otherwise they may become slack when the patient is moved from the position of extension, thereby resulting in a possible displacement of the tube if the patient coughs. Alternatively, the flanges of the plastic tube may be stitched directly to the underlying neck skin.

All forms of tracheostomy and cricothyroidotomy bypass the upper airway and have the following advantages:

- The anatomical dead space is reduced by approximately 50 per cent.
- The work of breathing is reduced.
- Alveolar ventilation is increased.
- The level of sedation needed for patient comfort is decreased and, unlike endotracheal intubation, the patient may be able to talk and eat with a tube in place.
However, there are several disadvantages:

- Loss of heat and moisture exchange performed in the upper respiratory tract.
- Desiccation of tracheal epithelium, loss of ciliated cells and metaplasia.
- The presence of a foreign body in the trachea stimulates mucous production; where no cilia are present, this mucociliary stream is arrested.
- The increased mucus is more viscid and thick crusts may form and block the tube.
- Although many patients with a tracheostomy can feed satisfactorily, there is some splinting of the larynx, which may prevent normal swallowing and lead to aspiration; this aspiration may not be apparent.

Postoperative treatment is designed to counteract these effects and frequent suction and humidification are most important.

A trolley must be placed by the bed containing a tracheal dilator, duplicate tubes and introducers, retractors and dressings. Oxygen is at hand and, in the initial period, a nurse must be in constant attendance. Humidification will render the secretions less viscid and a sucker with a catheter attached should be on hand to keep the tracheobronchial tree free from secretions (Summary box 48.11).

### Summary box 48.11

**Tracheostomy: postoperative management**
- Suction – efficient, sterile and as often as required
- Humidification (with or without oxygen)
- A warm, well-ventilated room
- Position of the tube and patient
- Spare tube, introducer, tapes, tracheal dilator
- Change of tube, inner tube, possible speaking valve
- Physiotherapy
- Initiation of local decannulation protocols where indicated

### Complications of tracheostomy

The intraoperative, early and late postoperative complications of tracheostomy are listed in Table 48.2.

### OTHER EMERGENCY AIRWAY PROCEDURES

#### Fibreoptic endotracheal intubation

In most emergency situations, endotracheal intubation is the most direct and satisfactory method of securing the airway. Nasotracheal intubation in expert hands is also a well-established technique and is particularly useful if the patient has trismus, severe mandibular injuries, cervical spine rigidity or an obstructing mass within the oral cavity. Both forms of intubation can be facilitated in case of difficulty by passing a fibreoptic endoscope through the centre of an endotracheal tube, hence guiding it into the larynx and trachea under direct vision.

### Table 48.2 Tracheostomy: complications.

Laryngeal mask airway

The laryngeal mask airway (LMA) is a wide-bore airway with an inflatable cuff at the distal end, which forms a seal in the pharynx around the laryngeal inlet. Provided the laryngotraheal airway is clear, the LMA provides a clear and secure airway. The technique can easily be learnt by non-anaesthetists and secures an airway in most cases. It comes in a range of sizes covering infants to large adults. It is particularly useful in cases of difficult intubation (Figure 48.41).

Transtracheal ventilation

This technique is simple and effective and allows ventilation for periods in excess of 1 hour providing time to allow for more elective intubation. The cricothyroid membrane is located by palpation of the neck with the index finger, and a 14- or 16-gauge plastic sheathed intravascular needle and a 10-mL syringe containing a few millilitres of lignocaine are introduced in the midline and directed downwards and backwards into the tracheal lumen. The needle is advanced steadily and negative pressure is placed on the syringe until bubbles of air are clearly seen (Figure 48.42). The tissues of the neck may be infiltrated with the anaesthetic if desired and the tracheal mucosa likewise partly anaesthetised by the introduction of 1–2 mL after gaining the lumen. The needle is removed and the plastic sheath cannula remains in the tracheal lumen and must be carefully held and fixed in place by the operator so that it does not come out of the lumen into the soft tissues of the neck. It is attached by means of a Luer connection to the high-pressure oxygen supply. Ventilation may be undertaken in a controlled manner with a jetting device with the chest being observed for appropriate movements.

If there is severe obstruction of the laryngopharynx by the foreign body or tumour, the exhaled outflow of gases can be aided by the placement of one or two further cannulae as exhalation ports. This procedure gains extremely rapid control of ventilation and requires a minimum of technical expertise. Its only notable complication is surgical emphysema of the neck tissues if the cannula dislodges from the tracheal lumen.

Cricothyroidotomy

Cricothyroidotomy has the advantages of speed and ease requiring little equipment and surgical expertise. However, its use for all but the briefest access to the airway remains controversial and there are conflicting reports with regard to the subsequent incidence of complications, particularly those of subglottic stenosis and long-term voice changes.

The patient’s neck is extended and the area between the prominence of the thyroid cartilage and the cricoid cartilage below is palpated with the index finger of the free hand. In the emergency situation, a vertical skin incision is recommended with dissection rapidly carried down to the cricothyroid membrane. A 1-cm transverse incision is made through the membrane immediately above the cricoid cartilage and the scalpel twisted through a right angle to gain access to the airway. If available, artery forceps, dilator or tracheal hook will improve the aperture and insertion of an available tube (Figures 48.43 and 48.44).

Depending on the degree of emergency, it may be necessary for the surgeon to assess the results of the procedure by direct laryngoscopy and the authors recommend that careful consideration should be given to conversion of the cricothyroidotomy to a tracheostomy. Although there is debate about the frequency of subglottic stenosis following this procedure, there is general agreement that it is much increased if any long-term ventilation is undertaken via even a modestly sized tracheostomy tube through the cricothyroid membrane.

LARYNGEAL DISEASE CAUSING VOICE DISORDERS

Vocal nodules

These are fibrous thickenings of the vocal folds at the junction of the middle and anterior third (Figure 48.45), and are the result of vocal abuse; they are known as singers’ nodules in adults and screamers’ nodules in children. Speech therapy is
therefore the preferred treatment and the lesions will resolve spontaneously in most cases. Occasionally, the nodules will need to be surgically removed using modern microlaryngoscopic dissection or laser techniques, but speech therapy will still be required for postoperative voice rehabilitation (Summary box 48.12).

**Summary box 48.12**

**Causes of hoarseness**

- Mucosal disease, e.g. vocal nodule, polyps or laryngeal papillomatosis, acute or chronic laryngitis
- Neurological disease, e.g. vocal fold palsy
- Neoplasia, e.g. laryngeal tumours
- Non-specific voice disorders, functional dysphonia

### Vocal fold polyps

These are usually unilateral and may be associated with an acute infective episode, cigarette smoking and vocal abuse (Figure 48.46). Speech therapy is again indicated, but they do usually require removal by microdissection or laser surgery.
Laryngeal papillomata
These are rare benign tumours occurring mainly in children, but can also present in adults. They are most commonly found on the vocal folds, but may spread throughout the larynx and tracheobronchial airway (Figure 48.47). They are caused by papillomaviruses and need removal by carbon dioxide laser or microsurgery to maintain a reasonable voice and airway. These patients are best managed in specialist centres, with the appropriate expertise. Antiviral treatment is of doubtful value at present. Papilloma vaccination is of unproven benefit.

Acute laryngitis
This often occurs in association with upper respiratory tract infections in association with a cough and pharyngitis. Usually viral, it may be localised to the larynx and it settles quickly if the voice is rested during the acute inflammation. Steam inhalations are soothing along with mild analgesia, but antibiotics are unnecessary (Summary box 48.13).

Chronic laryngitis
Chronic laryngitis may be specific and can be caused by mycobacteria, syphilis and fungi. Treatment is directed towards the causative organism. Non-specific laryngitis is common, the main predisposing factors being smoking, chronic upper and lower respiratory sepsis and voice abuse. Gastro-oesophageal reflux has been implicated as a factor in laryngitis, vocal fold nodules and polyps, but the evidence is controversial. There is, however, a vogue for treatment with antireflux medication and proton pump inhibitors. Diagnosis of chronic laryngitis should not be made unless the larynx has been fully evaluated by a laryngologist.

Vocal fold palsy
This may be unilateral or bilateral (Figure 48.48), but a unilateral left vocal fold palsy is the most common because of the long intrathoracic course of the left recurrent laryngeal nerve, which arches around the aorta and may be commonly involved in inflammatory and neoplastic conditions involving the left hilum. Lung cancer is the most common cancer in many parts of the world, and should be considered the cause of a left vocal palsy until proved otherwise.
Other malignant lesions can cause a similar effect and may arise in the nasopharynx, thyroid gland or oesophagus. Bilateral vocal fold paralysis is uncommon and tends to occur after thyroid surgery or head injuries (Summary box 48.14).

Summary box 48.14

Causes of vocal fold palsy
Congenital (infants)
Acquired
- Traumatic
  Direct to neck
  Post-surgical, e.g. thyroidectomy
- Infective
  Viral (rare)
- Neoplastic
  Carcinoma of the lung involving the left hilum
  Carcinoma of the larynx
  Carcinoma of the thyroid
  Carcinoma of the oesophagus
- Vascular
  Aortic aneurysm
- Neurological
  Lower motor neurone disease

Clinical features
Unilateral recurrent laryngeal nerve palsy of sudden onset produces hoarseness, difficulty in swallowing liquids and a weakened cough. These symptoms may be short-lived and the voice may return to normal within a few weeks as the muscles in the opposite vocal fold compensate and move it across the midline to meet the paralysed vocal fold, which usually lies in the paramedian position. Bilateral recurrent laryngeal nerve palsy is an occasional and serious complication of thyroidectomy. Acute
dyspnoea occurs as a result of the paramedian position of both vocal folds, which reduce the airway to 2–3 mm and which tend to get sucked together on inspiration. In severe cases, tracheostomy or intubation is necessary immediately, otherwise death occurs from asphyxia.

Investigation of vocal fold paralysis is by a CT scan from skull base (including posterior fossa) to diaphragm. Approximately 20–25 per cent of vocal fold paralysis occurs without known pathology and spontaneous recovery may occur. When compensation does not occur, a unilateral paralysed fold may be medialised by a small external operation on the thyroid cartilage (thyroplasty).

In bilateral vocal fold palsy, surgery may be carried out to remove a small portion of the posterior aspect of one vocal fold or a portion of one arytenoid cartilage. These procedures are most easily performed endoscopically with a carbon dioxide laser. They increase the size of the posterior glottic airway, allowing the patient to be decannulated or even the avoidance of an initial tracheostomy.

**TUMOURS OF THE LARYNX**

Benign tumours of the larynx are extremely rare. Squamous carcinoma is the most common malignant tumour, being responsible for more than 90 per cent of tumours within the larynx. It is the most common head and neck cancer and previously almost always occurred in elderly male smokers. However, over the past two decades, the incidence among women is rising as a consequence of increased smoking habits. The incidence of laryngeal cancer in the three compartments, supraglottis, glottis and subglottis, varies around the world. The glottis is generally the most common site for cancer in patients in the UK, followed by the supraglottis (Figure 48.49).

**Clinical features**

Patients almost always present with voice change. If an early diagnosis can be made, i.e. confined to one vocal fold, treatment with radiotherapy or carbon dioxide laser excision is associated with a five-year disease-free survival of approximately 90 per cent. This rate drops dramatically once the lympathically rich supraglottis or subglottis is involved because of spread to neck nodes. Tumour spread to just one neck gland halves the overall prognosis for the patient.

**Investigations**

Direct laryngoscopy, preferably a microlaryngoscopy, together with Hopkins’ rod examination, allows precise determination of the extent of the tumour and biopsy confirms the histology. CT and MRI give further details of the extent of larger tumours, demonstrating spread outside the larynx and suspicious nodal involvement within the neck, which may not be obvious clinically. The tumour–node–metastasis (TNM) classification of laryngeal cancer is given in Table 48.3.

**Treatment**

Supraglottic and glottic tumours, stages I and II, are optimally treated with either radiotherapy or endoscopic surgical resection, with the aim of preservation of some function. Subsite location of the primary tumour is an important consideration when selecting the appropriate therapy. Transoral laser resection is a popular surgical treatment modality of stage I and II disease.

---
A functional cricoarytenoid must be left intact. Both modalities are associated with similar survival rates. Chemotherapy is generally reserved for those patients with lymph node disease. Complications of organ-sparing treatment include aspiration, which if severe may require salvage laryngectomy.

**Advanced laryngeal disease**

Advanced stage laryngeal carcinomas (stage III) may be treated with radiotherapy for organ preservation or external partial laryngectomy. Stage IV disease is usually treated with total laryngectomy and adjuvant postoperative radiotherapy. In advanced stage disease chemotherapy is usually employed due to cervical lymph node spread.

After the larynx has been removed (Figure 48.50), the remaining trachea is brought out onto the lower neck as a permanent tracheal stoma and the hypopharynx, which is opened at the time of the operation, is closed to restore continuity for swallowing (Figure 48.51). Thus the upper aero- and digestive tracts are permanently disconnected. Part or all of the thyroid gland and associated parathyroid glands may also be removed, depending on the extent of the disease.

**Vocal rehabilitation**

The loss of the larynx as a generator of sound does not prevent patients speaking as long as an alternative source of vibration can be created in the pharynx. This can be achieved in one of three ways:
A small one-way valve may be inserted through the back wall of the tracheal stoma into the pharynx. This allows air from the trachea to pass into the pharynx, but does not allow food and liquid to pass into the airway. These valves must not be confused with tracheostomy tubes. Like all foreign bodies, the speaking valves are associated with minor complications, such as the formation of granulations, bleeding or leakage of pharyngeal contents, and have continuing financial cost attached.

An external device when applied to the soft tissues of the neck produces sound, which is turned into speech by the vocal tract comprising the tongue, pharynx, oral cavity, lips, teeth and nasal sinuses. These devices are usually battery powered.

Some patients may learn to swallow air into the pharynx and upper oesophagus. On regurgitating the air, a segment of the pharyngo-oesophageal mucosa vibrates to produce sound, which is modified by the vocal tract into speech (Figure 48.52).

The correct diagnosis of a lump in the neck can often be made with a careful history and examination. The clinical signs of size, site, shape, consistency, fixation to skin or deep structures, pulsation, compressibility, transillumination or the presence of a bruit still remain as important as ever (Summary box 48.15).

Summary box 48.15

Diagnosis of a lump in the neck

- History
- Physical signs
  - Size
  - Site
  - Shape
  - Surface
  - Consistency
  - Fixation: deep/superficial
  - Pulsatility
  - Compressibility
  - Transillumination
  - Bruit

Branchial cyst

A branchial cyst, thought to develop from the vestigial remnants of the second branchial cleft, is usually lined by squamous epithelium, and contains thick, turbid fluid full of cholesterol crystals. The cyst usually presents in the upper neck in early or middle adulthood and is found at the junction of the upper third and middle third of the sternomastoid muscle at its anterior border. It is a fluctuant swelling that may transilluminate and is often soft in its early stages so that it may be difficult to palpate. Other theories hypothesise that branchial cysts develop from cystic transformation of cervical lymph nodes.

If the cyst becomes infected, it becomes erythematous and tender and, on occasions, it may be difficult to differentiate from a tuberculous abscess. Ultrasound and fine-needle aspiration both aid diagnosis, and treatment is by complete excision, which is best undertaken when the lesion is quiescent. Although the anterior aspect of the cyst is easy to dissect, it may pass backwards and upwards through the bifurcation of the common carotid artery as far as the pharyngeal constrictors. It passes superficial to the hypoglossal and glossopharyngeal nerves, but deep to the posterior belly of the digastric. These structures and the spinal accessory nerve must be positively identified to avoid damage.

Branchial fistula

A branchial fistula may be unilateral or bilateral and is thought to represent a persistent second branchial cleft. The external orifice is nearly always situated in the lower third of the neck near the anterior border of the sternocleidomastoid, while the internal orifice is located on the anterior aspect of the posterior faucial pillar just behind the tonsil. However, the internal aspect of the tract may end blindly at or close to the lateral pharyngeal wall, constituting a sinus rather than a fistula. The tract is lined by ciliated columnar epithelium and, as such, there may be a small amount of recurrent mucous or mucopurulent discharge onto the neck. The tract follows the same path as a branchial cyst and requires complete excision, often by more than one transverse incision in the neck (Figure 48.53).

Cystic hygroma

Cystic hygromas usually present in the neonate or in early infancy, and occasionally may present at birth and be so large as to obstruct labour. The cysts are filled with clear lymph and
lined by a single layer of epithelium with a mosaic appearance (Figure 48.54). Swelling usually occurs in the neck and may involve the parotid, submandibular, tongue and floor of mouth areas. The swelling may be bilateral and is soft and partially compressible, visibly increasing in size when the child coughs or cries. The characteristic that distinguishes it from all other neck swellings is that it is brilliantly translucent. The cheek, axilla, groin and mediastinum are other less frequent sites for a cystic hygroma.

The behaviour of cystic hygromas during infancy is unpredictable. Sometimes the cyst expands rapidly and occasionally respiratory difficulty ensues, requiring immediate aspiration and even, occasionally, a tracheostomy. The cyst may become infected.

Definitive treatment is complete excision of the cyst at an early stage. Injection of a sclerosing agent, for example picibanil (OK-432), may reduce the size of the cyst; however, they are commonly multicystic and if the injection is extracystic subsequent surgery may be more difficult.

**Thyroglossal duct cysts**

**Embryology**

The thyroid gland descends early in fetal life from the base of the tongue towards its position in the lower neck with the isthmus lying over the second and third tracheal rings. At the time of its descent, the hyoid bone has not been formed and the track of the descent of the thyroid gland is variable, passing in front, through or behind the eventual position of the hyoid body. Thyroglossal duct cysts represent a persistence of this track and may therefore be found anywhere in or adjacent to the midline from the tongue base to the thyroid isthmus. Rarely, a thyroglossal cyst may contain the only functioning thyroid tissue in the body.

**Clinical features**

The cysts almost always arise in the midline but, when they are adjacent to the thyroid cartilage, they may lie slightly to one side of the midline. Classically, the cyst moves upwards on swallowing and with tongue protrusion, but this can also occur with other midline cysts such as dermoid cysts, as it merely indicates attachment to the hyoid bone.
Thyroglossal cysts may become infected and rupture onto the skin of the neck presenting as a discharging sinus. Although they often occur in children, they may also present in adults, even as late as the sixth or seventh decade of life (Figure 48.55).

**Treatment**
Treatment must include excision of the whole thyroglossal tract, which involves removal of the body of the hyoid bone and the suprathyroid tract through the tongue base to the vallecula at the site of the primitive foramen caecum, together with a core of tissue on either side. This operation is known as Sistrunk’s operation and prevents recurrence, most notably from small side branches of the thyroglossal tract.

**TRAUMA TO THE NECK**

**Wounds above the hyoid bone**
The cavity of the mouth or pharynx may have been entered and the epiglottis may be divided via the pre-epiglottic space. These wounds require repair with absorbable sutures on a formal basis under a general anaesthetic. If there is any degree of associated oedema or bleeding, particularly in relation to the tongue base or laryngeal inlet, it is advisable to perform a tracheostomy to avoid any subsequent respiratory distress.

**Wounds of the thyroid and cricoid cartilage**
Blunt crushing injuries or severe laceration injuries to the laryngeal skeleton can cause marked haematoma formation and rapid loss of the airway. There may be significant disruption of the laryngeal skeleton. These patients should not have an endotracheal intubation for any length of time, even if this is the initial emergency way of protecting the airway. The larynx is a delicate three-tiered sphincter and the presence of a foreign body in its lumen after severe disruption gives rise to major fibrosis and loss of laryngeal function. These injuries are frequently an absolute indication for a low tracheostomy, following which the larynx can be carefully explored, damaged cartilages repositioned and sutured, and the paraglottic space drained.

An indwelling stent of soft sponge shaped to fit the laryngeal lumen and held by a nylon retainer suture through the neck may be left in place for approximately 5 days. This stent can be removed endoscopically after cutting the retaining suture and, as the laryngeal damage heals, the patient may then be decannulated.

**Division of the trachea**
Wounds of the trachea are rare. They should all be formally explored and, in order to obtain adequate exposure, it is usually necessary to divide and ligate the thyroid isthmus. A small tracheostomy below the wound followed by repair of the trachea with a limited number of submucosal sutures is appropriate. In self-inflicted wounds, the recurrent laryngeal nerves, which lie protected in the tracheo-oesophageal grooves, are rarely injured. Primary repair is rarely possible but may be undertaken at the time of formal exploration of a major neck wound.

**Neurovascular injury**
Penetrating wounds of the neck may involve the common carotid or the external or internal carotid arteries. Major haemorrhagic shock may occur. Venous air embolism may occur as a result of damage to one of the major veins, most commonly the internal jugular. Compression, resuscitation and exploration under general anaesthetic, with control of vessels above and below the injury, and primary repair should be undertaken. All cervical nerves are vulnerable to injury, particularly the vagus and recurrent laryngeal nerves and cervical sympathetic chain.

**Thoracic duct injury**
Wounds to the thoracic duct are rare and most often occur in association with dissection of lymph nodes in the left supraclavicular fossa. When damage to the duct is not recognised at the time of operation, chyle may subsequently leak from the wound in amounts up to 2 litres per day with profound effects on nutrition.

**Treatment**
Should the damage be recognised during an operation, the proximal end of the duct must be ligated. Ligation of the duct is not harmful because there are a number of anastomotic channels between the lymphatic and venous system in the lower neck. If undetected, chyle usually starts to discharge from the neck wound within 24 hours of the operation. On occasion, firm pressure by a pad to the lower neck may stop the leakage, but frequently this is unsuccessful and the wound should be re-explored and the damaged duct ligated.
Inflammatory conditions of the neck

Ludwig’s angina
Ludwig described a clinical entity characterised by a brawny swelling of the submandibular region combined with inflammatory oedema of the mouth. It is these combined cervical and intraoral signs that constitute the characteristic feature of the lesion, as well as the accompanying putrid halitosis.

The infection is often caused by a virulent streptococcal infection associated with anaerobic organisms and sometimes with other lesions of the floor of the mouth, such as carcinoma. The infection encompasses both sides of the mylohyoid muscle causing oedema and inflammation such that the tongue may be displaced upwards and backwards, giving rise to dysphagia and subsequently to painful obstruction of the airway. Unless treated, cellulitis may extend beneath the deep fascial layers of the neck to involve the larynx, causing glottic oedema and airway compromise.

Antibiotic therapy should be instituted as soon as possible using intravenous broad-spectrum antibiotics, with additional anaerobic cover.

In advanced cases when the swelling does not subside rapidly with such treatment, a curved submental incision may be used to drain both submandibular triangles. The mylohyoid muscle may be incised to decompress the floor of the mouth and corrugated drains placed in the wound, which is then lightly sutured. This operation may be conducted under local anaesthetic. Rarely, a tracheostomy may be necessary.

Cervical lymphadenitis
Cervical lymphadenitis is common due to infection or inflammation in the oral and nasal cavities, pharynx, larynx, ear, scalp and face.

Acute lymphadenitis
The affected lymph nodes are enlarged and tender, and there may be varying degrees of general constitutional disturbance such as pyrexia, anorexia and general malaise. The treatment in the first instance is directed to the primary focus of infection, for example tonsillitis or a dental abscess.

Chronic lymphadenitis
Chronic, painless lymphadenopathy may be caused by tuberculosis in young children or adults, or be secondary to malignant disease, most commonly from a squamous carcinoma in older individuals. Lymphoma and/or HIV infection may also present in the cervical nodes (Summary box 48.16).

Tuberculous adenitis
The condition most commonly affects children or young adults, but can occur at any age. The deep upper cervical nodes are most commonly affected, but there may be a widespread cervical lymphadenitis with many matting together. In most cases, the tubercular bacilli gain entrance through the tonsil of the corresponding side as the lymphadenopathy. Both bovine and human tuberculosis may be responsible. In approximately 80 per cent of patients, the tuberculous process is limited to the clinically affected group of lymph nodes, but a primary focus in the lungs must always be suspected.

As renal and pulmonary tuberculosis occasionally coexist, the urine should be examined carefully. Rarely, the patient may develop a natural resistance to the infection and the nodes may be detected at a later date as evidenced by calcification on radiography. This can also be seen after appropriate general treatment of tuberculosis adenitis. If treatment is not instituted, the caseated node may liquefy and break down with the formation of a cold abscess in the neck. The pus is initially confined by the deep cervical fascia, but after weeks or months, this may become eroded at one point and the pus flows through the small opening into the space beneath the superficial fascia. The process has now reached the well-known stage of a ‘collar-stud’ abscess. The superficial abscess enlarges steadily and, unless suitably treated, a discharging sinus results.

Investigation
Fine-needle aspirate taken from neck nodes with a suspicion of tuberculosis should be tested for the presence of acid-fast bacilli. Systemic investigation should not be neglected, with chest x-ray and Mantoux testing useful first-line investigations. Depending on the country of origin, where tuberculosis is diagnosed or suspected, the coexistence of other infectious diseases, such as HIV and malaria, should not be overlooked.

Treatment
The patient should be treated by appropriate chemotherapy, dependent on the sensitivities derived from the abscess contents. If an abscess fails to resolve despite appropriate chemotherapy and general measures, occasionally excision of the abscess and its surrounding fibrous capsule is necessary, together with the relevant lymph nodes. If there is active tuberculosis of another system, for example pulmonary tuberculosis, then removal of tuberculous lymph nodes in the neck is inappropriate. The nodes are commonly related to the internal jugular vein, common carotid and vagus nerve, and are usually associated with significant fibrosis making surgery difficult. A portion of the internal jugular vein may require excision, taking considerable care to avoid damage to the vagus or the cervical sympathetic trunk. To facilitate access, the sternocleidomastoid muscle

Wilhelm Friedrich von Ludwig, 1790–1865, Professor of Surgery and Midwifery, Tübingen, Germany.
For 600 years, the king’s touch was believed to cure tuberculous adenitis. Charles II touched on average 10,000 sufferers a year. In addition, he presented each with half a sovereign.
should be divided, particularly if the disease is adjacent to the spinal accessory nerve or the hypoglossal nerve. The resected nodes should be sent for both histology and microbiology.

**PRIMARY TUMOURS OF THE NECK**

**Neurogenic tumours**

*Chemodectoma (carotid body tumour)*

This is a rare tumour that has a higher incidence in areas where people live at high altitudes because of chronic hypoxia leading to carotid body hyperplasia. The tumours most commonly present in the fifth decade and approximately 10 per cent of patients have a family history. There is an association with phaeochromocytoma. The tumours arise from the chemoreceptor cells on the medial side of the carotid bulb and, at this point, the tumour is adherent to the carotid wall. The cells of the chemodectoma are not hormonally active and the tumours are usually benign with only a small number of cases producing proven metastases.

**Clinical features**

There is often a long history of a slowly enlarging, painless lump at the carotid bifurcation. About one-third of patients present with a pharyngeal mass that pushes the tonsil medially and anteriorly. The mass is firm, rubbery, pulsatile, mobile from side to side but not up and down, and can sometimes be emptied by firm pressure, after which it slowly refills in a pulsatile manner. A bruit may also be present. Swellings in the parapharyngeal space, which often displace the tonsil medially, should not be biopsied from within the mouth.

**Investigations**

When a chemodectoma is suspected, a carotid angiogram can be carried out to demonstrate the carotid bifurcation, which is usually splayed, and a blush, which outlines the tumour vessels. MRI scanning also provides excellent detail in most cases. This tumour must not be biopsied and fine-needle aspiration is also contraindicated.

**Treatment**

Because these tumours rarely metastasise and their overall rate of growth is slow, the need for surgical removal must be considered carefully as complications of surgery are potentially serious. The operation is best avoided in elderly patients. Radiotherapy has no effect. In some cases, it may be possible to dissect the tumour away from the carotid bifurcation but, at times, when the tumour is large, it may not be separable from the vessels and resection will be necessary, such that all appropriate facilities should be available to establish a bypass while a vein graft is inserted to restore arterial continuity in the carotid system.

*Vagal body tumours*

Vagal paragangliomas arise from nests of paraganglionic tissue of the vagus nerve just below the base of the skull near the jugular foramen. They may also be found at various sites along the nerve down to the level of the carotid artery bifurcation (Figure 48.56).

They also present as slowly growing and painless masses in the anterolateral aspect of the neck, and may also have a long history, commonly of 2–3 years, before diagnosis. They may spread into the cranial cavity. Diagnosis is confirmed by CT and MRI scanning and additional MR angiogram or arteriography if necessary. Treatment is surgical excision.

**Peripheral nerve tumours**

Schwannomas are solitary and encapsulated tumours attached to or surrounded by nerve, although paralysis of the associated nerve is unusual. The vagus nerve is the most common site. Neurofibromas also arise from the Schwann cell and may be part of von Recklinghausen’s syndrome of multiple neurofibromatosis. Multiple neurofibromatosis is an autosomal dominant, hereditary disease and the neurofibromata may be present at birth and often multiply.

Diagnosis requires CT or MRI scanning to differentiate them from other parapharyngeal tumours but, on occasions, the diagnosis must wait until excision.

**Secondary carcinoma**

Metastatic spread of squamous carcinoma to the cervical lymph nodes is a common occurrence from head and neck primary cancers. The nasopharynx, tonsil, tongue, pyriform fossa and supraglottic larynx must be carefully examined by panendoscopy for the primary growth before considering biopsy or any surgery on the neck. Investigation is further assisted by ultrasound and fine-needle aspirate of the neck node.

**Management**

The management of malignant cervical lymph nodes depends on the overall treatment regime.
If surgery is being used to treat the primary disease and the cervical nodes are palpable and >3 cm, they may be excised with the primary lesion.

If radiotherapy is used initially, as is always the case in carcinoma of the nasopharynx, then radiotherapy may also be given to the neck nodes, whatever their stage. In the case of the tongue, pharynx or larynx, however, if the node exceeds 3 cm in diameter, then surgery may be necessary for the neck nodes, even if the primary tumour is treated by chemoradiation.

If radiotherapy is used initially with resolution of the primary tumour, but there is subsequent residual or recurrent nodal disease, then this situation will require cervical lymph node dissection.

**Type of neck dissection**

**Classical radical neck dissection (Crile)**
The classic operation involves resection of the cervical lymphatics and lymph nodes and those structures closely associated: the internal jugular vein, the accessory nerve, the submandibular gland and the sternocleidomastoid muscle. These structures are all removed en bloc and in continuity with the primary disease if possible. The main disability that follows the operation is weakness and drooping of the shoulder due to paralysis of the trapezius muscle as a consequence of excision of the accessory nerve.

**Modified radical neck dissection**
In selected cases, one or more of the three following structures are preserved: the accessory nerve, the sternocleidomastoid muscle or the internal jugular vein. Otherwise, all major lymph node groups and lymphatics are excised. Whichever structures are preserved should be clearly noted.

---

**Selective neck dissection**
In this type of dissection, one or more of the major lymph node groups is preserved along with the sternocleidomastoid muscle, accessory nerve and internal jugular vein. In these circumstances, the exact groups of nodes excised must be documented.

**SUMMARY**
The anatomical and physiological performance of the pharyngolarynx is involved in the important mechanisms of breathing, coughing, voice production and swallowing. A variety of congenital, traumatic, infectious and neoplastic conditions disturb these functions, giving rise to the common symptoms of pain, swelling, hoarseness, dyspnoea and dysphagia.

Squamous carcinomas are the most common malignancies, accounting for approximately 80 per cent of all head and neck tumours. Their incidence and anatomical site vary around the world, but they are mainly caused by the preventable aetiological agents of smoking and alcohol, although nasopharyngeal squamous carcinomas have additional genetic and environmental factors. These head and neck cancers have a high morbidity and mortality, and require expert treatment.

INTRODUCTION AND EPIDEMIOLOGY

In the Western world, oral/oropharyngeal cancer is uncommon, accounting for only 2–4 per cent of all malignant tumours, although there is increasing evidence that the incidence is on the increase, particularly among young people. In the Indian subcontinent, however, oropharyngeal cancer remains the most common malignant tumour, accounting for 40 per cent of all cancers.

Epidemiology

The principal aetiological agents are tobacco and alcohol. In Europe and North America, this is mainly through cigarette smoking combined with alcohol abuse. Synergism between alcohol abuse and tobacco use in the development of squamous cell carcinoma (SCC) of the head and neck is well established, although evidence is gathering that the human papillomavirus (HPV16) is becoming increasingly responsible for tumours that arise particularly in the oropharynx of younger/middle-aged patients. Risk factors associated with cancer of the head and neck are outlined in Summary box 49.1.

Summary box 49.1

Risk factors associated with cancer of the head and neck
- Tobacco
- Alcohol
- Areca nut/pan masala
- Human papillomavirus
- Epstein–Barr virus
- Plummer–Vinson syndrome
- Poor nutrition

In the Indian subcontinent, the use of ‘pan’ (a combination of betel nut, areca nut, lime and tobacco) as well as reverse smoking (smoking a cheroot with the burning end inside the mouth) are responsible for the high incidence of oropharyngeal cancer. Betel quid appears to be the major carcinogen, although there is also a relationship between slaked lime and the areca nut and cancer.

INCIDENCE

The incidence is greater in men than in women and it is predominantly a disease of the elderly (those over 60 years of age). The incidence in women is increasing, particularly in younger patients, with oral tongue cancer being the cancer that is usually, but not exclusively, present.

ANATOMY

Lip and oral cavity

The oral cavity extends from the skin–vermilion border of the lips anteriorly to the junction of the soft palate superiorly and the line of the circumvallate papillae on the junction of the posterior one-third and anterior two-thirds of the tongue posteriorly. The anatomical sites that are frequently involved in mouth cancer include the floor of the mouth, the lateral border of the anterior tongue and the retromolar trigone (Figure 49.1). The retromolar trigone is defined as the attached mucosa overlying the ascending ramus of the mandible posterior to the last molar tooth and extending superiorly to the maxillary tuberosity.

Oropharynx

The oropharynx extends vertically from the oral surface of the soft palate to the superior surface of the hyoid bone (floor of vallecula). This includes the base of the tongue, the soft palate and the anterior and posterior tonsillar pillars, as well as the pharyngeal tonsils and the lateral and posterior pharyngeal walls. The

Porter Paisley Vinson, 1890–1959, physician, The Mayo Clinic, Rochester, MN, who later practised in Richmond, VA, USA.
lateral boundaries include the pharyngeal constrictor muscles and the medial aspect of the mandible.

**PATHOLOGY**

The anatomy of the oral cavity and the oropharynx is complex and the course of the nerves, blood vessels, lymphatic pathways and fascial planes influences the spread of disease. Fascial planes, including the periosteum, serve as barriers to the direct spread of tumours but contribute to the spread of tumours into the cervical lymph nodes. Perineural invasion acts as a conduit for the direct spread of tumours and profoundly impacts on prognosis and survival. Angioinvasion also carries a negative prognosis and correlates directly with distant metastases, particularly of oral tongue cancer.

**Histology**

Squamous cell carcinoma is the predominant histology for tumours arising in the oral cavity and oropharynx. Tumours mainly arise from the mucosal epithelium, although malignant salivary gland tumours from the minor salivary glands are a rare but important group of lesions. Lymphomas, particularly around Waldeyer’s ring (tonsils, tongue base, lingual tonsil regions, posterior one-third of the tongue (see Figure 48.2, p. 674)), make up the last of the three principal pathological groups of oropharyngeal cancer.

Chronic exposure of the mucosal surface to carcinogenic substances, i.e. tobacco and alcohol, can produce multiple subclinical sites of carcinoma that can at any stage develop into malignant tumour. This pathological process supports the preventative measures of smoking cessation and alcohol rehabilitation in patients with head and neck cancer, thereby minimising the occurrence of synchronous and metachronous tumours (see below under Field changes and second primary tumours).

**Premalignant lesions**

The majority of oral carcinomas are not preceded by or associated with clinically obvious premalignant lesions. There is, however, a group of oral pathological conditions in which an association with malignant transformation exists (Summary box 49.2).

**Clinical features**

Premalignant lesions of the oral mucosa and oropharyngeal mucosa present as either:

- leukoplakia
- speckled leukoplakia
- erythroplakia/plasia.

**Leukoplakia**

Leukoplakia is defined as any white patch or plaque that cannot be characterised clinically or pathologically. It is purely a descriptive term with no histological correlation. Leukoplakia varies from a small, well-circumscribed, homogenous white plaque to an extensive lesion involving large surface areas of the oral mucosa. It may be smooth or wrinkled, fissured and vary in colour depending on the thickness of the lesion.

**Speckled leukoplakia**

This is a variation of leukoplakia arising on an erythematous base (Figure 49.2). It has the highest rate of malignant transformation.

![Figure 49.2](image-url) Speckled leukoplakia on the lateral border of the tongue. Histology confirms carcinoma *in situ.*
Erythroplakia
Erythroplakia is defined as any lesion of the oral mucosa that presents as a bright red plaque which cannot be characterised clinically or pathologically as any other recognisable condition. The lesions are irregular in outline and separated from adjacent normal mucosa (Figure 49.3). The surfaces may be nodular. These lesions occasionally coexist with leukoplakia.

FIELD CHANGE AND SECOND PRIMARY TUMOURS
The diffuse and chronic exposure of the mucosa of the upper aerodigestive tract to carcinogenic substances, e.g. tobacco and alcohol, causes widespread adverse changes in the mucosal epithelium. The consequence of the diffuse exposure is the development of separate tumours at different anatomical sites. These may present simultaneously, within six months (synchronous) or may be delayed (metachronous). Slaughter, in 1950, first proposed the concept of field change or ‘cancerisation’. Separate primary tumours may not represent distinct genetic mutational events but rather the same clonal origin of cells, which migrate to separate sites in the upper aerodigestive tract. Nevertheless, minimising exposure of the oropharyngeal tissues to potential insults is the cornerstone of long-term management for patients with head and neck cancer.

Patients who develop a first tumour in the oral cavity and the oropharynx are more likely to develop a second primary tumour in the upper oesophagus. The overall rate of second primary tumour development is 15 per cent. In total, 80 per cent of these are metachronous tumours, of which 50 per cent develop within the first two years of initial presentation (Figure 49.4). The prevalence of synchronous second primary tumours is 4 per cent.

Potential for malignant change
The potential risk for malignant transformation:
• increases with increasing age of the patient;
• increases with increasing age of the lesion;
• is higher in smokers;
• increases with alcohol consumption;
• depends on the anatomical site of the premalignant lesion;
• is particularly high for leukoplakia on the floor of the mouth and ventral surface of the tongue, particularly in younger women, even in the absence of associated risk factors.

PREMALIGNANT CONDITIONS
Chronic hyperplastic candidiasis
Chronic hyperplastic candidiasis produces dense plaques of leukoplakia, particularly around the commissures of the mouth. The lesions occasionally extend on to the vermilion and even the facial skin (Figure 49.5). These lesions have a high incidence of malignant transformation, thought to be the result of invasion of the lesion by Candida albicans. A small percentage of patients have an associated immunological defect, which encourages the invasion of C. albicans, rendering the patient susceptible to malignant transformation. Specific management of chronic hyperplastic candidiasis includes prolonged (6 weeks) topical antifungal treatment or systemic antifungal treatment (2 weeks). If the lesions persist after medical therapy, surgical excision or laser vapourisation is strongly recommended.

Oral submucous fibrosis
Oral submucous fibrosis is a progressive disease in which fibrous bands form beneath the oral mucosa. Scarring produces con...
tracture, resulting in limited mouth opening and restricted tongue movement. The condition is almost entirely confined to the Asian population and is characterised pathologically by epithelial fibrosis with associated atrophy and hyperplasia of the overlying epithelium (Figure 49.6). The epithelium also shows changes of epithelial dysplasia. Restricted mouth opening can be treated with either intralesional steroids or surgical excision and skin grafts.

Research strongly indicates that oral submucous fibrosis is significantly associated with the use of pan masala areca nut, with or without concurrent alcohol use. Tobacco smoking alone is not associated with oral submucous fibrosis.

Sideropenic dysphagia (Plummer–Vincent and Paterson–Kelly syndromes)

There is a well-known relationship between sideropenia (iron deficiency in the absence of anaemia) and the development of oral cancer. Sideropenia is common in Scandinavian women and leads to epithelial atrophy, which renders the oral mucosa vulnerable to irritation from topical carcinogens. Correction of the sideropenia with iron supplements reduces the epithelial atrophy and risk of malignant transformation.

CLASSIFICATION AND STAGING

TNM staging

Staging of head and neck cancer is defined by the American Joint Committee on Cancer (AJCC) and follows the TNM system. The system also takes into account the pretreatment computed tomography (CT) or magnetic resonance imaging (MRI) of the tumour. The T classification indicates the extent of the primary tumour and the N classification relates to the extent of regional neck metastases to the cervical lymph nodes; this is identical for all mucosal sites of the head and neck except for the nasopharynx. The M classification relates to distant metastasis. The risk of distant metastasis is dependent on nodal disease rather than the size of the primary tumour. Tumours close to the midline are at a greater risk of developing bilateral or contralateral cervical node metastasis.

The TNM staging system is outlined in Table 49.1.

Patterns of lymph node metastasis

The cervical lymph nodes are divided into five principal levels as outlined in Figure 49.7.

The spread of tumour from the primary site has been well addressed. SCC in the oral cavity and lips tends to metastasise to lymph nodes at levels I, II and III. However, with SCC of the oral tongue there is a risk of skip metastasis directly to lymph node levels III or IV, without the involvement of higher-level lymph node groups. Tumours arising in the oropharynx commonly metastasise to lymph node levels II, III and IV, as well as retropharyngeal and contralateral nodal groups.

Distant metastases are relatively uncommon but sites involved include lung, brain, liver, bone and skin.

CLINICAL FEATURES

Between 25 and 50 per cent of patients with cancer of the oral cavity or oropharynx present late. Many of these patients are elderly and frail and delay visiting the doctor or the dentist partly because they wear dentures and are accustomed to the discomfort and associated ulceration. Occasionally, dental and medical practitioners fail to recognise that a lesion may be
malignant and further delay referral. Moreover, early oral cancer is usually not painful until either the ulcer becomes infected or the tumour invades local sensory nerve fibres. Clinical presentation is markedly dependent on the anatomical site.

### Lip cancer

Lip cancer presents early as it is readily visible to the patient. It usually arises as an ulcer on the vermilion border (Figure 49.8). In total, 95 per cent of carcinomas of the lip arise on the lower lip and 15 per cent arise in the central one-third and commissures. Tumours tend to spread laterally over the mucosal surface. Lymph node metastases, usually to the submental or submandibular nodes, occur late.

### Oral cavity

Cancers of the oral cavity present in a variable way (Figure 49.9) but are often associated with persisting swelling or ulceration within the oral cavity (Summary box 49.3).

The duration of symptoms is highly variable, from several weeks to many months.

---

**Summary box 49.3**

**Clinical features of oral cancer**

- Persistent oral swelling for >4 weeks
- Mouth ulceration for >4 weeks
- Sore tongue
- Difficulty swallowing
- Jaw or facial swelling
- Painless neck lump
- Unexplained tooth mobility
- Trismus

---

**Oropharynx**

Cancer of the oropharynx frequently presents much later than cancer of the lip and oral cavity. An ipsilateral or contralateral lump in the neck may be the single presenting complaint from a patient with a carcinoma arising from the tongue base, tonsil or soft palate. Palpable asymmetry, particularly in the tonsil, often represents submucosal infiltration of tumour. Deeper infiltration of the tongue base, pterygoid muscles or adherence of the tumour to the jaw results in poor mobility of the tongue or palate. Common clinical features of oropharyngeal cancer are outlined in Summary box 49.4.

INVESTIGATIONS

When a clinical diagnosis of oropharyngeal cancer is suspected, a comprehensive protocol of investigations should be instituted. An incisional biopsy should be carried out in all cases. Formal examination under anaesthetic is preferred in the vast majority of cases, not only to carry out the biopsy, but also to palpate and examine the extent of the tumour, which can be exquisitely tender in the conscious patient. Under the same anaesthetic, extraction of teeth with a dubious prognosis can be performed. Where available, and where the diagnosis is clear-cut, insertion of a percutaneous endoscopic gastrostomy (PEG) should be performed to facilitate feeding in the treatment phase. The biopsy should be generous and include the most suspicious area of the lesion, as well as normal adjacent tissue. Areas of necrosis or gross infection should be avoided.

Radiography
Plain radiography of the jaw is of limited value but does provide an opportunity for dental assessment. Before examination under anaesthesia, an orthopantomogram of the jaws is helpful to assess bony invasion, particularly from tumours arising on the alveolus and maxillary antrum.

Magnetic resonance imaging
MRI is the investigation of choice for cancer of the oral cavity and oropharynx, as it is not distorted by metallic dental restorations and provides excellent visualisation of soft-tissue infiltration of the tumour (Figure 49.10). Ideally, it should be performed before diagnostic biopsy as biopsy frequently distorts the image of the primary tumour. The specificity and sensitivity of MRI in diagnosing cervical node metastasis are similar to that of CT. Patients who suffer with claustrophobia may have difficulty in tolerating the investigation.

Computed tomography
CT is much more widely available than MRI but has limited value in oral cavity and oropharyngeal cancer. It is useful when bony invasion is suspected. CT of the thorax and abdomen is now indicated for all patients and not just those with proven cervical lymph node metastasis and large-volume disease.

Radionuclide studies
A radioisotope bone scan of the facial skeleton adds little to the diagnosis and assessment of oropharyngeal cancer. The scan is not specific and tends to show increased uptake wherever there is increased metabolic activity in bone. A false-positive diagnosis is common and ‘over-staging’ of the disease frequent.

Fine-needle aspiration cytology
Fine-needle aspiration cytology (FNAC) is useful for the assessment and pathological diagnosis of enlarged cervical lymph nodes. It involves the use of a fine-needle puncture into the mass and immediate aspiration for cytological examination. It has few complications and does not spread tumour. It requires no specialist equipment other than a 21G or 23G needle and a 10-mL syringe. Aspiration should be carried out only when the needle enters the swelling. If the specimen can be assessed immediately by an expert cytologist, then it can be sent without fixation. If there is delay in microscopic examination, then the specimen, smeared on a microscope slide, should be fixed before transfer to the laboratory. The positive yield from FNAC is dependent not only on the quality of the aspirate, but also on the skill of the cytologist.

Ultrasound
Ultrasound has limited use in the management of oropharyngeal cancer. It is useful as an adjunct in FNAC to ensure accurate aspiration of a deeply seated neck node swelling.

TREATMENT

General principles
The two principal treatment modalities of oropharyngeal cancer are surgery and radiotherapy. Small tumours can be managed either by primary radiotherapy or surgery. Large-volume disease, i.e. advanced tumour, usually requires a combination of surgery and radiotherapy. There is an increasing move to manage extensive disease of the oropharynx with chemoradiotherapy, provided that patients are medically fit to tolerate the toxicity. Factors that need to be taken into consideration include:

- the site of disease
- the stage
The management of head and neck cancer involves a team approach, whereby patients are assessed objectively by several specialists who agree on an optimum treatment strategy.

Cancer of the oral cavity is frequently managed with primary surgery whereas cancer of the oropharynx can be treated with either primary radiotherapy or primary surgery, or a combination, i.e. surgery for neck nodes and radiotherapy for the primary site.

When the tumour invades bone, e.g. the mandible, primary surgery is deemed appropriate as radiotherapy is less effective in controlling disease. Surgery is also more appropriate for bulky advanced disease, usually followed by postoperative radiotherapy. Tumours of intermediate size, e.g. T2 and T3 tumours, are more problematic and treatment regimes more controversial, hence the need for planning by a multidisciplinary team.

Cervical node involvement
When cervical lymph node involvement occurs, treatment should be geared towards a single modality to deal simultaneously with the lymph node disease and the primary tumour.

Histology
The degree of differentiation of SCC does not normally influence the management of the tumour alone. Management of verrucous carcinoma, a variant of SCC, is identical to that of any other SCC.

Malignant tumours of the minor salivary glands require primary surgery whereas lymphoma is managed by radiotherapy, or chemotherapy and radiotherapy, depending on the stage. Postoperative radiotherapy for minor salivary gland tumours is often indicated to reduce the risk of locoregional recurrence.

Age
Modern anaesthesia and postoperative critical care facilities have allowed major head and neck surgery to be carried out on patients with significant medical comorbidity. Advancing age is now not considered to be a contraindication to major head and neck cancer surgery. Conversely, young patients should not be denied radiotherapy for fear of inducing a second malignancy, e.g. sarcoma, in later life.

Previous radiotherapy
A second course of radiotherapy to a previously irradiated site is contraindicated as the tumour is likely to be radioresistant and reirradiation will invariably result in extensive tissue necrosis.

Field change
Surgery is preferred when multiple tumours are present or there is extensive premalignant change of the oropharyngeal mucosa. Radiotherapy is unsatisfactory as the entire oral cavity requires treatment, causing severe morbidity. In addition, subsequent postradiotherapy changes make the diagnosis of future premalignancy and malignancy more difficult.

Management of premalignant conditions
Elimination of associated aetiological factors is the basis of the management of premalignant oral mucosal lesions. Cessation of smoking, elimination of the areca nut/pan habit and reduction in alcohol consumption should be encouraged in all patients with premalignant lesions. A photographic record of the lesion is useful, particularly for long-term follow up. All erythroplakia and speckled leukoplakia should undergo urgent incisional biopsy. Biopsy from more than one site provides a better representation of histological changes within a lesion.

Severe epithelial dysplasia and carcinoma in situ should be ablated by surgical excision or laser vaporisation. Small lesions, particularly on the lateral border of the tongue or buccal mucosa, may be managed with surgical excision and primary closure by undermining the adjacent mucosa. Larger defects can be managed with laser vaporisation and allowed to epithelialise spontaneously (Figure 49.11). With mild-to-moderate epithelial dysplasia, treatment is facilitated by elimination of causative agents. Patients who continue to smoke should be managed as for severe dysplasia and carcinoma in situ. Patients who cease smoking and areca nut/pan habits may be followed up closely at three-monthly intervals.

LIP CANCER
Surgery and external beam radiotherapy are highly effective methods of treatment for lip cancer. The cure rate approaches 90 per cent for either modality.

Premalignant changes on the lower lip mucosa are frequently extensive and are best managed by a lower lip shave, in which...
the vermilion defect is closed by advancement of the lower labial mucosa.

**Small tumours**

Small tumours (<2 cm) of the lip can be managed with either a V- or W-shaped excision under local or general anaesthesia. The defect, which should be no larger than one-third of the total lip size, is closed in three layers – mucosa, muscle and skin – with particular attention paid to the correct alignment of the vermilion border (Figure 49.12).

**Intermediate tumours**

Larger tumours, which produce defects of between one-third and two-thirds the size of the lower lip, require local flaps for reconstruction. V or W excision will result in microstomia. Large central defects are best managed using the Johansen step technique (Figure 49.13). This allows closure of the defect by symmetrical advancement of soft-tissue flaps, utilising the excess skin in the labiomental grooves. Alternative techniques include the Bernard rotational flap.

**Total lip reconstruction**

Extensive tumours of the lower lip, which invade adjacent tissues (T4), have a high incidence of neck node metastasis. Patients with such advanced disease require surgery that may include unilateral or bilateral selective neck dissection and total excision of the lower lip and chin. The lower lip defect is best reconstructed with a forearm flap suspended with palmaris longus tendon (Figure 49.14).

**TONGUE CANCER**

Up to 30 per cent of patients with a T1 (<2 cm diameter) tumour (Figure 49.15) have occult metastasis at presentation and should undergo simultaneous treatment of the neck by either selective neck dissection or radiotherapy. When performing surgical excision of the primary tumour, a 2-cm margin in all planes should be achieved to ensure a wide, complete excision. Resection resulting in partial or hemiglossectomy can be performed with either a cutting diathermy or laser if available. Advanced tumours (T3 and T4) often encroach upon the floor of the mouth and, occasionally, the mandible. In these circumstances, a major resection of the tongue and floor of the mouth and mandible is required. T4 tumours of the oral tongue often cross the midline, for which total glossectomy is the only option to achieve adequate tumour clearance.

When a patient undergoes simultaneous neck dissection, the resection of the primary tumour should preferably be in continuity with the neck node specimen. This eliminating "lingual" lymph nodes (lying between the primary tumour and submandibular (level I) nodes); these nodes may contain micro-deposits of tumour, which may lead to local recurrence.

**Access**

Access for oropharyngeal cancer is important to allow accurate assessment and clear visualisation to enable tumour clearance to be achieved. Access techniques include:
- transoral – small anterior oral tumours only;
- lip-split technique and paramedian or median mandibulotomy (Figure 49.16);
- visor incision (Figure 49.17).

**Reconstruction**

Small defects of the lateral tongue can be managed by primary closure or allowed to heal by secondary intention. Larger defects, e.g. T2, T3 and T4 resections, require formal reconstruction to encourage good speech and swallowing. A radial forearm flap either with skin (Figure 49.18) and/or fascia, utilising microvascular anastomosis, gives a good functional

![Figure 49.12 (a) Skin markings for wedge excision of the lower lip. (b) Primary closure.](image-url)
result. Large-volume defects, including total glossectomy, require more bulky flaps such as the rectus abdominus free flap. If feasible, the preservation of one or both hypoglossal nerves is useful to encourage floor of mouth function to help relearn swallowing.

**FLOOR OF MOUTH**

Carcinoma of the floor of the mouth can spread to the ventral surface of the anterior tongue or encroach upon the lower anterior alveolus (Figure 49.19). Surgical excision may include a partial anterior glossectomy and anterior mandibular resection. Only very small tumours of the floor of mouth can be managed by simple excision. The visor procedure provides excellent access (see Figure 49.17).

Ulcerative squamous cell carcinoma of the right lateral border of the tongue.
Small tumours of the floor of the mouth frequently require formal reconstruction. It is unacceptable to advance the cut surface of the ventral tongue to the labial mucosa as severe difficulties with speech, swallowing and mastication ensue. Simple soft-tissue defects of the anterior floor of mouth are best reconstructed with a radial artery forearm flap. If a patient

Figure 49.18 Radial artery forearm flap raised before division of vascular pedicle and cephalic vein (arrow).

Reconstruction
Small tumours of the floor of the mouth frequently require formal reconstruction. It is unacceptable to advance the cut surface of the ventral tongue to the labial mucosa as severe difficulties with speech, swallowing and mastication ensue. Simple soft-tissue defects of the anterior floor of mouth are best reconstructed with a radial artery forearm flap. If a patient
is unfit for microvascular free flap surgery or the facilities are limited, bilateral nasolabial flaps tunneled into the mouth and interdigitated provide an acceptable alternative (Figure 49.20). Three weeks later their pedicles are divided and inset into the lateral floor of mouth defects. Large defects that involve rim resection of the anterior mandible may also be managed with soft tissue reconstruction only. Full-thickness resection of the anterior mandible, however, requires immediate reconstruction to prevent severe functional defects or a cosmetic deformity. Vascularised bone with a soft-tissue component provides the most up-to-date method of reconstruction. A fibula flap or a vascularised iliac crest graft (deep circumflex iliac artery (DCIA)) are two options in the management of anterior mandible defects with simultaneous floor of mouth defects.

**BUCCAL MUCOSA**

Squamous cell carcinoma of the buccal mucosa (Figure 49.21) should be excised widely, including the underlying buccinator muscle. Larger tumours occasionally extend onto the maxillary tuberosity, tonsillar fossa or mandibular alveolus. Facial skin involvement is rare but carries a poor prognosis. Although cervical node metastasis from buccal mucosa usually occurs less readily than in tongue and floor of mouth cancer, a simultaneous ipsilateral selective supraomohyoid neck dissection (levels I, II, III) is considered good practice.

Access for buccal carcinoma can be achieved either transorally for smaller lesions (T1, T2) or using the lip-splitting technique for larger lesions (T3, T4). Reconstruction of the buccal mucosa prevents scarring and trismus. Options include the radial artery forearm flap or a temporalis muscle flap. Raw temporalis muscle inset into the buccal mucosal defect will epithelialise spontaneously over several weeks.

**LOWER ALVEOLUS**

Surgery is the treatment of choice for tumours that involve the mandibular alveolus (Figure 49.22a). Ipsilateral selective neck dissections should be performed for lateral tumours although the incidence of occult neck node metastasis is low. Bilateral selective neck dissection should be considered for anterior tumours. Bone invasion (Figure 49.22b) demands segmental resection of the mandible in continuity with neck dissection. Primary or immediate reconstruction is preferred as the functional and cosmetic outcomes are usually superior to those of delayed reconstruction. Options for bony reconstruction are shown in Table 49.2. They include the fibula flap for the edentulous mandible (Figure 49.22c and d) and the iliac crest (DCIA) for patients with a dentate mandible (Figure 49.23). The vascularised iliac crest can be wrapped with internal oblique abdominal wall muscle, which epithelialises spontaneously. This intraoral epithelialisation provides an excellent surface for prosthetic replacement.

Although non-vascularised bone grafts have a place in mandibular reconstruction, the long-term success is frequently low as many patients receive postoperative radiotherapy, which results in the loss of the bone and dehiscence of the titanium tray or reconstruction plate.

(b) Plain radiography (orthopantomogram) revealing bony destruction of the anterior mandible. (c) Osseocutaneous fibula flap. (d) Postoperative radiograph of the reconstructed mandible with fibula flap and reconstruction plate.
**RETROMOLAR PAD**

Tumours at this site frequently, but not always, invade the ascending ramus of the mandible. They also spread medially into the soft palate or even the tonsillar fossa. Access for excision is carried out via a lip split and mandibulotomy (see Figure 49.16). Small defects are managed either with a temporalis muscle flap or a radial artery forearm flap. Segmental mandibular resections require vascularised bone to achieve adequate reconstruction.

**HARD PALATE AND MAXILLARY ALVEOLUS**

The maxillary alveolus and hard palate are relatively uncommon sites for SCC. A tumour arising in these areas may arise either from the oral mucosa per se or from the maxillary antrum penetrating the oral cavity. In the Indian subcontinent, carcinoma of the hard palate is common and particularly associated with reverse smoking. Occasionally, malignant tumours of minor salivary glands present as swellings of the hard palate. Small tumours of the maxillary alveolus can be managed by transoral partial maxillectomy. More extensive tumours involving the floor of the maxillary sinus require wider access by a Weber–Ferguson incision (Figure 49.24). If the preoperative investigations demonstrate extension of the disease into the pterygoid space or the infratemporal fossa, the prognosis is poor as surgical clearance is difficult if not impossible. Tumour extending into the orbit requires simultaneous orbital exenteration or even a combined neurosurgical resection. The vascularised iliac crest graft is the method of choice for immediate maxillary reconstruction although the fibula provides adequate bony replacement to maintain facial contour.

Microvascular free tissue transfer remains the method of choice for the management of defects in the oropharynx (Table 49.3). Free flaps are superior reconstructive options to pedicled or local flaps, which may be used for salvage procedures or recurrent disease. Each ‘free’ flap has a principal blood supply and a concomitant venous drainage. The flaps can be tailored to the defect to include skin, fascia, bone and muscle. The techniques of free tissue transfer demand specialist training and a microscope to connect blood vessels in the neck after neck dissection, e.g. facial artery to the prepared artery attached to the flap. The vascular anatomy of microvascular free flaps is summarised in Table 49.4.

Tumours of the oropharynx are frequently not amenable to surgery because of the morbid nature of the resection – small and intermediate (T1, T2) tongue base tumours may necessitate total glossectomy to achieve adequate clearance at the root of the tongue. Tumours of the soft palate and tonsil, however, can be managed with either primary surgery in continuity with neck dissection or primary radiotherapy. Subsequent defects of the tonsillar area can be managed with a forearm flap. Defects of the soft palate, including total soft palate reconstruction, are best managed with a combined reconstruction consisting of a superiorly based pharyngeal flap to line the nasal surface and a forearm flap for the oral surface of the new soft palate.

Chemoradiotherapy is now increasingly used to manage tumours of the oropharynx in which organ preservation, but not necessarily function, is the goal. In patients with large-volume neck disease, e.g. N2 and N3, a combined modality of neck dissection followed by chemoradiotherapy to manage the tumour at the primary site and residual neck disease is gaining popularity.
Chemotherapy

The role of chemotherapy has evolved over the last 20–30 years. It was initially reserved for treatment of recurrent and incurable disease, often using single-agent therapy. Combination chemotherapy, particularly platinum agents and 5-fluorouracil, is now more effective in controlling recurrent and incurable disease. However, combination chemotherapy is associated with more severe side effects and a balance needs to be reached between efficacy, palliation and quality of life.

Chemotherapy also now has an important role in the treatment of locally advanced and previously untreated oropharyngeal carcinoma. There is compelling evidence that tumours of the tongue base may best be managed with primary chemoradiotherapy rather than radical surgery. The addition of chemotherapy with radiotherapy does, however, increase the morbidity and mortality rates. Patients who are frail or who have significant medical comorbidities may not tolerate the regime.

Chemoradiotherapy has been shown to improve survival in patients whose tumours are deemed unresectable, although organ preservation, i.e. swallowing and speech, is not always sustained. There is good evidence for the superiority of chemoradiotherapy over radiotherapy alone; however, chemoradiotherapy is rarely effective in large-volume disease.

Management of the neck

The management of the cervical lymph nodes is highly dependent on the planned treatment of the primary tumour. When surgery is deemed appropriate for the primary tumour, simultaneous neck dissection should be considered. If radiotherapy is preferred, treatment to the neck should be contemplated, particularly when there is a high risk of occult metastases, e.g. tongue.

The clinically node-negative neck

The cervical lymph nodes contain occult metastases in up to 30 per cent of patients. This is particularly significant with patients presenting with primary carcinomas of the tongue and, to a lesser extent, floor of mouth. Tumours arising in the buccal mucosa and mandibular alveolus are less likely to have occult metastasis. Nevertheless, increasing evidence exists that active treatment of cervical lymph nodes in the absence of obvious disease is considered good practice. Patients with carcinoma of the lateral tongue, floor of mouth and mandibular alveolus are best managed by supraomohyoid neck dissection (surgical removal of lymph node levels I, II and III in continuity with the primary tumour) (Figure 49.25).

</tr>
</tbody>
</table>

Good evidence exists that carcinoma of the tongue can produce occult cervical metastasis directly to lymph node level IV. Consequently, the extended supraomohyoid neck dissection removing lymph node levels I, II, III and IV is indicated for patients with carcinoma of the tongue with N0 neck disease. Selective neck dissection is regarded as a staging as much as a therapeutic procedure. Patients who have two or more positive nodes or evidence of extracapsular spread should be managed with postoperative radiotherapy to the neck and the primary site.

Elective external beam radiotherapy is an alternative when radiotherapy is planned for the primary site.

The clinically node-positive neck

The presence of an isolated ipsilateral cytologically positive lymph node of <3 cm is now considered best managed by selective supraomohyoid neck dissection. There is good evidence that radical or modified radical neck dissection is not required for patients with N1 neck disease associated with oropharyngeal cancer.

N2a and N2b disease

Radical or modified radical neck dissection (Figure 49.26), often followed by postoperative radiotherapy, is appropriate to control neck disease. Patients unfit for surgery can be offered external beam radiotherapy palliation.

N2c disease

Patients with mouth cancer presenting with bilateral nodes often have a large, inoperable, primary tumour. Bilateral neck dissection can be undertaken, although morbidity is high. One internal jugular vein needs to be spared, usually on the side that is less involved with disease. Postoperative radiotherapy is indicated if there is multiple node involvement or extracapsular spread. Postoperative neck oedema and facial congestion occurs and may take months to resolve.

N3 disease

In N3 disease, there is extensive involvement of the neck, often with fixation to the overlying skin. This is associated with advanced primary disease. Radical neck dissection may be feasible in such circumstances, but strong consideration should be given to radiotherapy if there is evidence of tumour involving the internal carotid artery or the skull base.

The different types of neck dissection and their indications are summarised in Table 49.5.
ComplIcations

Notwithstanding the general complications of major surgery, complications specifically associated with the treatment of oropharyngeal cancer are speech deficiencies, especially with resection of the anterior floor of the mouth and tongue; swallowing dysfunction and aspiration, especially after oropharyngeal resection; neurological injury, e.g. lingual nerve, hypoglossal nerve palsy; wound breakdown and cervical fistula formation; failure of internal fixation/reconstruction plates; failure of microvascular anastomosis; and flap failure. Other complications that may occur are listed in Summary box 49.5.

Patients undergoing treatment for oropharyngeal cancer frequently develop severe functional problems. The size and location of the tumour will dictate the extent of resection and the sacrifice of important structures.

Loss of tongue and floor of mouth musculature and the removal of bone and associated muscle attachments together

**Summary box 49.5**

Complications of treatment for oropharyngeal cancer

Surgical
- Accessory nerve palsy – shoulder dysfunction and pain
- Soft-tissue oedema, especially bilateral neck dissection
- Phrenic nerve injury
- Thoracic duct injury
- Cranial nerve injury
- Rupture of the carotid artery

Radiotherapy
- Osteoradionecrosis of the mandible
- Hypothyroidism
- Atherosclerosis of the carotid artery
- Neck and shoulder dysfunction
- Trismus
- Xerostomia
- Visual impairment
- Radiation neuritis

Chemotherapy
- Nausea and vomiting
- Diarrhoea
- Stomatitis
- Gastrointestinal upset
- Renal toxicity
- Leukopenia and thrombocytopenia
with the sacrifice of sensory and motor cranial nerves all greatly affect not only appearance but also speech, swallowing and nutritional status. Psychological disturbance is universal in patients undergoing major head and neck cancer surgery and radiotherapy.

The techniques of immediate reconstruction, particularly with microvascular flaps, minimise the complications and side effects but many patients are, nevertheless, radially changed for the remainder of their lives. Patients undergoing ‘salvage’ surgery following primary radiotherapy frequently undergo delayed wound healing, cervical fistula formation and, occasionally, carotid artery blowout/rupture. Skin anaesthesia associated with scar contracture creates additional problems, particularly with neck mobility and trismus.

**POST-TREATMENT MANAGEMENT**

Patients with oropharyngeal cancer need to be followed up regularly, not only to detect possible recurrence but also to manage the morbidity associated with treatment. In total, 70 per cent of recurrences occur in the first 12 months following treatment and 90 per cent in the first two years. Patients who survive for five years are cured and discharged. Recurrence after extensive surgery and radiotherapy is frequently beyond any further treatment and palliative care is a logical pathway.

**OUTCOME AND PROGNOSIS**

Survival after oropharyngeal cancer is directly related to:

- the size of the primary tumour (T stage);
- the evidence of neck node metastasis (N stage);
- concomitant medical problems, e.g. cardiorespiratory disease.

Patients with large primary tumours are more likely to develop cervical node metastasis. Cervical node metastasis, particularly with extracapsular spread, is the most significant factor in determining prognosis for oropharyngeal cancer. The overall five-year survival rates are shown in Table 49.6.

Supportive treatment is important for patients with oropharyngeal cancer, particularly in the form of speech and language support and dietetic and psychological input. Smoking cessation and a drastic reduction in alcohol intake reduces the risk of developing further metachronous carcinomas in the aerodigestive tract.

CHAPTER 50
Disorders of the salivary glands

LEARNING OBJECTIVES
To understand:
- The surgical anatomy of the salivary glands
- The presentation, pathology and investigation of salivary gland disease
- The medical and surgical treatment of stones, infections and tumours that affect salivary glands

INTRODUCTION
There are four main salivary glands, two submandibular glands and two parotid glands. In addition, there are multiple minor salivary glands.

MINOR SALIVARY GLANDS
Anatomy
The mucosa of the oral cavity contains approximately 450 minor salivary glands. They are distributed in the mucosa of the lips, cheeks, palate, floor of the mouth and retromolar area. These minor salivary glands also appear in other areas of the upper aerodigestive tract including the oropharynx, larynx and trachea as well as the sinuses. They have a histological structure similar to that of mucous-secreting major salivary glands. Overall, they contribute to 10 per cent of the total salivary volume (Summary box 50.1).

Summary box 50.1
Anatomy of salivary glands
- Two submandibular glands
- Two parotid glands
- Two sublingual glands
- Approximately 450 minor salivary glands

Common disorders of minor salivary glands
Cysts
Extravasation cysts are common and result from trauma to the overlying mucosa. They usually affect minor salivary glands within the lower lip, producing a variable swelling that is painless and usually, but not always, translucent (Figure 50.1). Some resolve spontaneously, but most require formal surgical excision that includes the overlying mucosa and the underlying minor salivary gland. Recurrence is rare.

Figure 50.1 Mucous retention cyst. A translucent swelling on the lower lip is typical.

Tumours
Few tumours show more diversity in histological appearance and anatomical site than those that arise from mucous glands of the upper aerodigestive tract. Tumours of minor salivary glands are histologically similar to those of major glands; however, up to 90 per cent of minor salivary gland tumours are malignant. Although tumours of minor salivary gland origin occur anywhere in the upper aerodigestive tract, common sites for tumour formation include the upper lip, palate and retromolar regions. Less common sites for minor salivary gland tumours include the nasal and pharyngeal cavities. Minor salivary gland tumours have also been reported in the paranasal sinuses and throughout the pharynx. These tumours arise in submucosal seromucous glands that are found throughout the upper aerodigestive tract. Very rarely, a mucoepidermoid carcinoma can present as an intraosseous tumour of the mandible.

Benign minor salivary gland tumours present as painless, firm, slow-growing swellings. Overlying ulceration is extremely rare. Minor salivary gland tumours of the upper lip are managed by excision to include the overlying mucosa, with primary closure (Figure 50.2a–c).

Benign tumours of the palate, less than 1 cm in diameter, can be managed by excisional biopsy, and the defect is allowed to heal by secondary intention (Figure 50.3a–d). Where tumours of
the palate are greater than 1 cm in diameter, incisional biopsy is recommended to establish a diagnosis prior to formal excision.

Malignant minor salivary gland tumours are rare. They have a firm consistency, and the overlying mucosa may have a varied discolouration from pink to blue or black (Figure 50.4). The tumour may become necrotic with ulceration as a late presentation.

Malignant minor salivary gland tumours of the palate are managed by wide excision which may involve partial or total maxillectomy. The subsequent defect can be managed by either prosthetic obturation or immediate reconstruction. Various microvascular flaps have been designed to reconstruct maxillectomy defects, including radial forearm flap, fibular flap, rectus abdominus, latissimus dorsi and the vascularised iliac crest graft (Figure 50.5a and b).

THE SUBLINGUAL GLANDS

Anatomy
The sublingual glands are a paired set of minor salivary glands lying in the anterior part of the floor of mouth between the mucous membrane, the mylohyoid muscle and the body of the mandible close to the mental symphysis. Each gland has numerous excretory ducts that open either directly into the oral cavity or indirectly via ducts that drain into the submandibular duct (Summary box 50.2).

Summary box 50.2

Sublingual glands
- Problems are rare
- Minor mucous retention cysts may need surgery
- Plunging ranula is a retention cyst that tunnels deep
- Nearly all tumours are malignant
The sublingual glands

725

Plunging ranula

Plunging ranula is a rare form of mucous retention cyst that can arise from both sublingual and submandibular salivary glands. Mucus collects within the cyst, which perforates through the mylohyoid muscle diaphragm to enter the neck. Patients present with a dumb-bell-shaped swelling that is soft, fluctuant and painless in the submandibular or submental region of the neck (Figure 50.7a and b). Diagnosis is made on ultrasound or magnetic resonance imaging (MRI) examination. Excision is usually performed via a cervical approach removing the cyst and both the submandibular and sublingual glands. Smaller plunging ranulas can be treated successfully by transoral sublingual gland excision, with or without marsupialisation.

Tumours

Tumours involving the sublingual gland are extremely rare and are usually (85 per cent) malignant. They present as a hard or firm painless swelling in the floor of the mouth. Treatment requires wide excision involving the overlying mucosa and simultaneous neck dissection. Immediate reconstruction of the intraoral defect is recommended using, for example, a radial artery forearm flap.

Common disorders of the sublingual glands

Cysts

Minor mucous retention cysts develop in the floor of the mouth either from an obstructed minor salivary gland or from the sublingual salivary gland. The term ‘ranula’ should be applied only to a mucous extravasation cyst that arises from a sublingual gland. It produces a characteristic translucent swelling that takes on the appearance of a ‘frog’s belly’ (ranula) (Figure 50.6). A ranula can resolve spontaneously, but many also require formal surgical excision of the cyst and the affected sublingual gland. Incision and drainage, however tempting, usually results in recurrence.

Ranula is derived from ‘rana’, the Latin for frog.

Thomas Wharton, 1616–1673, physician, St Thomas’s Hospital, London, UK, described the submandibular duct in 1656.
THE SUBMANDIBULAR GLANDS

Anatomy

The submandibular glands are paired salivary glands that lie below the mandible on either side. They consist of a larger superficial and a smaller deep lobe that are continuous around the posterior border of the mylohyoid muscle. Important anatomical relations include the anterior facial vein running over the surface of the gland and the facial artery. The deep part of the gland lies on the hyoglossus muscle closely related to the lingual nerve and inferior to the hypoglossal nerve. The gland is surrounded by a well-defined capsule that is derived from the deep cervical fascia which splits to enclose it. The gland is drained by a single submandibular duct (Wharton’s duct) that emerges from its deep surface and runs in the space between the hyoglossus and mylohyoid muscles. It drains into the anterior floor of the mouth at the sublingual papilla. There are several lymph nodes immediately adjacent and sometimes within the superficial part of the gland (Summary box 50.3).

Summary box 50.3

Important anatomical relationships of the submandibular glands
- Lingual nerve
- Hypoglossal nerve
- Anterior facial vein
- Facial artery
- Marginal mandibular branch of the facial nerve

Ectopic/aberrant salivary gland tissue

The most common ectopic salivary tissue is the Stafne bone cyst. This presents as an asymptomatic, clearly demarcated radiolucency of the angle of the mandible, characteristically below the inferior dental neurovascular bundle (Figure 50.8). It is formed by invagination into the bone on the lingual aspect of the mandible of an ectopic lobe of the juxtaposed submandibular gland. No treatment is required.

Inflammatory disorders of the submandibular gland

Inflammation of the submandibular gland is termed sialadenitis. Submandibular sialadenitis may be acute, chronic or acute on chronic.

Common causes are:
- Acute submandibular sialadenitis:
  - Viral. The paramyxovirus (mumps) is a viral illness of the salivary glands that usually produces parotitis. The submandibular glands are occasionally involved, causing painful tender swollen glands. Other viral infections of the submandibular gland are extremely rare.
  - Bacterial. Bacterial sialadenitis is more common than viral sialadenitis and occurs secondary to obstruction. Following infection and despite control of acute symptoms with antibiotics, the gland frequently becomes chronically inflamed and requires formal excision.
- Chronic submandibular sialadenitis.

Obstruction and trauma

The most common cause of obstruction within the submandibular gland is stone formation (sialolithiasis) within the gland and its associated duct system. Eighty per cent of all salivary stones occur in the submandibular glands because their secretions are highly viscous. Eighty per cent of submandibular stones are radio-opaque and can be identified on plain radiography (Figure 50.9).

Clinical symptoms

Patients usually present with acute painful swelling in the region of the submandibular gland, precipitated by eating (Figure 50.10). The swelling occurs rapidly and often resolves spontaneously over 1–2 hours after the meal is completed. This classical picture occurs when the stone causes complete obstruction, usually at the opening of the submandibular duct. More frequently, the stone causes only partial obstruction when it lies within the hilum of the gland or within the duct in the floor of the mouth. In such circumstances, symptoms are more infrequent, producing minimal discomfort and swelling, not confined to mealtimes. Clinical examination reveals an enlarged firm submandibular gland, tender on bimanual examination. Pus may

Figure 50.8 Plain radiographic appearance of a Stafne bone cyst.

Figure 50.9 Lower occlusal x-ray highlighting a radio-opaque submandibular duct stone (arrowhead). Note the larger stone posteriorly located in the hilum of the gland (arrow).
be visible, draining from the sublingual papilla (Figure 50.11), the consequence of chronic and non-specific bacterial infection.

Management

If the stone is lying within the submandibular duct in the floor of the mouth anterior to the point at which the duct crosses the lingual nerve (second molar region), the stone can be removed by incising longitudinally over the duct. Once the stone has been delivered, the wall of the duct should be left open to promote free drainage of saliva. Suturing the duct will lead to stricture formation and the recurrence of obstructive symptoms. Where the stone is proximal to the lingual nerve, i.e. at the hilum of the gland, stone retrieval via an intraoral approach should be avoided as there is a high risk of damage to the lingual nerve during exploration in the posterior lingual gutter. Treatment is by simultaneous submandibular gland excision and removal of the stone and ligation of the submandibular duct under direct vision. The retrieval of stone via an endoscopic approach, and/or removal by lithotripsy is gaining favour in some centres, but specialist equipment including a sialadenoscope is required.

Other causes of submandibular duct obstruction include external pressure, particularly trauma to the floor of the mouth from an overextended flange on a lower denture which impinges on the sublingual papilla causing inflammation and subsequent stricture.

Submandibular gland excision

Submandibular gland excision is indicated for:

- sialadenitis
- salivary tumours.

Excision of the submandibular gland involves four distinct phases.

Incision and exposure of gland

Surgery is usually performed under endotracheal general anaesthesia with moderate neck extension and the chin rotated to the opposite side. The incision should be marked at least 3–4 cm below the lower border of the mandible to avoid damage to the marginal mandibular branch of the facial nerve (Figure 50.12a). The incision should be sited within the nearest skin crease and should be no more than 6 cm long. Infiltration with lidocaine with adrenaline is optional. Sharp dissection is performed down to the platysma muscle, which should be clearly identified to facilitate later closure (Figure 50.12b). The muscle is incised and then retracted. The underlying investing layer of deep cervical fascia is then divided, and the marginal mandibular branch of the facial nerve that normally runs on the deep surface of the platysma muscle is preserved. Posteriorly, the incision approaches the angular tract where the deep cervical fascia splits to form the investing layer around the sternomastoid muscle. Superficial veins, including the anterior facial vein, require ligation.

Gland mobilisation

Deepening the incision divides the submandibular gland capsule. In inflammatory conditions, the submandibular gland is excised by intracapsular dissection, mobilising the gland by sharp dissection. For tumours of the submandibular gland, extracapsular dissection by suprahyoid neck dissection is performed.

The superficial lobe of the submandibular gland is first mobilised by retracting superiorly with an Allis forceps. As dissection proceeds, the posterior belly and anterior belly of the digastric muscle are identified. Dissection posteriorly identifies the facial artery (Figure 50.13), which is divided to facilitate further mobilisation. The course of the facial artery is variable, sometimes penetrating the gland emerging on the upper border, and...
sometimes lying in a groove on the deeper aspect of the gland. The gland is further mobilised by blunt and sharp dissection. A number of small arteries and veins are encountered, which require control with bipolar diathermy.

Dissection of the deep lobe and identification of the lingual nerve
An important landmark in submandibular gland dissection is the posterior border of the mylohyoid muscle. Once identified, it can be retracted forwards to reveal the deep lobe of the gland. Several veins are usually encountered, which need to be controlled with diathermy. The gland is then retracted inferiorly, invariably attached to the lingual nerve through parasympathetic secretor motor fibres. In the presence of chronic infection and subsequent fibrosis, identification of the lingual nerve on the deep aspect of the gland is sometimes difficult. It is imperative that the lingual nerve is formally identified prior to division of the parasympathetic fibres. The gland is then pedicled entirely on the submandibular duct, which, once identified, is ligated. The gland is delivered and sent for histological examination. The hypoglossal nerves lie deep to the submandibular capsule and should not be damaged during intracapsular dissection (Figure 50.14).

Three cranial nerves are at risk during removal of the submandibular gland:
1. the marginal mandibular branch of the facial nerve
2. the lingual nerve
3. the hypoglossal nerve.

An adequate incision coupled with meticulous haemostasis allows the surgeon to identify these important structures during surgery.

Wound closure
Haemostasis is confirmed and a vacuum suction drain inserted. The wound is closed using a continuous resorbable suture to the platysma muscle, as the platysma muscle has a direct contribution to the depressor activity of the corner of the mouth. The skin may be closed with a subcuticular non-resorbable suture, removed 7 days after surgery. The drain remains for 24 hours.

Complications of submandibular gland excision
Complications are:
- haematoma
- wound infection
- marginal mandibular nerve injury
- lingual nerve injury
- hypoglossal nerve injury
- transection of the nerve to the mylohyoid muscle producing submental skin anaesthesia.

Tumours of the submandibular gland
Tumours of the submandibular gland are uncommon and usually present as a slow-growing, painless swelling within the submandibular triangle (Figure 50.15). Only 50 per cent of submandibular gland tumours are benign, in contrast to 80–90 per cent of parotid gland tumours (Table 50.1). In many circumstances, the swelling cannot, on clinical examination, be differentiated from submandibular lymphadenopathy. Most salivary neoplasms, even malignant tumours, are often slow-growing, painless swellings. Unfortunately, pain is not a reliable indication of malignancy as benign tumours often present with pain in the affected gland, presumably due to capsular distension or outflow obstruction.

Clinical features of malignant salivary tumours
These include:
- facial nerve weakness
- rapid enlargement of the swelling
- induration and/or ulceration of the overlying skin
- cervical node enlargement.

Figure 50.15 Benign tumour of the right submandibular gland.
Investigation

Computed tomography (CT) and MRI scanning are the most helpful techniques for imaging tumours arising in the major salivary glands. The tumour is intrinsic to the gland, and its border can be imaged to highlight whether it is circumscribed and probably benign, or diffuse, invasive and probably malignant. The scan will highlight the relationship of the tumour to other anatomical structures, which is helpful in planning surgery.

Open surgical biopsy is contraindicated as this may seed the tumour into surrounding tissues, making it impossible to eradicate microscopic deposits of tumour cells.

Fine-needle aspiration biopsy is a safe alternative to open biopsy. There is evidence to suggest that, provided the needle gauge does not exceed 18G, there is no risk of seeding viable tumour cells. The role of fine-needle aspiration biopsy is, however, controversial as it rarely alters surgical management.

Management of submandibular gland tumours

As with all salivary gland tumours, surgical excision with a cuff of normal tissue is the goal. When the tumour is small and entirely encased within the submandibular gland parenchyma, straightforward intracapsular submandibular gland excision is appropriate. However, benign tumours that are large and project beyond the submandibular gland are best served by suprahyoid neck dissection, preserving the marginal mandibular branch of the facial nerve, lingual nerve and hypoglossal nerves. This entails a full clearance of the submandibular triangle, involving the development of a subplatysmal skin flap (Figure 50.16a–e), dissection of periosteum along the lower border and inner aspect of the mandible, and delivery of the gland and tumour with a cuff of normal tissue. In cases of overt malignancy, modified neck dissection or radical neck dissection is appropriate. This may necessitate sacrifice of the lingual and hypoglossal nerves if the tumour is adherent to the deep bed of the gland (Figure 50.17a–d).

THE PAROTID GLAND

Anatomy

The parotid gland lies in a recess bounded by the ramus of the mandible, the base of the skull and the mastoid process. It lies on the carotid sheath and the XIth and XIIth cranial nerves and extends forward over the masseter muscle. The gland is enclosed in a sheath of dense deep cervical fascia. Its upper pole extends just below the zygoma and its lower pole into the neck.

Several important structures run through the parotid gland. These include:

- branches of the facial nerve;
- the terminal branch of the external carotid artery that divides into the maxillary artery and the superficial temporal artery;

![Figure 50.16](image_url) (a) Landmarks and incision for suprahyoid neck dissection to remove a large pleomorphic adenoma of the submandibular gland. (b) Skin flap raised at the subplatysmal level. (c) Mobilisation of the contents of the anterior triangle of the neck along the anterior border of the sternomastoid. (d) Suprahyoid neck dissection completed, revealing digastric tendon (yellow arrow) and great vessels (black arrow). (e) Specimen revealing tumour with a cuff of normal tissue with artery forceps attached to the submandibular duct.
the retromandibular vein;
• intraparotid lymph nodes.

The gland is arbitrarily divided into deep and superficial lobes, separated by the facial nerve. Eighty per cent of the parotid gland lies superficial and 20 per cent deep to the nerve. An accessory lobe is occasionally present lying anterior to the superficial lobe on the masseter muscle.

**Developmental disorders**

Developmental disorders such as agenesis, duct atresia and congenital fistula are extremely rare.

**Inflammatory disorders**

**Viral infections**

Mumps is the most common cause of acute painful parotid swelling and predominantly affects children. It is spread via airborne droplets of infected saliva. The disease starts with a prodromal period of 1–2 days, during which the patient experiences fever, nausea and headache. This is followed by pain and swelling in one or both parotid glands. Parotid pain can be very severe and exacerbated by eating and drinking. Symptoms resolve within 5–10 days. The diagnosis is based on history and clinical examination; a recent contact with an infected patient with a painful parotid swelling is often sufficient to lead to a diagnosis. Atypical viral parotitis does occur and may present with predominantly unilateral swelling or even submandibular involvement. A single episode of infection confers lifelong immunity. Treatment of mumps is symptomatic with regular paracetamol and adequate oral fluid intake. Complications of orchitis, oophoritis, pancreatitis, sensorineural deafness and meningoencephalitis are rare, but are more likely to occur in adults.

Other viral agents that produce parotitis include Coxsackie A and B, parainfluenza 1 and 3, Echo and lymphocytic choriomeningitis.

**Bacterial infections**

Acute ascending bacterial sialadenitis is historically described in dehydrated elderly patients following major surgery. Reduced salivary flow secondary to dehydration results in ascending infection via the parotid duct into the parotid parenchyma. Acute bacterial parotitis is now more common with no obvious precipitating factors. The patient presents with a tender, painful parotid swelling that arises over several hours (Figure 50.18). There is generalised malaise, pyrexia and occasional cervical lymphadenopathy. The pain is exacerbated by eating or drinking. The parotid swelling may be diffuse, but often localises to the lower pole of the gland. Intraoral examination may reveal pus exuding from the parotid gland papilla. The infecting organism is usually *Staphylococcus aureus* or *Streptococcus viridans*, and treatment is with appropriate intravenous antibiotics. If the gland becomes fluctuant, ultrasound may identify abscess formation within the gland that may require aspiration with a large-bore needle or formal drainage under general anaesthesia. In the latter procedure, the skin incision should be made low to avoid the great vessels of the neck (arrow).

![Figure 50.17](a) Landmarks and incision for radical neck dissection for carcinoma of the left submandibular gland. (b) Computed tomographic scan revealing a large tumour of the left submandibular gland with central necrosis (arrow). (c) Skin flap developed for radical neck dissection. (d) Completion of radical neck dissection revealing the great vessels of the neck (arrow).
damage to the lower branch of the facial nerve. Blunt dissection using sinus forceps is preferred, and the cavity is opened to facilitate drainage. A drain is inserted and left in situ for 24–72 hours. Sialography is contraindicated during acute infection. Chronic bacterial sialadenitis is rare in the parotid gland.

**Recurrent parotitis of childhood**

Recurrent parotitis of childhood is a distinct clinical entity of unknown aetiology and variable prognosis. It is characterized by rapid swelling of one or both parotid glands, in which the symptoms are made worse by chewing and eating. Systemic upset with fever and malaise is variable. The symptoms usually last from 3 to 7 days, and are then followed by a quiescent period of weeks to several months. Children usually present between the ages of three and six years, although symptoms have been reported in infants as young as four months. The diagnosis is based on the characteristic history and can be confirmed by sialography. This shows a characteristic punctate sialectasis likened to a ‘snowstorm’ (Figure 50.19). The condition usually responds to short courses of antibiotics although, if recurrence is frequent, prophylactic low-dose antibiotics may be required for several months or even years. Few children require formal parotidectomy. However, if the onset of symptoms is late, e.g. adolescence/early adulthood, fewer patients respond to conservative measures and may require total conservative parotidectomy.

**Human immunodeficiency virus-associated sialadenitis**

Chronic parotitis in children is pathognomonic of human immunodeficiency virus (HIV) infection. The presentation of HIV-associated sialadenitis is very similar to classical Sjögren’s syndrome in adulthood. Although HIV-associated sialadenitis and Sjögren’s syndrome are histologically similar, the former condition is usually associated with a negative autoimmune screen. Other presentations of salivary gland disease in HIV-positive patients include multiple parotid cysts, which cause gross parotid swelling and facial disfigurement. CT and MRI demonstrate the characteristic ‘Swiss cheese’ appearance of multiple large cystic lesions (Figure 50.20). The swollen glands are usually painless and may regress on the institution of antiviral therapy. Parotidectomy, however, may be indicated to improve the appearance.

**Obstructive parotitis**

There are several causes of obstructive parotitis, which produces intermittent painful swelling of the parotid gland, particularly at mealtimes.

**Papillary obstruction**

Obstructive parotitis is less common than obstructive submandibular sialadenitis but, nevertheless, can be caused by trauma to the parotid papilla through either an overextended upper denture flange or a fractured upper molar tooth. The subsequent inflammation and oedema obstructs salivary flow, particularly at mealtimes. The patient usually experiences rapid onset pain and swelling at mealtimes. If left untreated, progressive scarring and fibrosis in and around the parotid duct papilla will produce a permanent stenosis. Symptoms are unlikely to resolve unless a papillotomy is performed. This is a simple procedure performed under either local or general anaesthesia. The parotid duct is

---

**Figure 50.20** Magnetic resonance imaging scan. Giant bilateral parotid cysts in human immunodeficiency virus infection.
cannulated, and the distal parotid duct is laid open by incising longitudinally down onto the probe allowing free drainage of saliva.

**Stone formation**

Sialolithiasis is less common in the parotid gland (20 per cent) than in the submandibular gland (80 per cent). Parotid duct stones are usually radiolucent and rarely visible on plain radiography. They are frequently located at the confluence of the collecting ducts or located in the distal aspect of the parotid duct adjacent to the parotid papilla. Parotid gland sialography is usually required to identify the stone. A stone located in the collecting duct or within the gland may be managed by either endoscopic retrieval, lithotripsy or, least likely, surgical removal via a parotidectomy approach.

**Tumours of the parotid gland**

The parotid gland is the most common site for salivary tumours. Most tumours arise in the superficial lobe and present as slow-growing, painless swellings below the ear (Figure 50.21a), in front of the ear (Figure 50.21b) or in the upper aspect of the neck. Less commonly, tumours may arise from the accessory lobe and present as persistent swellings within the cheek. Rarely, tumours may arise from the deep lobe of the gland and present as parapharyngeal masses (Figure 50.21c and d). Symptoms include difficulty in swallowing and snoring. Clinical examination reveals a diffuse firm swelling in the soft palate and tonsil.

Some 80–90 per cent of tumours of the parotid gland are benign, the most common being pleomorphic adenoma (Table 50.2).

Malignant salivary gland tumours are divided into two distinct subgroups:

1. **Low-grade malignant tumours**, e.g. acinic cell carcinoma, are indistinguishable on clinical examination from benign neoplasms.
2. **High-grade malignant tumours** usually present as rapidly growing, often painless swellings in and around the parotid gland. The tumour presents as either a discrete mass with infiltration into the overlying skin (Figure 50.22) or a diffuse but hard swelling of the gland with no discrete mass. Presentation with advanced disease is common, and cervical lymph node metastases may be present.

**Investigations**

CT and MRI scanning are the most useful imaging techniques (Figure 50.23a and b). Fine-needle aspiration biopsy may aid in obtaining a preoperative diagnosis, but open surgical biopsy...
The parotid gland is contraindicated unless malignancy is suspected, and preoperative histological diagnosis is required as a prelude to radical parotidectomy.

All tumours of the superficial lobe of the parotid gland should be managed by superficial parotidectomy. There is no role for enucleation even if a benign lesion is suspected. The aim of superficial parotidectomy is to remove the tumour with a cuff of normal surrounding tissue. The term ‘suprafacial parotidectomy’ has been used as not all branches of the facial nerve need be formally dissected, particularly if a tumour lies in the lower pole of the parotid gland.

**Parotidectomy**

**Superficial parotidectomy**

Superficial parotidectomy is the most common procedure for parotid gland pathology. Surgery is performed under endotracheal general anaesthesia, which may or may not be accompanied by hypotensive anaesthesia to facilitate dissection, improve the visual surgical field and reduce blood loss. The operation has several distinct phases.

**Incision and development of a skin flap**

The most commonly used incision is the ‘lazy S’ pre-auricular–mastoid–cervical (Figure 50.24a). The incision is marked out and marked at three points along its length to facilitate closure. Infiltration with local anaesthetic and adrenaline is optional, but does aid in the development of the skin flap, improves visibility and reduces blood loss in the initial phase. The skin flap is developed in an anterior direction by either scalpel or scissors dissection. The plane of dissection is well below the hair follicles, just above the parotid fascia. The skin flap is developed forwards to the anterior border of the sterno-mastoid muscle.

**Mobilisation of the gland**

This phase of the dissection aims to free the posterior margin of the gland, allowing identification of the facial nerve. Clips are applied along the fascia overlying the sterno-mastoid muscle, with the assistant applying traction anteriorly. By sharp dissection along the anterior border of the sterno-mastoid, an avascular plane is developed (Figure 50.24b), which requires elective transection of the great auricular nerve. At the lower end of the dissection, the external jugular vein is often encountered and ligated. The gland is gradually mobilised by sharp dissection up to and on to the anterior aspect of the mastoid process, identifying the posterior belly of the digastric muscle.

A second avascular plane is developed along the anterior border of the cartilaginous and bony external auditory meatus immediately anterior to the tragus. The two avascular planes are then connected by blunt and sharp dissection. By developing two broad avascular planes, identification of the facial nerve trunk is facilitated (Figure 50.24c). It is best achieved by scissors dissection in the plane of the facial nerve trunk. Use of a facial nerve stimulator is optional. Landmarks commonly used to aid identification of the trunk of the facial nerve are:

HEAD AND NECK
DISORDERS OF THE SALIVARY GLANDS

manner, usually beginning with the upper division. The upper division of the facial nerve are followed to the periphery in a sequential manner. Once the facial nerve trunk is identified, gentle traction anteriorly facilitates further mobilisation. Control of haemorrhage at this stage is vital as bleeding, no matter how minor, significantly impedes visibility for the surgeon. Haemostasis can be achieved with bipolar diathermy, although caution is necessary, particularly when the facial nerve is approached. Damage to the stylo-mastoid artery, which lies immediately lateral to the nerve, can result in troublesome bleeding immediately prior to identification. Pledget swabs soaked in adrenaline are sometimes helpful in reducing the oozing associated with this phase of the dissection.

Location of the facial nerve trunk
Once the facial nerve trunk is identified, gentle traction anteriorly facilitates further mobilisation. Control of haemorrhage at this stage is vital as bleeding, no matter how minor, significantly impedes visibility for the surgeon. Haemostasis can be achieved with bipolar diathermy, although caution is necessary, particularly when the facial nerve is approached. Damage to the stylo-mastoid artery, which lies immediately lateral to the nerve, can result in troublesome bleeding immediately prior to identification. Pledget swabs soaked in adrenaline are sometimes helpful in reducing the oozing associated with this phase of the dissection.

Dissection of the gland off the facial nerve
Once the facial nerve trunk is identified, further exposure of the branch of the facial nerve can be achieved by scissors dissection in the perineural plane immediately above the nerve. The tunnel thus created is then laid open, and divisions and branches of the facial nerve are followed to the periphery in a sequential manner, usually beginning with the upper division. The upper division divides into a temporal and a zygomatic branch, and the lower division into mandibular and cervical branches. In this way, the superficial lobe and its associated tumour are mobilised in a superior to inferior direction (Figure 50.24d). The upper division of the nerve is frequently tortuous in its course and can be damaged unless great care is taken during perineural dissection. It is often not necessary to dissect all branches of the facial nerve completely, as adequate tumour clearance can be achieved with a more conservative resection of the superficial lobe. When a branch of the facial nerve is adherent to the tumour or running through the tumour, it may require elective division. With the exception of the buccal branch, the transected nerve should be repaired immediately with a cable graft, harvested from the great auricular nerve.

Closure
The patient is placed into a Trendelenburg position to identify any residual bleeding vessels. A suction drain is applied for a period of 24–48 hours, and the wound closed in layers (Figure 50.24f).

Radical parotidectomy
Radical parotidectomy is performed for patients in whom there is clear histological evidence of a high-grade malignant tumour, e.g. squamous cell carcinoma. Low-grade malignant tumours can usually be managed by standard superficial parotidectomy. Radical parotidectomy involves removal of all parotid gland tissue and elective sectioning of the facial nerve, usually through the main trunk (Figure 50.25a–f). The surgery inevitably removes the ipsilateral masseter muscle and may also require simultaneous neck dissection, particularly where there is clinical, radiological and cytological evidence of lymph node metastases in the ipsilateral neck.

Complications of parotid gland surgery
Complications of parotid gland surgery include:

- haematoma formation;
- infection;
- temporary facial nerve weakness;
- transection of the facial nerve and permanent facial weakness;
- sialocele;
- facial numbness;
- permanent numbness of the ear lobe associated with great auricular nerve transection;
- Frey’s syndrome.

Frey’s syndrome
Frey’s syndrome (gustatory sweating) is now considered an inevitable consequence of parotidectomy, unless preventative measures are taken (see below). It results from damage to the autonomic innervation of the salivary gland with inappropriate regeneration of parasympathetic nerve fibres that stimulate the sweat glands of the overlying skin. The clinical features include sweating and erythema over the region of surgical excision of the parotid gland as a consequence of autonomic stimulation of salivation by the smell or taste of food. The symptoms are entirely variable and are clinically demonstrated by a starch iodine test. This involves painting the affected area with iodine, which is allowed to dry before applying dry starch, which turns blue on exposure to iodine in the presence of sweat. Sweating
The parotid gland

The parotid gland is stimulated by salivary stimulation. The management of Frey's syndrome involves the prevention as well as the management of established symptoms.

**Prevention**

There are a number of techniques described to prevent Frey's syndrome following parotidectomy. These include:
- sternomastoid muscle flap;
- temporalis fascial flap;
- insertion of artificial membranes between the skin and the parotid bed.

All these methods place a barrier between the skin and the parotid bed to minimise inappropriate regeneration of autonomic nerve fibres.

**Management of established Frey's syndrome**

Methods of managing Frey's syndrome include:
- antiperspirants, usually containing aluminium chloride;
- denervation by tympanic neurectomy;
- the injection of botulinum toxin into the affected skin.

The last is the most effective and can be performed as an outpatient.

**Granulomatous sialadenitis**

This is a group of rare conditions that affect the salivary glands producing a variety of signs and symptoms, particularly painless swellings of the parotid and/or submandibular glands. Systemic upset is variable. These include the following.

**Mycobacterial infection**

Tuberculosis and non-tuberculous sialadenitis typically present as a tumour-like swelling of the salivary gland. There is little pain and no fever. Preoperative investigations may be of some help, and the diagnosis is only confirmed when the swelling has...
been excised by either submandibular gland excision or formal parotidectomy.

**Sarcoidosis**

Sarcoidosis can affect the salivary tissue and presents with persistent salivary gland swelling that may be associated with xerostomia. Occasionally, the patient will present with a localised tumour-like swelling in one salivary gland, more commonly the parotid – the so-called sarcoid pseudotumour. In such circumstances, the diagnosis is only likely to be made following surgical excision for a presumed neoplasm.

Heerfordt’s syndrome is sarcoidosis that involves parotid swelling, anterior uveitis, facial palsy and fever.

**Other**

These include cat scratch disease, toxoplasmosis, syphilis, deep mycoses and Wegener’s granulomatosis, allergic sialadenitis and sialadenitis associated with radiotherapy of the head and neck.

---

Christian Frederick Heerfordt, 1871–1953, a Danish ophthalmologist, described this syndrome in 1909.

**Tumour-like lesions**

There is a group of pathological conditions that affect the salivary glands which do not fall into any particular classification or category and are often difficult to diagnose. These include such conditions as sialadenosis, adenomatoid hyperplasia and multifocal monomorphic adenomatosis.

**Sialadenosis**

Sialadenosis (sialosis) is used to describe non-inflammatory swelling particularly affecting the parotid gland. It is usually occurs in association with a variety of conditions including diabetes mellitus, alcoholism, other endocrine diseases, pregnancy, drugs, bulimia and other eating disorders, and idiopathic diseases.

Most patients present between 40 and 70 years of age, and the salivary swellings are soft and often symmetrical (Figure 50.26). When the parotid glands are affected, patients may complain of...
a hamster-like appearance. Drug-induced sialosis is particularly common with sympathomimetic drugs. In many patients, no underlying disorder can be identified. Severe and prolonged malnutrition, as seen in eating disorders, produces sialadenosis by a process of glandular atrophy and fatty replacement. The pathological mechanism of sialadenosis can be associated with a process of neuropathy, which interferes with salivary gland function and subsequent acinar cell atrophy. This may be the case in diabetes mellitus, where autonomic neuropathy is a recognised complication as well as drug-induced sialosis.

The treatment of sialosis is unsatisfactory, but treatment is aimed at the correction of the underlying disorder. Drug-associated sialadenosis may regress when the drug responsible is withdrawn.

**Degenerative conditions**

**Sjögren’s syndrome**

Sjögren’s syndrome is an autoimmune condition causing progressive destruction of salivary and lacrimal glands. Primary Sjögren’s syndrome differs from secondary Sjögren’s syndrome in that xerostomia and keratoconjunctivitis sicca occur without the associated connective tissue disorder. However, the symptoms are often more severe, and the incidence of lymphomatous transformation (see below) in the primary group is higher than that in the secondary group (Table 50.3).

</tbody>
</table>

Females are affected more than males in the ratio 10:1. Occasionally, there is enlargement of the salivary glands, more commonly the parotid rather than the submandibular glands. The glands are occasionally painful, and the patient sometimes develops a bacterial sialadenitis due to ascending infection from the associated xerostomia.

The characteristic pathological feature of Sjögren’s syndrome is the progressive lymphocytic infiltration, acinar cell destruction and proliferation of duct epithelium in all salivary and lacrimal gland tissue. The diagnosis is based on the history as no single laboratory investigation is pathognomonic of either primary or secondary Sjögren’s syndrome (Figure 50.27).

**Complications of Sjögren’s syndrome**

There is an increased incidence of developing lymphoma (most commonly monocytoid B-cell lymphoma) in patients with Sjögren’s syndrome. The risk is highest within the primary group, and the onset of lymphoma is heralded by immunological change within the blood.
Benign lymphoepithelial lesion
The use of the word 'benign' to describe this lesion is misleading because 20 per cent of patients with benign lymphoepithelial lesion ultimately develop lymphoma. It is not possible to distinguish on histological grounds benign lymphoepithelial lesion from Sjögren’s syndrome. Both are characterised by lymphocytic infiltration, acinar atrophy and ductal epithelial proliferation. Clinically, benign lymphoepithelial lesion presents as a diffuse swelling of the parotid gland. The swelling is firm, often painful and, in 20 per cent of patients, the presentation is bilateral. Most patients are female and over 50 years of age. Parotidectomy is often undertaken to establish a diagnosis. Prolonged follow up is essential.

Xerostomia
Xerostomia is a common symptom in many aspects of medical practice. Normal salivary flows decrease with age in both men and women, although many patients with xerostomia are post-menopausal women who also complain of a burning tongue or mouth. Common causes of xerostomia are:
- chronic anxiety states and depression;
- dehydration;
- anticholinergic drugs, especially antidepressants;
- salivary gland disorders – Sjögren’s syndrome. Ascending parotitis is an occasional complication of xerostomia and is managed with antibiotics and increased fluid intake;
- radiotherapy to the head and neck.

Sialorrhoea
Certain drugs and oral infection produce a transient increase in salivary flow rates. In healthy individuals, excess salivation is rarely a symptom as excess saliva is swallowed spontaneously. Uncontrolled drooling is usually seen in the presence of normal salivary production. It is seen in children with mental and physical handicap, notably cerebral palsy.

Management
Uncontrollable drooling is managed surgically, and many operations are available. Surgical options include:
- bilateral submandibular duct repositioning and simultaneous sublingual gland excision;
- bilateral submandibular gland excision;
- transposition of the parotid ducts and simultaneous submandibular gland excision.

Most resting salivary gland flow arises from the submandibular glands, and surgery should be focused on this gland to control uncontrolled sialorrhoea.

Breast and endocrine

51 The thyroid and parathyroid glands 741
52 The adrenal glands and other abdominal endocrine disorders 778
53 The breast 798
The thyroglossal duct develops from the median bud of the pharynx. The foramen caecum at the base of the tongue is the vestigial remnant of the duct. This initially hollow structure migrates caudally and passes in close continuity with, and sometimes through, the developing hyoid cartilage. The parathyroid glands develop from the third and fourth pharyngeal pouches (Figure 51.1). The thymus also develops from the third pouch. As it descends it takes the associated parathyroid gland with it which explains why the inferior parathyroid which arises from the third pharyngeal pouch normally lies inferior to the superior gland. However, the inferior parathyroid may be found anywhere along this line of descent. The developing thyroid lobes amalgamate with the structures that arise in the fourth pharyngeal pouch, i.e. the superior parathyroid gland and the ultimobranchial body. Parafollicular cells (C cells) from the neural crest reach the thyroid via the ultimobranchial body.

SURGICAL ANATOMY

The normal thyroid gland weighs 20–25 g. The functioning unit is the lobule supplied by a single arteriole and consists of 24–40 follicles lined with cuboidal epithelium. The follicle contains colloid in which thyroglobulin is stored (Figure 51.2). The arterial supply is rich, and extensive anastomoses occur between the main thyroid arteries and branches of the tracheal and oesophageal arteries (Figure 51.3). There is an extensive lymphatic network within the gland. Although some lymph channels pass directly to the deep cervical nodes, the subcapsular plexus drains principally to the central compartment juxtathyroid – ‘Delphian’ – and paratracheal nodes and nodes on the superior and inferior

Figure 51.1 Embryology of thyroid and parathyroid. thyroid veins (level VI), and from there to the deep cervical (levels II, III, IV and V) and mediastinal groups of nodes (level VII) (Figure 51.4).

The normal parathyroid gland weighs up to 50 mg with a characteristic orange/brown colour and mobility within the surrounding fat and thymic tissue. Most adults have four parathyroid glands but supernumerary glands occur and nests of parathyroid tissue are commonly found in the thymus. The superior parathyroid is more consistent in position than the inferior. The superior gland is commonly found in fat above the inferior thyroid artery and close to the cricothyroid articulation. It should be noted that the anatomical and radiological site, usually described as above the artery and posterior to the recurrent laryngeal nerve (RLN), is different from the surgical anatomy when the thyroid lobe is mobilised and rotated anteriorly. When the superior gland enlarges it tends to pass behind the inferior thyroid artery and descend inferiorly behind the oesophagus. The inferior parathyroid gland is usually found under the capsule of the upper horn of the thymus or on the inferior pole of the thyroid lobe. A maldescended gland, however, can be found anywhere along the line of descent, virtually from the base of the skull to the aortopulmonary window (Figure 51.5) (Summary box 51.1).

(see Figure 51.52).
PHYSIOLOGY

Thyroxine
The hormones tri-iodothyronine ($T_3$) and l-thyroxine ($T_4$) (extracted by EC Kendall in 1915) are bound to thyroglobulin within the colloid. Synthesis within the thyroglobulin complex is controlled by several enzymes, in distinct steps:

- trapping of inorganic iodide from the blood;
- oxidation of iodide to iodine;
- binding of iodine with tyrosine to form iodotyrosines;
- coupling of moniodotyrosines and di-iodotyrosines to form $T_3$ and $T_4$.

When hormones are required, the complex is resorbed into the cell and thyroglobulin is broken down. $T_4$ and $T_3$ are liberated and enter the blood, where they are bound to serum proteins: albumin, thyroxine-binding globulin (TBG) and thyroxine-binding prealbumin (TBPA). The amount of hormone that remains free in the serum is biologically active.

The metabolic effects of the thyroid hormones are due to unbound free $T_3$ and $T_4$ (0.03 and 0.3 per cent of the total circulating hormones, respectively). $T_4$ is the more important physiological hormone and is also produced in the periphery by conversion from $T_4$. $T_3$ is quick acting (within a few hours), whereas $T_4$ acts more slowly (4–14 days).

Parathormone
The parathyroid glands secrete the 84-amino acid peptide parathyroid hormone (PTH), which controls the level of serum calcium in extracellular fluid. PTH is released in response to a low serum calcium or high serum magnesium level. PTH activates osteoclasts to resorb bone, and increases calcium reabsorption from urine and renal activation of vitamin D with subsequent increased gut absorption of calcium. Renal excretion of phosphate is also increased.

Calcitonin
The parafollicular C cells of the thyroid are of neuroendocrine origin and arrive in the thyroid via the ultimobranchial body (Figure 51.1). They produce calcitonin which is a serum marker for recurrence of medullary thyroid cancer.

The pituitary-thyroid axis
Synthesis and liberation of thyroid hormones from the thyroid is controlled by thyroid-stimulating hormone (TSH) from the anterior pituitary. Secretion of TSH depends upon the level of circulating thyroid hormones and is modified in a classic negative feedback manner. In hyperthyroidism, when hormone levels in the blood are high, TSH production is suppressed whereas in hypothyroidism it is stimulated. Regulation of TSH secretion also results from the action of thyrotrophin-releasing hormone (TRH) produced in the hypothalamus.

Thyroid-stimulating antibodies
A family of IgG immunoglobulins bind with TSH receptor sites (TRAbs) and activate TSH receptors on the follicular cell membrane. They have a more protracted action than TSH (16–24 versus 1.5–3 hours) and are responsible for virtually all cases of thyrotoxicosis not due to autonomous toxic nodules. Serum concentrations are very low but their measurement is not essential to make the diagnosis.

Therapeutic notes
$T_4$ is given once daily; an average replacement dose is 0.15 mg and a suppressive dose is 0.2 mg. $T_3$ is given three times daily, usually as a suppressive dose of 20 μg three times a day. Recombinant human TSH is now available and is used to maximise (radioactive) iodine uptake as an alternative to thyroid hormone withdrawal.

TESTS OF THYROID FUNCTION

There is a large variety of tests of thyroid function available to the endocrinologist; however, in a surgical setting investigations requested should be the minimum necessary to reach a diagnosis and formulate a management plan. Only a small number of parameters need to be measured as a routine, although this may require supplementation or to be repeated when inconclusive.

Serum thyroid hormones

Serum TSH
TSH levels can be measured accurately down to very low serum concentrations with an immunochemiluminometric assay. When the serum TSH level is in the normal range, it is redundant to measure the $T_3$ and $T_4$ levels. Interpretation of deranged TSH levels, however, depends on knowledge of the $T_4$ and $T_3$ values (Table 51.1). In the euthyroid state, $T_3$, $T_4$ and TSH levels will all be within the normal range. Florid thyroid failure results in depressed $T_4$ and $T_3$ levels, with gross elevation of the TSH. Incipient or developing thyroid failure is characterised by low normal values of the $T_3$ and $T_4$ and elevation of the TSH. In toxic states, the TSH level is suppressed and undetectable.

**Thyroxine (T₄) and tri-iodothyronine (T₃)**

These are transported in plasma bound to specific proteins (TBG). Only a small fraction of the total (0.03 per cent of T₄ and 0.3 per cent of T₃) is free and physiologically active. Assays of total hormone for both are now obsolete because of the confounding effect of circulating protein concentrations, influenced by the level of circulating oestrogen and nutritional state. Highly accurate radioimmunoassays of free T₃ and free T₄ are now routine. T₃ toxicity (with a normal T₄) is a distinct entity and may only be diagnosed by measuring the serum T₃, although a suppressed TSH level with a normal T₄ may suggest the diagnosis.

An appropriate combination to establish the functional thyroid status at initial assessment is serum TSH and assay of antithyroid antibodies supplemented by free T₄ and T₃ evaluation when TSH is abnormal.

**Thyroid autoantibodies**

Serum levels of antibodies against thyroid peroxidase (TPO) (previously referred to as thyroid microsomal antigen) and thyroglobulin are useful in determining the cause of thyroid dysfunction and swellings. Autoimmune thyroiditis may be associated with thyroid toxicity, failure or euthyroid goitre. Levels above 25 units/mL for TPO antibody and titres of greater than 1:100 for antithyroglobulin are considered significant, although a proportion of patients with histological evidence of lymphocytic (autoimmune) thyroiditis are seronegative. The presence of antithyroglobulin antibody interferes with assays of serum thyroglobulin with implications for follow up of thyroid cancers. TSH receptor antibodies (TSH-Rab or TRAB) are often present in Graves’ disease. They are largely produced within the thyroid itself (Summary box 51.2).

**Summary box 51.2**

**Thyroid investigations**

Essential
- Serum: TSH (T₃ and T₄ if abnormal); thyroid autoantibodies
- FNAC of palpable discrete swellings; ultrasound guidance may reduce the ‘Thy1’ rate

Optional
- Corrected serum calcium
- Serum calcitonin (cancerembryonic antigen may be used as an alternative screening test for medullary cancer)
- Imaging: chest radiograph and thoracic inlet if tracheal deviation/retrosternal goitre; ultrasound, CT and MRI scan for known cancer, some reoperations and some retrosternal goitres; isotope scan if discrete swelling and toxicity coexist

**Thyroid imaging**

**Chest and thoracic inlet x-rays**

Simple radiographs of the chest and thoracic inlet will rapidly and economically confirm the presence of significant retrosternal goitre and clinically important degrees of tracheal deviation and compression (Figure 51.6). Chest x-ray tends to underestimate the extent of retrosternal extensions. Pulmonary metastases may also be detected.

**Ultrasound scanning**

Ultrasound scanning gives good anatomical images of the thyroid and surrounding structures and while previously out of favour, high frequency ultrasound is now widely used (Figure 51.7). The drawback of ultrasound is that it may reveal thyroid swellings that are not clinically relevant and risks a cascade of unnecessary investigation, intervention and anxiety when used indiscriminately. However, in experienced hands, ultrasound can reduce the number of unsatisfactory aspiration cytology samples by permitting more targeted sampling, and is very reliable in the identification of nodes involved in thyroid cancer and the identification of larger parathyroid adenomas.
Computed tomography, magnetic resonance imaging and positron emission tomography scanning

Routine computed tomography (CT) and magnetic resonance imaging (MRI) of unexceptional thyroid swellings is not indicated and is reserved for the assessment of known malignancy, to assess the extent of retrosternal and occasionally recurrent goitres (Figure 51.8). Iodine containing contrast agents may interfere with subsequent radioactive iodine uptake used for diagnostic scanning or therapy. The appearance and reporting of a retrosternal goitre on CT can give a misleading impression of the operative difficulty in delivery through a neck incision.

Positron emission tomography (PET)/CT scanning has an occasional role in the management of patients with obscure recurrent thyroid cancer but increasingly identifies incidental thyroid cancers in patients undergoing this investigation for other malignancies.

Isotope scanning

The uptake by the thyroid of a low dose of either radiolabelled iodine ($^{123}$I) or the cheaper technetium ($^{99m}$Tc) will demonstrate the distribution of activity in the whole gland (Figure 51.9). Routine isotope scanning is unnecessary and inappropriate for distinguishing benign from malignant lesions because the majority (80 per cent) of ‘cold’ swellings are benign and some (5 per cent) functioning or ‘warm’ swellings will be malignant. Its principal value is in the toxic patient with a nodule or nodularity of the thyroid. Localisation of overactivity in the gland will differentiate between a toxic nodule with suppression of the remainder of the gland, and toxic multinodular goitre with several areas of increased uptake with important implications for therapy.

Whole body scanning is used to demonstrate metastases, but the patient must have all normally functioning thyroid tissue ablated either by surgery or radiiodine before the scan is performed, because metastatic thyroid cancer tissue cannot compete with normal thyroid tissue in the uptake of iodine.

Fine-needle aspiration cytology

Fine-needle aspiration cytology (FNAC) is the investigation of choice in discrete thyroid swellings. FNAC has excellent patient compliance, is simple and quick to perform in the outpatient department and is readily repeated. This technique, developed in Scandinavia 40 years ago, is now routine throughout the world. FNAC results should be reported using standard terminology (Table 51.2). There is a trend to use ultrasound to guide the needle to achieve more accurate sampling and reduce the rate of unsatisfactory aspirates.

HYPOTHYROIDISM

A scheme for classifying hypothyroidism is given in Table 51.3.

Cretinism (fetal or infantile hypothyroidism)

Cretinism is the consequence of inadequate thyroid hormone production during fetal and neonatal development. ‘Endemic
cretinism’ is due to dietary iodine deficiency, whereas sporadic cases are due either to an inborn error of thyroid metabolism or complete or partial agenesis of the gland. A hoarse cry, macroglossia and umbilical hernia in a neonate with features of thyroid failure suggest the diagnosis. Immediate diagnosis and treatment with thyroxine within a few days of birth are essential to prevent in utero damage progressing and if physical and mental development is to be normal. In non-endemic areas and societies with iodised salt, sporadic hypothyroidism still occurs in 1 in 4000 live births, and biochemical screening of neonates for hypothyroidism using TSH and T4 assays on a heel-prick blood sample is widespread. Women taking antithyroid drugs may give birth to a hypothyroid infant and radioactive iodine must never be given to pregnant women.

**Adult hypothyroidism**

The term myxoedema should be reserved for severe thyroid failure and not applied to the much more common mild thyroid deficiency. The signs of thyroid deficiency are:

- Bradycardia
- Cold extremities
- Dry skin and hair
- Periorbital puffiness
- Hoarse voice
- Bradykinesis, slow movements
- Delayed relaxation phase of ankle jerks.

The symptoms are:

- Tiredness
- Mental lethargy
- Cold intolerance
- Weight gain
- Constipation
- Menstrual disturbance
- Carpal tunnel syndrome.

Comparison of the facial appearance with a previous photograph may be helpful. Delayed relaxation of the ankle jerk reflex is the most useful clinical sign in making the diagnosis.

**Thyroid function tests**

These show low T4 and T3 levels with a high TSH (except in the rare event of pituitary failure) (Table 51.1). High serum levels of TPO antibodies are characteristic of autoimmune disease.

**Treatment**

Oral thyroxine (0.10–0.20 mg) as a single daily dose is curative. Caution is required in the elderly or those with cardiac disease and the replacement dose is then commenced at 0.05 mg daily and increased cautiously. If a rapid response is required, triiodothyronine (20 µg three times a day) may be used.

**Myxoedema**

The signs and symptoms of hypothyroidism are accentuated. The facial appearance is typical, and there is often supraclevicular puffiness, a malar flush and a yellow tinge to the skin (Figure 51.10). Myxoedema coma, characterised by altered mental state, hypothermia and a precipitating medical condition, for example cardiac failure or infection, carries a high mortality. Treatment comprises thyroid replacement, either a bolus of 0.50 mg of T4 or 10 µg of T3, either i.v. or orally every 4–6 hours. If the body

---

**in utero** is Latin for ‘in the uterus’.

*Myxoedema* was first described in 1873 by Sir William Wither Gull, 1816–1890, physician, Guy’s Hospital, London, UK.
temperature is less than 30°C, the patient must be warmed slowly. Intravenous broad-spectrum antibiotics and hydrocortisone (in divided doses) are recommended.

Primary or atrophic myxoedema is considered to be an autoimmune disease similar to chronic lymphocytic (Hashimoto’s) thyroiditis (see below) but without goitre formation. Delay in diagnosis is common and the degree of hypothyroidism is usually more severe than in goitrous autoimmune thyroiditis.

**Dyshormonogenesis**

Genetic deficiencies in the enzymes controlling the synthesis of thyroid hormones account for a minority of cases of neonatal hypothyroidism and goitre. These are usually inherited in an autosomal recessive pattern and a family history is common. If the biochemical effect is of moderate degree, thyroid enlargement may be the only manifestation and dyshormonogenesis should be considered in young patients presenting with euthyroid goitre. The most common abnormalities affect TPO activity and thyroglobulin synthesis. A classic example of dyshormonogenesis due to TPO deficiency is Pendred syndrome, in which goitre is associated with severe sensorineural hearing impairment and abnormality of the bony labyrinth observed on CT examination of the temporal bones.

**THYROID ENLARGEMENT**

The normal thyroid gland is impalpable. The term goitre (from the Latin guttur = the throat) is used to describe generalised enlargement of the thyroid gland. A discrete swelling (nodule) in one lobe with no palpable abnormality elsewhere is termed an isolated (or solitary) swelling. Discrete swellings with evidence of abnormality elsewhere in the gland are termed dominant (Summary box 51.3).

**Simple goitre**

**Aetiology**

Simple goitre may develop as a result of stimulation of the thyroid gland by TSH, either as a result of inappropriate secretion from a microadenoma in the anterior pituitary (which is rare), or in response to a chronically low level of circulating thyroid hormones. The most important factor in endemic goitre is dietary deficiency of iodine (see below) but defective hormone synthesis probably accounts for many sporadic goitres (see below).

TSH is not the only stimulus to thyroid follicular cell proliferation and other growth factors, including immunoglobulins, exert an influence. The heterogeneous structural and functional response in the thyroid resulting in characteristic nodularity may
be due to the presence of clones of cells particularly sensitive to growth stimulation.

Iodine deficiency

The daily requirement of iodine is about 0.1–0.15 mg. In nearly all districts where simple goitre is endemic, there is a very low iodide content in the water and food. Endemic areas are in mountain ranges, such as the Rockies, Alps, Andes and Himalayas, and in the UK, areas of Derbyshire and Yorkshire. Endemic goitre is also found in lowland areas where the soil lacks iodide or the water supply comes from distant mountain ranges, e.g. the Great Lakes of North America, the plains of Lombardy, the Struma valley, the Nile valley and the Congo. Calcium is also goitrogenic and goitre is common in low iodine areas on chalk or limestone, for example Derbyshire and Southern Ireland. Although iodides in food and water may be adequate, failure of intestinal absorption may produce iodine deficiency.

Dyshormonogenesis

Enzyme deficiencies of varying severity may be responsible for many sporadic goitres, i.e. in non-endemic areas (Figure 51.11). There is often a family history, suggesting a genetic defect. Environmental factors may compensate in areas of high iodine intake, e.g. goitre is almost unknown in Iceland where the fish diet is rich in iodine. Similarly, a low intake of iodine encourages goitre formation in those with a metabolic predisposition.

Goitrogens

Well-known goitrogens are the vegetables of the brassica family (cabbage, kale and rape), which contain thiocyanate, drugs such as para-aminosalicylic acid (PAS) and, of course, the antithyroid drugs. Thiocyanates and perchlorates interfere with iodide trapping; carbimazole and thioracil compounds interfere with the oxidation of iodide and the binding of iodine to tyrosine.

Surprisingly enough, iodides in large quantities are goitrogenic because they inhibit the organic binding of iodine and produce an iodide goitre. Excessive iodine intake may be associated with an increased incidence of autoimmune thyroid disease.

**The natural history of simple goitre**

Stages in goitre formation are:

- Persistent growth stimulation causes diffuse hyperplasia; all lobules are composed of active follicles and iodine uptake is uniform. This is a diffuse hyperplastic goitre, which may persist for a long time but is reversible if stimulation ceases.
- Later, as a result of fluctuating stimulation, a mixed pattern develops with areas of active lobules and areas of inactive lobules.
- Active lobules become more vascular and hyperplastic until haemorrhage occurs, causing central necrosis and leaving only a surrounding rind of active follicles.
- Necrotic lobules coalesce to form nodules filled either with iodine-free colloid or a mass of new but inactive follicles.
- Continual repetition of this process results in a nodular goitre. Most nodules are inactive, and active follicles are present only in the intermodal tissue.

**Diffuse hyperplastic goitre**

Diffuse hyperplasia corresponds to the first stages of the natural history. The goitre appears in childhood in endemic areas but, in sporadic cases, it usually occurs at puberty when metabolic demands are high. If TSH stimulation ceases, the goitre may regress, but tends to recur later at times of stress, such as pregnancy. The goitre is soft, diffuse and may become large enough to cause discomfort. A colloid goitre is a late stage of diffuse hyperplasia when TSH stimulation has fallen off and when many follicles are inactive and full of colloid (Figure 51.12).

**Nodular goitre**

Nodules are usually multiple, forming a multinodular goitre (Figure 51.13). Occasionally, only one macroscopic nodule is found, but microscopic changes will be present throughout the gland; this is one form of a clinically solitary nodule. Nodules may be colloid or cellular, and cystic degeneration and haemorrhage are common, as is subsequent calcification. Nodules appear early in endemic goitre and later (between 20 and 30 years) in sporadic goitre, although the patient may be unaware of the goitre until his or her late 40s or 50s. All types of simple goitre are more common in the female than in the male owing to the presence of oestrogen receptors in thyroid tissue.

**Diagnosis**

Diagnosis is usually straightforward. The patient is euthyroid, the nodules are palpable and often visible; they are smooth, usually firm and not hard, and the goitre is painless and moves freely on swallowing. Hardness and irregularity, due to calcification, may simulate carcinoma. A painful nodule, sudden appearance, or rapid enlargement of a nodule raises suspicion of carcinoma but is usually due to haemorrhage into a simple nodule. Differential diagnosis from autoimmune thyroiditis may be difficult and the two conditions frequently coexist.

**Investigations**

Thyroid function should be assessed to exclude mild hyperthyroidism, and the presence of circulating thyroid antibodies tested.
Thyroid enlargement

Sir Thomas Peel Dunhill, 1876–1957, surgeon, St Bartholomew’s Hospital, London, UK.

to differentiate from autoimmune thyroiditis. Plain radiographs of the chest and thoracic inlet will rapidly demonstrate clinically significant tracheal deviation or compression. Ultrasound and CT give more detailed images but rarely influence clinical management. FNAC is only required for a dominant swelling in a generalised goitre.

Complications

Tracheal obstruction may be due to gross lateral displacement or compression in a lateral or anteroposterior plane by retrosternal extension of the goitre (Figures 51.6 and 51.8). Acute respiratory obstruction may follow haemorrhage into a nodule impacted in the thoracic inlet.

Secondary thyrotoxicosis

Transient episodes of mild hyperthyroidism are common, occurring in up to 30 per cent of patients.

Carcinoma

An increased incidence of cancer (usually follicular) has been reported from endemic areas. Dominant or rapidly growing nodules in long-standing goitres should always be subjected to aspiration cytology.

Prevention and treatment of simple goitre

In endemic areas, e.g. Switzerland, parts of the USA and Argentina, the incidence of goitre has been strikingly reduced by the introduction of iodised salt.

In the early stages, a hyperplastic goitre may regress if thyroxine is given in a dose of 0.15–0.2 mg daily for a few months.

Although the nodular stage of simple goitre is irreversible, more than half of benign nodules will regress in size over ten years. Most patients with multinodular goitre are asymptomatic and do not require operation. Operation may be indicated on cosmetic grounds, for pressure symptoms or in response to patient anxiety. Retrosternal extension with actual or incipient tracheal compression is also an indication for operation, as is the presence of a dominant area of enlargement that may be neoplastic.

There is a choice of surgical treatment in multinodular goitre: total thyroidectomy with immediate and lifelong replacement of thyroxine, or some form of partial resection, to conserve sufficient functioning thyroid tissue to subserve normal function while reducing the risk of hypoparathyroidism that accompanies total thyroidectomy. Subtotal thyroidectomy involves partial resection of each lobe, removing the bulk of the gland, leaving up to 8 g of relatively normal tissue in each remnant. The technique is essentially the same as described for toxic goitre, as are the postoperative complications. More often, however, the multinodular change is asymmetrically distributed, with one lobe more significantly involved than the other. In these circumstances, particularly in older patients, total lobectomy on the more affected side is the appropriate management with either subtotal resection (Dunhill procedure) or no intervention on the less affected side. In many cases, the causative factors persist and recurrence is likely. Reoperation for recurrent nodular goitre is more difficult and hazardous and, for this reason, an increasing number of thyroid surgeons favour total thyroidectomy in younger patients. However, when the first operation comprised unilateral lobectomy alone for asymmetric goitre, reoperation and completion total thyroidectomy is straightforward if required for progression of nodularity in the remaining lobe. Total lobectomy and total thyroidectomy have the additional advantage of being therapeutic for incidental carcinomas (see below).

After subtotal resection, it has been customary to give thyroxine to suppress TSH secretion, with the aim of preventing recurrence. Whether this is either necessary or effective is uncertain, although the evidence of benefit in endemic areas is better than elsewhere. There is some evidence that radioactive iodine may reduce the size of recurrent nodular goitre after previous...
subtotal resection and, in some circumstances, this may be a safer alternative than reoperation, particularly if there has been more than one previous thyroid procedure.

**Clinically discrete swellings**

Discrete thyroid swellings (thyroid nodules) are common and are present in 3–4 per cent of the adult population in the UK and USA. They are three to four times more frequent in women than men.

**Diagnosis**

A discrete swelling in an otherwise impalpable gland is termed isolated or solitary, whereas the preferred term is dominant for a similar swelling in a gland with clinical evidence of generalised abnormality in the form of a palpable contralateral lobe or generalised mild nodularity. About 70 per cent of discrete thyroid swellings are clinically isolated and about 30 per cent are dominant. The true incidence of isolated swellings is somewhat less than the clinical estimate. Clinical classification is inevitably subjective and overestimates the frequency of truly isolated swellings. When such a gland is exposed at operation or examined by ultrasonography, CT or MRI, clinically impalpable nodules are often detected. The true frequency of thyroid nodularity compared with the clinical detection rate by palpation is shown in Figure 51.14. Demonstrating the presence of impalpable nodules does not change the management of palpatable discrete swellings and begs the question of the necessity of investigating incidentally found nodules. The importance of discrete swellings lies in the risk of neoplasia compared with other thyroid swellings. Some 15 per cent of isolated swellings prove to be malignant, and an additional 30–40 per cent are follicular adenomas. The remainder are non-neoplastic, largely consisting of areas of colloid degeneration, thyroiditis or cysts. Although the incidence of malignancy or follicular adenoma in clinically dominant swellings is approximately half of that of truly isolated swellings, it is substantial and cannot be ignored (Figure 51.15).

**Investigation**

**Thyroid function**

Serum TSH and thyroid hormone levels should be measured. If hyperthyroidism associated with a discrete swelling is confirmed biochemically, it indicates either a ‘toxic adenoma’ or a manifestation of toxic multinodular goitre. The combination of toxicity and nodularity is important and is an indication for isotope scanning to localise the area(s) of hyperfunction.

**Autoantibody titres**

The autoantibody status may determine whether a swelling is a manifestation of chronic lymphocytic thyroiditis. The presence of circulating antibodies increases the risk of thyroid failure after lobectomy.

**Isotope scan**

Isotope scanning used to be the mainstay of investigation of discrete thyroid swellings to determine the functional activity relative to the surrounding gland according to isotope uptake. On scanning, swellings are categorised as ‘hot’ (overactive), ‘warm’ (active) or ‘cold’ (underactive). A hot nodule is one that takes up isotope, while the surrounding thyroid tissue does not. Here the surrounding thyroid tissue is inactive because the nodule is producing such high levels of thyroid hormones that TSH secretion is suppressed (Figure 51.9). A warm nodule takes up isotope and so does normal thyroid tissue around it. A cold nodule takes up no isotope.

About 80 per cent of discrete swellings are cold, but only 15 per cent subsequently prove to be malignant and the use of this criterion as an indication for operation lacks discrimination. Routine isotope scanning has been abandoned except when toxicity is associated with nodularity.

**Ultrasonography**

This is widely used as a non-invasive supplement to clinical examination in determining the physical characteristics of...
thyroid swellings. It can demonstrate subclinical nodularity and cyst formation, the former is clinically irrelevant and the latter apparent at aspiration, which should be routine in all discrete swellings. There are a number of ultrasonic features in a thyroid swelling associated with thyroid neoplasia, including microcalcification and increased vascularity, but only macroscopic capsular breach and nodal involvement are diagnostic of malignancy. As an adjunct to FNAC it can reduce the rate of unsatisfactory specimens and is invaluable in the mapping of malignant lymphadenopathy.

**Fine-needle aspiration cytology**

Fine-needle aspiration cytology is the investigation of choice in discrete thyroid swellings. FNAC has excellent patient compliance, is simple and quick to perform in the outpatient department and is readily repeated.

Thyroid conditions that may be diagnosed by FNAC include colloid nodules (Figure 51.16), thyroiditis, papillary carcinoma (Figure 51.17), medullary carcinoma, anaplastic carcinoma and lymphoma. FNAC cannot distinguish between a benign follicular adenoma (Figure 51.18) and follicular carcinoma, as this distinction is dependent not on cytology but on histological criteria, which include capsular and vascular invasion.

Although FNAC was reported as highly accurate by Lowhagen and his colleagues (who were its pioneers) at the Karolinska Hospital, such high accuracy has not always been reproducible. There are very few false positives with respect to malignancy, but there is a definite false-negative rate with respect to both benign and malignant neoplasia. In addition, there can be a high rate of unsatisfactory aspirates, particularly in cystic or partly cystic swellings. These often yield only cyst fluid with macrophages and degenerate cells with few thyroid follicular cells upon which to report. After aspiration, a further sample for cytology should be taken from the cyst wall. There has been a recent trend to use ultrasound to guide the needle to achieve more accurate sampling and reduce the rate of unsatisfactory aspirates. Relatively few cysts are permanently abolished by one or more aspirations and, because of the risk of malignancy, recurrent cysts should be removed.

**Radiology**

Chest and thoracic inlet radiographs may confirm tracheal deviation, compression or retrosternal extension and are required when either clinical suspicion or FNAC indicates malignancy.

**Other scans**

CT and MRI scans give excellent anatomical detail of thyroid swellings but have no role in the first line of investigation. They are most useful in assessing retrosternal (Figure 51.8) and recurrent swellings, particularly if initial surgery has been performed elsewhere. PET scan (Figure 51.19) may be useful, particularly in localising disease which does not take up radioiodine.

**Laryngoscopy**

Flexible laryngoscopy has rendered indirect laryngoscopy obsolete and is widely used preoperatively to determine the mobility of the vocal cords, although usually for medicolegal rather than clinical reasons. Nevertheless, the presence of a unilateral cord palsy coexisting with a swelling suggestive of malignancy is usually diagnostic.
Core biopsy
Core biopsy gives a strip of tissue for histological rather than cytological assessment. It has a high diagnostic accuracy but requires local anaesthesia, and may be associated with complications such as pain, bleeding, tracheal and recurrent laryngeal nerve damage. It has little application in routine assessment except in locally advanced, surgically unresectable malignancy (either anaplastic carcinoma or lymphoma) when a core biopsy may obviate the need for an operative biopsy. In some centres core biopsy is recommended following FNAC when a Thy1 FNAC (inadequate cytology) specimen has been obtained to avoid operating where the risk of malignancy is very low. It is unlikely to be useful in differentiating benign from malignant Thy3 specimens (follicular lesions) as explained below.

Treatment
The main indication for operation is the risk of neoplasia, which includes follicular adenoma as well as malignant swellings. The reason for advocating the removal of all follicular neoplasms is that it is seldom possible to distinguish between a follicular adenoma and carcinoma cytologically. The distinction usually depends on histological evidence of capsular or vascular invasion and FNAC cannot make this distinction although, on occasion, cellular nuclear features may be so abnormal as to suggest malignant change. On this basis, some 50 per cent of isolated swellings and 25 per cent of dominant swellings should be removed on the grounds of neoplasia. Even when the cytology is negative, the age and sex of the patient and the size of the swelling may be relative indications for surgery, especially when a large swelling is responsible for symptoms. Some patients are happier to have a swelling removed even when cytology is negative.

There are useful clinical criteria to assist in selection for operation according to the risk of neoplasia and malignancy. Hard texture alone is not reliable as tense cystic swellings may be suspiciously hard but a hard, irregular swelling with any apparent fixity, which is unusual, is highly suspicious. Evidence of recurrent laryngeal nerve paralysis, suggested by hoarseness and a non-occlusive cough and confirmed by laryngoscopy, is almost pathognomonic. Deep cervical lymphadenopathy along the internal jugular vein in association with a clinically suspicious swelling is almost diagnostic of papillary carcinoma. In most patients, however, such features are absent but there are risk factors associated with sex and age. The incidence of thyroid carcinoma in women is about three times that in men, but a discrete swelling in a male is much more likely to be malignant than in a female and it is seldom justifiable to avoid removing such a swelling in a man. The risk of carcinoma is increased at either end of the age range and a discrete swelling in a teenager of either sex must be provisionally diagnosed as carcinoma.

The risk increases as age advances beyond 50 years, more so in males.

Thyroid cysts
Routine FNAC (or ultrasonography) shows that over 30 per cent of clinically isolated swellings contain fluid and are cystic or partly cystic. Tense cysts may be hard and mimic carcinoma. Bleeding into a cyst often presents with a history of sudden painful swelling, which resolves to a variable extent over a period of weeks if untreated. Aspiration yields altered blood but reaccumulation is frequent. About 50 per cent of cystic swellings are the result of colloid degeneration, or of uncertain aetiology, because of an absence of epithelial cells in the lining. Although most of the remainder are the result of involution in follicular adenomas (Figure 51.20), some 10–15 per cent of cystic follicular swellings are histologically malignant (30 per cent in men and 10 per cent in women). Papillary carcinoma is often associated with cyst formation (Figure 51.21).

Most patients with discrete swellings, however, are women, aged 20–40 years, in whom the risk of malignancy, although significant, is low and the indications for operation are not clear-cut. FNAC is the most appropriate investigation to aid selection.

The indications for operation in isolated or dominant thyroid swellings are listed in Table 51.5.

**Selection of thyroid procedure**

The choice of thyroid operation depends on:
- Diagnosis (if known preoperatively);
- Risk of thyroid failure;
- Risk of recurrent laryngeal nerve injury;
- Risk of recurrence;
- Graves' disease;
- Multinodular goitre;
- Differentiated thyroid cancer;
- Risk of hypoparathyroidism.

Total and near-total thyroidectomy do not conserve sufficient thyroid tissue for normal thyroid function and thyroid replacement therapy is necessary. In most patients with negative antithyroid antibodies, one thyroid lobe will maintain normal function. In subtotal thyroidectomy, the volume of thyroid tissue preserved influences the risk of thyroid failure and larger remnants have a better chance of normal function but a higher risk of recurrence in Graves' disease.

Subtotal resections for colloid goitre run the risk of later growth of the remnant and, if a second operation is required years later, this greatly increases the risk to the RLN and parathyroids. In young patients, total thyroidectomy should be considered. It may be preferable to leave the least affected lobe untouched to permit a straightforward lobectomy in the future if required, rather than carry out subtotal resections.

In Graves' disease, preserving large remnants increases the risk of recurrence of the toxicity and, in these cases, it is better to err on the side of removing too much thyroid tissue rather than too little (Table 51.6). Thyroid failure need not be regarded as a failure of treatment but recurrent toxicity is.

The relative merits of routine total versus selective total thyroidectomy in differentiated thyroid cancer are discussed below (Summary box 51.4).

**Summary box 51.4**

**Thyroid operations**

All thyroid operations can be assembled from three basic elements:

1. Total lobectomy
2. Isthmusectomy
3. Subtotal lobectomy

Total thyroidectomy = 2 x total lobectomy + isthmusectomy

Subtotal thyroidectomy = 2 subtotal lobectomy + isthmusectomy

Near-total thyroidectomy = total lobectomy + isthmusectomy + subtotal lobectomy (Dunhill procedure)

Lobectomy = total lobectomy + isthmusectomy

**Retrosternal goitre**

Very few retrosternal goitres arise from ectopic thyroid tissue; most arise from the lower pole of a nodular goitre. If the neck is short and the pretracheal muscles are strong, as in men, the negative intrathoracic pressure tends to draw these nodules into the superior mediastinum.

**Clinical features**

A retrosternal goitre is often symptomless and discovered on a routine chest radiograph (Figure 51.6). There may, however, be severe symptoms:

**Table 51.6  Comparison of surgical options for Graves' disease.**

<sup>a</sup>The risk of recurrence and late failure are a function of the size of the remnant as a proportion of the total gland weight. Large remnants in small glands have a higher risk of recurrence and a low risk of failure, and small remnants in large glands have a higher risk of thyroid failure but a low risk of recurrence.
Dyspnoea, particularly at night, cough and stridor (harsh sound on inspiration). Many patients attend a chest clinic with a diagnosis of asthma before the true nature of the problem is discovered.

- Dysphagia.
- Engorgement of facial, neck and superficial chest wall veins; in severe cases there may be obstruction of the superior vena cava (Figure 51.22).
- Recurrent nerve paralysis is rare; the goitre may also be malignant or toxic.

Chest and thoracic inlet radiographs show a soft-tissue shadow in the superior mediastinum, sometimes with calcification, and often causing deviation and compression of the trachea. CT scan gives the most accurate and, often dramatic, anatomical visualisation (Figure 51.8).

Significant tracheal compression and obstruction may be demonstrated objectively by a flow–volume loop pulmonary function test in which the rate of flow is plotted against the volume of air inspired and then expired. Deterioration in flow due to increase in tracheal compression, either acutely or in the long term, may be used to monitor progression of the disease and indicate the need for surgery. The changes are reversed by operation (Figure 51.23).

**Treatment**

If obstructive symptoms are present in association with thyrotoxicosis it is unwise to treat a retrosternal goitre with antithyroid drugs or radioiodine as these may enlarge the goitre. Resection can almost always be carried out from the neck, but median sternotomy is sometimes necessary (Figure 51.22b). The cervical part of the goitre should first be mobilised following division of the superior thyroid vessels and middle thyroid vein. Early division of the isthmus is often helpful. The retrosternal goitre can then be delivered by traction, which may be facilitated by inserting a series of sutures, finger or, traditionally, a spoon. Haemorrhage is rarely a problem because the goitre takes its blood supply with it from the neck. The recurrent laryngeal nerve should be identified before delivering the retrosternal goitre, as it may be abnormally displaced and is particularly vulnerable to injury from traction or tearing. If a large retrosternal goitre cannot be delivered intact, piecemeal delivery is possible but risks leaving a fragment of nodular goitre deep in the mediastinum resulting in

a very difficult reoperation many years later. Fragmentation must be avoided when malignancy is likely and all these problems are avoided with a timely median sternotomy.

**Thyroid incidentaloma**

The increased use of imaging modalities for non-thyroid head and neck pathology has created the clinical conundrum of the ‘thyroid incidentaloma’. These are clinically unsuspected and impalpable thyroid swellings and, in some parts of the world, have reached ‘epidemic’ proportions. Injudicious reporting generates needless anxiety if the possibility of malignancy is raised inappropriately. The vast majority of impalpable thyroid swellings can be safely managed expectantly by a single annual review, with no intervention unless certain criteria are met or the swelling becomes palpable (Figure 51.24).

**HYPERTHYROIDISM**

**Thyrotoxicosis**

The term thyrotoxicosis is retained because hyperthyroidism, i.e. symptoms due to a raised level of circulating thyroid hormones, is not responsible for all manifestations of the disease. Clinical types are:

- diffuse toxic goitre (Graves’ disease);
- toxic nodular goitre;
- toxic nodule;
- hyperthyroidism due to rarer causes.

**Diffuse toxic goitre**

Graves’ disease, a diffuse vascular goitre appearing at the same time as the hyperthyroidism, usually occurs in younger women and is frequently associated with eye signs. The syndrome is that of primary thyrotoxicosis (Figure 51.25); 50 per cent of patients have a family history of autoimmune endocrine diseases. The whole of the functioning thyroid tissue is involved, and the hypertrophy and hyperplasia are due to abnormal thyroid-stimulating antibodies (TSH-RAb) that bind to TSH receptor sites and produce a disproportionate and prolonged effect.

**Toxic nodular goitre**

A simple nodular goitre is present for a long time before the hyperthyroidism, usually in the middle-aged or elderly, and very infrequently is associated with eye signs. The syndrome is that of secondary thyrotoxicosis.

In many cases of toxic nodular goitre, the nodules are inactive, and it is the internodular thyroid tissue which is overactive. However, in some toxic nodular goitres, one or more nodules are overactive and here the hyperthyroidism is due to autonomous thyroid tissue as in a toxic adenoma.

**Toxic nodule**

A toxic nodule is a solitary overactive nodule, which may be part of a generalised nodularity or a true toxic adenoma. It is autonomous and its hypertrophy and hyperplasia are not due to TSH-RAb. TSH secretion is suppressed by the high level of circulating thyroid hormones and the normal thyroid tissue surrounding the nodule is itself suppressed and inactive.

**Histology**

The normal thyroid gland consists of acini lined with flattened cuboidal epithelium and filled with homogeneous colloid (Figure 51.3). In hyperthyroidism (Figure 51.26), there is hyperplasia of acini, which are lined by high columnar epithelium. Many of them are empty, and others contain vacuolated colloid with a characteristic ‘scalloped’ pattern adjacent to the thyrocytes.

**Clinical features**

The symptoms are:

- tiredness
- emotional lability
- heat intolerance
- weight loss
- excessive appetite
- palpitations.
The signs of thyrotoxicosis are:

- tachycardia
- hot, moist palms
- exophthalmos
- eyelid lag/retraction
- agitation
- thyroid goitre and bruit.

**Symptomatology**

Thyrotoxicosis is eight times more common in women than in men. It may occur at any age. The most significant symptoms are loss of weight despite a good appetite, a recent preference for cold, and palpitations. The most significant signs are the excitability of the patient, the presence of a goitre, exophthalmos and tachycardia or cardiac arrhythmia.

The goitre in primary thyrotoxicosis is diffuse and vascular; it may be large or small, firm or soft, and a thrill and a bruit may be present. The onset is abrupt, but remissions and exacerbations are not infrequent. Hyperthyroidism is usually more severe than in secondary thyrotoxicosis but cardiac failure is rare. Manifestations of thyrotoxicosis not due to hyperthyroidism per se, for example orbital proptosis, ophthalmoplegia and pretibial myxoedema, may occur in primary thyrotoxicosis.

In secondary thyrotoxicosis, the goitre is nodular. The onset is insidious and may present with cardiac failure or atrial fibrillation. It is characteristic that the hyperthyroidism is not severe. Eye signs other than lid lag and lid spasm (due to hyperthyroidism) are very rare.

**Cardiac rhythm**

A fast heart rate, which persists during sleep, is characteristic. Cardiac arrhythmias are superimposed on the sinus tachycardia as the disease progresses, and they are more common in older patients with thyrotoxicosis because of the prevalence of coincidental heart disease. Stages of development of thyrotoxic arrhythmias are:

1. multiple extrasystoles
2. paroxysmal atrial tachycardia
3. paroxysmal atrial fibrillation
4. persistent atrial fibrillation, not responsive to digoxin.

**Myopathy**

Weakness of the proximal limb muscles is commonly found if looked for. Severe muscular weakness (thyrotoxic myopathy), resembling myasthenia gravis, occurs occasionally. Recovery proceeds as hyperthyroidism is controlled.

**Eye signs**

Some degree of exophthalmos is common (Figure 51.25). It may be unilateral. True exophthalmos is a proptosis of the eye, caused by infiltration of the retrobulbar tissues with fluid and round cells, with a varying degree of retraction or spasm of the upper eyelid. (Lid spasm occurs because the levator palpebrae superioris muscle is partly innervated by sympathetic fibres.) This results in widening of the palpebral fissure so that the sclera may be seen clearly above the upper margin of the iris and cornea (above the “limbus”).

Spasm and retraction usually disappear when the hyperthyroidism is controlled. They may be improved by beta-adrenergic blocking drugs, for example guanethidine eye drops. Oedema of the eyelids, conjunctival injection and chemosis are aggravated by compression of the ophthalmic veins (Figure 51.27). Weakness of the extraocular muscles, particularly the elevators (inferior oblique), results in diplopia. In severe cases, papilloedema and corneal ulceration occur. When severe and progressive, it is known as malignant exophthalmos (Figure 51.28) and the eye may be destroyed. Graves’ ophthalmopathy is an autoimmune disease in which there are antibody-mediated effects on the ocular muscles.

Exophthalmos tends to improve with time. Sleeping propped up and lateral tarsorrhaphy will help to protect the eye but will not prevent progression. Hypothyroidism increases proptosis by a few millimetres and should be avoided.

Improvement has been reported with massive doses of prednisone. Intraorbital injection of steroids is dangerous because of the venous congestion, and total thyroid ablation has not proved effective. When the eye is in danger, orbital decompression may be required (see Orbital swellings in Chapter 44).

Thyroid dermopathy (“pretibial myxoedema”) (Figure 51.29) is a rare condition characterised by thickening of the skin, usually in areas of trauma, by deposition of hyaluronic acid in the dermis and subcutis. It usually occurs a few years after the onset of thyrotoxicosis and usually responds to treatment of the underlying thyroid disorder and topical steroids.
Diagnosis of thyrotoxicosis

Most cases are readily diagnosed clinically. Difficulty is most likely to arise in the differentiation of mild hyperthyroidism from an anxiety state when a goitre is present. In these cases, the thyroid status is determined by the diagnostic tests described earlier. A TRH test is rarely indicated.

T₃ thyrotoxicosis is diagnosed by estimating the free T₃. It should be suspected if the clinical picture is suggestive but routine tests of thyroid function reveal a normal T₄ but suppressed TSH. A thyroid scan is required to diagnose an autonomous toxic nodule (Figure 51.8) and differentiate it from a dominant swelling in a toxic multinodular goitre.

Figure 51.28 (a) Progressive (malignant) exophthalmos. (b) Following treatment with steroids, orbital radiotherapy and bilateral tarsorrhaphy (courtesy of Professor JS Bevan, Aberdeen, UK).

Principles of treatment of thyrotoxicosis

Non-specific measures are rest and sedation and in established thyrotoxicosis should be used only in conjunction with specific measures, i.e. the use of antithyroid drugs, surgery and radioiodine.

Antithyroid drugs

Those in common use are carbimazole and propylthiouracil. β-Adrenergic blockers, such as propranolol and nadolol, are used to block the cardiovascular effects of the elevated T₄. Iodides, which may reduce the vascularity of the thyroid, should only be used as immediate preoperative preparation in the 10 days before surgery. Antithyroid drugs are used to restore the patient to a euthyroid state and to maintain this for a prolonged period in the hope that a permanent remission will occur, i.e. that production of thyroid-stimulating antibodies (TSH-RAb) will diminish or cease. Antithyroid drugs cannot cure a toxic nodule.

- **Advantages.** No surgery and no use of radioactive materials.
- **Disadvantages.** Treatment is prolonged and the failure rate is at least 50 per cent. The duration of treatment may be tailored to the severity of the toxicity with milder cases being treated for only six months and severe for two years before stopping therapy.

It is impossible to predict which patient is likely to go into permanent remission although large gland size, severity of disease and TSH-RAb levels are indicators of poor prognosis.

Some goitres enlarge and become very vascular during treatment, even if thyroxine is given at the same time. This is probably due to TSH-RAb stimulation during the prolonged course of treatment and not a direct effect of the drug.

Very rarely, there is a dangerous drug reaction, particularly agranulocytosis or aplastic anaemia. If a sore throat develops, the patient should be instructed to discontinue treatment, until...
the white cell count has been checked because of the risk of agranulocytosis.

Initially, 10 mg of carbimazole is given three or four times a day, with a latent interval of 7–14 days before clinical improvement is apparent. It is important to maintain a high concentration of the drug throughout the 24 hours by spacing the doses at 8- or 6-hourly intervals. When the patient becomes biochemically euthyroid, a maintenance dose of 5 mg two or three times a day is given for 6–24 months. An alternative technique is to continue with the high dose of carbimazole and inhibit all T\(_3\) and T\(_4\) production then giving a maintenance dose of 0.1–0.15 mg of thyroxine daily. There is no risk of producing iatrogenic thyroid insufficiency and follow up is less demanding ('block and replacement treatment').

The levels of TSH-RAb usually fall during treatment and this accounts for the permanent cure that occurs in 50 per cent of patients.

**Surgery**

In diffuse toxic goitre and toxic nodular goitre with overactive internodular tissue, surgery cures by reducing the mass of overactive tissue. Surgery achieves a cure by reducing the thyroid below a critical mass. After subtotal thyroidectomy the patient should return to a euthyroid state, albeit after a variable period of hypothyroidism. There are, however, the long-term risks of recurrence and eventual thyroid failure. In contrast, total/near total thyroidectomy accepts immediate thyroid failure and lifelong thyroxine replacement to eliminate the risk of recurrence and simplify follow up. Operation may result in a reduction in TSH-RAb. In the autonomous toxic nodule, and in toxic nodular goitre with overactive autonomous toxic nodules, surgery cures by removing all the overactive thyroid tissue: this allows the suppressed normal tissue to function again.

- **Advantages.** The goitre is removed, the cure is rapid, and the cure rate is high if surgery has been adequate.
- **Disadvantages.** Recurrence of thyrotoxicosis occurs in approximately 5 per cent of cases when subtotal thyroidectomy is carried out. There is a risk of permanent hypoparathyroidism and nerve injury. Young women tend to have a poorer cosmetic result from the scar.

Every operation carries a risk, but with suitable preparation and an experienced surgeon the mortality is negligible and the morbidity low.

After subtotal resection thyroid failure is almost universal by 30 years although a few patients can develop recurrent toxicity many years after surgery. Long-term follow up is necessary to detect and treat both. The incidence of permanent parathyroid insufficiency should be less than 5 per cent.

**Radioiodine**

Radioiodine destroys thyroid cells and, as in thyroidectomy, reduces the mass of functioning thyroid tissue to below a critical level.

- **Advantages.** No surgery and no prolonged drug therapy.
- **Disadvantages.** Isotope facilities must be available. The patient must be quarantined while radiation levels are high and avoid pregnancy and close physical contact, particularly with children. Eye signs may be aggravated.

The rate and timing of late thyroid failure are influenced by the dose selected (200–600 MBq). The higher dose is likely to result in thyroid failure in six months, whereas the lower dose may result in insufficiency which may reach a rate of 75–80 per cent after ten years. This is due to sublethal damage to those cells not actually destroyed by the initial treatment and this eventually causes failure of cellular reproduction. Indefinite follow up is essential.

There is no evidence that therapeutic radioiodine is carcinogenic or teratogenic. In some clinics, radioiodine is given to almost all patients including children. Response is slow, but a substantial improvement is to be expected in 8–12 weeks. Accurate dosage is difficult and, should there be no clinical improvement after 12 weeks, a further dose is given. Two or more doses are necessary in 20–30 per cent of cases. Follow-up requirements are reduced if a larger ablative dose of radioiodine is administered followed by routine replacement treatment with thyroxine.

**Choice of therapy**

Each case must be considered individually. Below are listed guiding principles on the most satisfactory treatment for a particular toxic goitre at a particular age; these must, however, be modified according to the facilities available and the personality, intelligence and wishes of the individual patient, business or family commitments and any other coexistent medical or surgical condition. Access to post-treatment care and availability of replacement thyroxine can be important considerations in the Third World.

In advising treatment, compliance, influenced by social and intellectual factors, is important; many patients cannot be trusted to take drugs regularly if they feel well, and indefinite follow up, which is essential after radioiodine or subtotal thyroidectomy, is a burden for all.

**Diffuse toxic goitre**

Most patients have an initial course of antithyroid drugs with radioiodine for relapse. Exceptions are those who refuse radiation, have large goitres, progressive eye signs or are pregnant.

**Toxic nodular goitre**

Toxic nodular goitre is often large and uncomfortable and enlarges still further with antithyroid drugs. A large goitre should be treated surgically because it does not respond as well or as rapidly to radioiodine or antithyroid drugs as does a diffuse toxic goitre.

**Toxic nodule**

Surgery or radioiodine treatment is appropriate. Resection is easy, certain and without morbidity. Radioiodine is a good alternative over the age of 45 years because the suppressed thyroid tissue does not take up iodine and there is thus no risk of delayed thyroid insufficiency.

**Recurrent thyrotoxicosis after surgery**

In general, radioiodine is the treatment of choice, but antithyroid drugs may be used in young women intending to have children. Further surgery has little place.
Failure of previous treatment with antithyroid drugs or radioiodine
In this case, surgery or thyroid ablation with $^{131}$I is appropriate.

Special problems in treatment

Pregnancy
Radioiodine is absolutely contraindicated because of the risk to the fetus. The danger of surgery is miscarriage and the danger of antithyroid drugs is of inducing thyroid insufficiency in the mother and, because both TSH and antithyroid drugs cross the placenta, of the baby being born goitrous (Figure 51.30) and hypothyroid. The risk of either surgery in the second trimester, in competent hands, or careful administration of antithyroid drugs is very small and the choice is exactly as in the uncomplicated case.

Postpartum hyperthyroidism
Pregnancy may lead to an exacerbation of a variety of autoimmune diseases in the postpartum period. Postpartum hyperthyroidism may be a problem in a patient previously diagnosed with hyperthyroidism or may occur in a patient without any previous history of thyroid disease.

Children
Radioiodine is relatively contraindicated because of the theoretical risk of inducing thyroid carcinoma. There is an increased risk of recurrence after thyroidectomy because thyroid cells are highly active in the young. Children and adolescents should be treated with anti-thyroid drugs until the late teens, failing which total or near-total thyroidectomy by an expert surgeon should be undertaken.

The thyrocardiac
This is a patient with severe cardiac damage due wholly or partly to hyperthyroidism. The patient is usually middle aged or elderly with secondary thyrotoxicosis and the hyperthyroidism is not very severe; untreated Graves’ disease sufficient to produce the level of emaciation and cardiomyopathy is rare in contemporary Western practice. The cardiac condition is far more significant than the hyperthyroidism, but this must be rapidly controlled to prevent further cardiac damage. Beta-blockade (propranolol or nadolol) can assist rapid control of cardiac effects.

Radioiodine is the treatment of choice together with antithyroid drugs started either before or after and continued until the radioiodine has had effect (usually 6 weeks).

High titres of thyroid antibodies
Their presence indicates lymphatic infiltration of the goitre, i.e. a diffuse or focal thyroiditis, and a liability to spontaneous remission.

These patients are best treated with antithyroid drugs but if medical treatment fails, definitive treatment by operation or radioiodine is not contraindicated. Steroids may help to reduce pain and swelling.

Proposis of recent onset
There is a conventional view that to terminate thyrotoxicosis abruptly by thyroidectomy or radioiodine when proptosis is recent may induce malignant exophthalmos. Although there is no real proof of this, it is reasonable to treat these patients with antithyroid drugs until the proptosis has been static for six months.

Hyperthyroidism due to other causes

Thyrotoxicosis factitia
Hyperthyroidism may be induced by taking thyroxine, but only if the dosage exceeds the normal requirements of 0.15–0.25 mg per day. Doses below the normal requirements simply suppress normal hormone production by the thyroid.

Jod–Basedow thyrotoxicosis
In European countries, diffuse toxic goitre is often called Basedow’s disease or Jod–Basedow thyrotoxicosis (jod = German for iodine + Basedow). Large doses of iodide given to a patient with a hyperplastic endemic goitre that is iodine avid may produce temporary hyperthyroidism and, very occasionally, persistent hyperthyroidism.

Subacute/acute forms of autoimmune thyroiditis or of de Quervain’s thyroiditis
In subacute or acute forms of autoimmune thyroiditis or of de Quervain’s thyroiditis (see later), mild hyperthyroidism may occur in the early stages due to liberation of thyroid hormones from damaged tissue.

Secondary carcinoma
A large mass of secondary carcinoma will rarely produce sufficient hormone to induce mild hyperthyroidism.

Neonatal thyrotoxicosis
Neonatal thyrotoxicosis occurs in babies born to hyperthyroid mothers or to euthyroid mothers who have had thyrotoxicosis. High TSH-RAb titres are present in both mother and child because TSH-RAb can cross the placental barrier. The hyperthyroidism gradually subsides in 3–4 weeks time as the TSH-RAb titres fall in the baby’s serum.

Figure 51.30 Transmitted thiouracil goitre. This does not occur if T3 is given with antithyroid drugs, as it too crosses the placenta.

Karl Adolf Basedow, 1799–1854, a general practitioner of Merseburg, Germany, published his account of exophthalmic goitre in 1840. Friedrich Joseph de Quervain, 1868–1940, Professor of Surgery, Berne, Switzerland, described his form of thyroiditis in 1902.

The soil of New Zealand is highly impregnated with iodine, but this does not prevent goitre in man, sheep and other animals (Sir Charles Hercus, former Professor of Public Health, University of Otago, New Zealand).
Surgery for thyrotoxicosis
Preoperative preparation
Traditional preparation aims to make the patient biochemically euthyroid at operation. The thyroid state is determined by clinical assessment, i.e. by improvement in previous symptoms and by objective signs such as weight gain and lowering of the pulse rate, and by serial estimations of the thyroid profile.

Preparation is as an outpatient and only rarely is admission to hospital necessary on account of severe symptoms at presentation, failure to control the hyperthyroidism or non-compliance with medication. Failure to control with antithyroid drugs is unusual but may be due to uneven dosage, i.e. not taking the drug at 6- or 8-hourly intervals.

Carbimazole 30-40 mg per day is the drug of choice for preparation. When euthyroid (after 8-12 weeks), the dose may be reduced to 5 mg 8-hourly or a ‘block and replace’ regime used (see above). The last dose of carbimazole may be given on the evening before surgery. Iodides are not used alone because, if the patient needs preoperative treatment, a more effective drug should be given.

An alternative method of preparation is to abolish the clinical manifestations of the toxic state, using β-adrenergic blocking drugs. These act on the target organs and not on the gland itself. Propranolol also inhibits the peripheral conversion of T4 to T3. The appropriate dosages are propranolol 40 mg three times a day or the longer-acting nadolol 160 mg once daily. Clinical response to beta-blockade is rapid and the patient may be rendered clinically euthyroid and operation arranged in a few days rather than weeks. The dose of β-adrenergic blocking drug is increased to achieve the required clinical response and quite often larger doses (propranolol 80 mg three times a day or nadolol 320 mg once daily) are necessary.

β-Adrenergic blocking drugs do not interfere with synthesis of thyroid hormones, and hormone levels remain high during treatment and for some days after thyroidectomy. It is, therefore, important to continue to give the drug for 7 days postoperatively.

Iodine may be given with carbimazole or a β-adrenergic blocking drug for the 10 days before operation. Iodide alone produces a transient remission and may reduce vascularity, thereby marginally improving safety. The use of iodine preparations is not universal because of more effective alternatives. Iodine gives an additional measure of safety in case the early morning dose of β-adrenergic blocking drug is mistakenly omitted on the day of operation.

Surgery
Preoperative investigations to be carried out and recorded are:

- Thyroid function tests.
- Laryngoscopy. Whether this is routine is a matter for local protocols. The outcome should have little impact on the operation because every recurrent laryngeal nerve must be routinely and obsessively preserved.
- Thyroid antibodies.
- Serum calcium estimation.
- An isotope scan before preoperative preparation is necessary in patients with toxic nodular goitre if total thyroidectomy is not planned.

The extent of the resection depends on the size of the gland, the age of the patient, the experience of the surgeon, the need to minimise the risk of recurrent toxicity and the wish to avoid postoperative thyroid replacement (Table 51.6).

Technique
General anaesthesia with endotracheal intubation and muscle relaxation is routine. The patient is supine on the operating table with the table tilted up 15° at the head end to reduce venous engorgement (reversed Trendelenburg). A gel pad or sandbag is placed transversely under the shoulders and the neck is extended (with care particularly in the elderly) to make the thyroid gland more prominent and apply tension to skin, platysma and strap muscles, which makes dissection easier.

A gently curved skin crease incision is made midway between the notch of the thyroid cartilage and the suprasternal notch; a lower incision is easier to hide but is more likely to result in a hypertrophic scar. Flaps of skin, subcutaneous tissue and platysma are raised upwards to the superior thyroid notch and downwards to the suprasternal notch. The deep cervical fascia is divided in the midline between the sternothyroid muscles down to the plane of the thyroid capsule. The strap muscles are not divided as a routine but may be if greater exposure is required. The sternothyroid muscle is mobilised off the thyroid lobes, taking care to stay close to the muscle and outside the capsule.

In 30 per cent of patients, middle thyroid veins passing directly into the internal jugular vein require ligation and division. The plane between the medial aspect of the upper pole and the cricothyroid muscle is developed by keeping close to the thyroid artery splay out over the upper pole and the author’s preference is to ligate these individually. This permits progressive downward delivery of even the highest upper pole. The lobe is then free to rotate medially out of its bed. The inferior thyroid arteries are not routinely ligated to preserve parathyroid blood supply.

The recurrent laryngeal nerve should be identified in its course in the operative field. It should first be sought below the level of the inferior thyroid cartilage and the suprasternal notch; the plane between the medial aspect of the upper pole and the cricothyroid muscle is developed by keeping close to the thyroid artery splay out over the upper pole and the author’s preference is to ligate these individually. This permits progressive downward delivery of even the highest upper pole. The lobe is then free to rotate medially out of its bed. The inferior thyroid arteries are not routinely ligated to preserve parathyroid blood supply.

The inferior thyroid arteries are not routinely ligated to preserve parathyroid blood supply.

Figure 51.31 Identification of the recurrent laryngeal nerve (see text). Note how rotating the gland medially anteriorly kinks the nerve that is normally intimately related to the terminal branches of the inferior thyroid artery.
Hyperthyroidism passes into the larynx under the inferior border of the inferior constrictor immediately behind the inferior cornu of the thyroid cartilage. If the right nerve cannot be found in its usual course, an anomalous (non-recurrent) nerve, present in 1 per cent of cases, should be suspected; this arises from the vagus trunk and usually passes from behind the carotid sheath, curving medially, forwards and upwards and may be mistaken for the inferior thyroid artery (Figure 51.32). The parathyroid glands are identified by careful inspection in the common sites (Figure 51.4). The thymus is detached by serially dividing the inferior thyroid veins.

In subtotal thyroidectomy the isthmus is transected and the lobe resected obliquely from the medial and lateral aspects to produce a V-shaped surface (Figure 51.33). This facilitates subsequent suture of the divided surface for haemostasis. Care is required to avoid devascularisation of the parathyroids and damage to the recurrent laryngeal nerves particularly from the medial aspect. If a parathyroid gland is inadvertently or unavoidably excised or devascularised, it should be fragmented and autotransplanted immediately within the sternomastoid muscle.

Subtotal resection of each lobe is carried out, leaving a remnant of 4–5 g on each side. Absolute haemostasis is secured by ligation of individual vessels and by suture of the thyroid remnants to the tracheal fascia.

Total thyroidectomy (Figure 51.11) avoids transection of thyroid tissue by complete excision of the gland including the pyramidal lobe with preservation in situ or autotransplantation of as many parathyroids as can be identified. The pretracheal muscles and cervical fascia are sutured and the wound closed. Randomised clinical trials have confirmed that routine drainage to the deep cervical space is not required.

New technology in thyroidectomy

The major immediate risk following thyroidectomy is haemorrhage and conventionally artery forceps, ligature and suture have been used to secure the meticulous haemostasis necessary to minimise the frequency. Ultrasonic shears and enhanced bipolar diathermy are increasingly used in thyroid surgery and may be advantageous in complex procedures. Identification of the RLN by electrical stimulation is popular in some centres but has no measurable impact on the incidence of RLN injury.

Postoperative complications

Haemorrhage

A tension haematoma deep to the cervical fascia is usually due to reactionary haemorrhage from one of the thyroid arteries; occasionally, haemorrhage from a thyroid remnant or a thyroid vein may be responsible. This is a rare but desperate emergency which requires urgent decompression by opening the layers of the wound, not simply the skin closure, to relieve tension before urgent transfer to theatre to secure the bleeding vessel (Figure 51.34).

A subcutaneous haematoma or collection of serum may form under the skin flaps and require evacuation in the following 48 hours. This should not be confused with the potentially life-threatening deep tension haematoma.
PART 8 \ THE THYROID AND PARATHYROID GLANDS

Respiratory obstruction
This is very rarely due to collapse or kinking of the trachea (tracheomalacia). Most cases are due to laryngeal oedema. The most important cause of laryngeal oedema is a tension haematoma. However, trauma to the larynx by anaesthetic intubation and surgical manipulation are important contributory factors, particularly if the goitre is very vascular, and may cause laryngeal oedema without a tension haematoma. Unilateral or bilateral recurrent nerve paralysis will not cause immediate postoperative respiratory obstruction unless laryngeal oedema is also present, but will aggravate the obstruction.

If releasing a tension haematoma does not immediately relieve airway obstruction, the trachea should be intubated at once. An endotracheal tube can be left in place for several days; steroids are given to reduce oedema and a tracheostomy is rarely necessary. Intubation in the presence of laryngeal oedema may be very difficult and should be carried out by an experienced anaesthetist. Repeated unsuccessful attempts may aggravate the problem and, in a crisis, it is safer to perform a needle tracheostomy as a temporary measure; a large bore 12G intravenous cannula (diameter 2.3 mm) is satisfactory (see Emergency airway measures in Chapter 48).

Recurrent laryngeal nerve paralysis and voice change
Recurrent laryngeal nerve injury may be unilateral or bilateral. Early routine postoperative laryngoscopy reveals a much higher incidence of transient cord paralysis than is detectable by simple assessment of the integrity of the voice and cough. Such temporary dysfunction is not clinically important, but voice and cord function should be assessed at first follow up 4 weeks postoperatively. The British Association of Endocrine Surgeons audit revealed a RLN palsy rate of 1.8 per cent at one month declining to 0.5 per cent at three months for first-time operations. Permanent paralysis is rare if the nerve has been identified at operation. Injury to the external branch of the superior laryngeal nerve is more common because of its proximity to the superior thyroid artery. This leads to loss of tension in the vocal cord with diminished power and range in the voice. Patients, particularly those who use their voice professionally, must be advised that any thyroid operation will result in change which is common, ultimately regain normality. Even when there is no autoimmune disease present.

Thyroid insufficiency
Following subtotal thyroidectomy this usually occurs within two years, but there is a small but progressive annual incidence over many years which is often insidious and difficult to recognise. With longer follow up it is clear that the majority of patients will eventually develop thyroid failure. This results from a change in the autoimmune response from stimulation to destruction of thyroid cells. There is, however, a definite relationship between the estimated weight of the thyroid remnant and the development of thyroid failure after subtotal thyroidectomy for Graves’ disease. Thyroid insufficiency is rare after surgery for a toxic adenoma, because there is no autoimmune disease present.

Parathyroid insufficiency
This is due to removal of the parathyroid glands or infarction through damage to the parathyroid end artery; often, both factors occur together. Vascular injury is probably far more important than inadvertent removal. The incidence of permanent hypoparathyroidism should be less than 1 per cent and most cases present dramatically 2–5 days after operation but, very rarely, the onset is delayed for 2–3 weeks or if a patient with marked hypocalcaemia is asymptomatic.

Thyrotoxic crisis (storm)
This is an acute exacerbation of hyperthyroidism. It occurs if a thyrotoxic patient has been inadequately prepared for thyroidec- tomy and is now extremely rare. Very rarely, a thyrotoxic patient presents in a crisis and this may follow an unrelated operation. Symptomatic and supportive treatment is for dehydration, hyperpyrexia and restlessness. This requires the administration of intravenous fluids, cooling the patient with ice packs, administration of oxygen, diuretics for cardiac failure, digoxin for uncontrolled atrial fibrillation, sedation and intravenous hydrocortisone. Specific treatment is by carbimazole 10–20 mg 6-hourly, Lugol's iodine 10 drops 8-hourly by mouth or sodium iodide 1 g i.v. Propranolol intravenously (1–2 mg) or orally (40 mg 6-hourly) will block β-adrenergic effects.

Wound infection
Cellulitis requiring prescription of antibiotics, often by the general practitioner, is more common than most surgeons appreciate. A significant subcutaneous or deep cervical abscess is exceptionally rare and should be drained.

Hypertrrophic or keloid scar
This is more likely to form if the incision overlies the sternum and in dark-skinned individuals. Intradermal injections of corticosteroid should be given at once and repeated monthly if necessary. Scar revision rarely results in significant long-term improvement.

Stitch granuloma
This may occur with or without sinus formation and is seen after the use of non-absorbable, particularly silk, suture material. Absorbable ligatures and sutures must be used throughout thy-roid surgery. Some surgeons use a subcuticular absorbable skin suture rather than the traditional skin clips or staples. Skin staples, if used, can be removed safely in less than 48 hours because the skin closure is supported by the platysma stitch.

Postoperative care
About 25 per cent of patients develop transient hypocalcaemia and oral calcium may be necessary (1 g three to four times daily). If associated symptoms are severe, and serum calcium less than 1.90 mmol/L, 10 mL intravenous calcium gluconate 10 per cent (10 mL equivalent to 8.9 mg or 2.3 mmol calcium) should be given and alfacalcidol (1–2 µg oral daily) may be required to maintain normocalcaemia. To screen for parathyroid insufficiency, the serum calcium should be measured at the first review attendance 4–6 weeks after operation.

After subtotal resection, stability in terms of thyroid function takes time. It is important that biochemical (subclinical) thyroid failure should not be an indication for treatment during the first year, as the majority of patients with early subclinical failure, which is common, ultimately regain normality. Even when there are clinical features of failure, thyroxine should be withheld if possible during the first six months. Most patients who develop thyroid failure do so within the first two years, but there is a

Jean Guillaume Lugol, 1786–1851, physician, Hôpital St Louis, Paris, France.
continuing incidence thereafter. Recurrent thyrotoxicosis may occur at any time after operation. Follow up should therefore be for life.

Once a stable situation has been achieved, follow up after thyroid surgery should be carried out by an automated computerised system, which dramatically reduces the number of patient attendances at the thyroid clinic (Summary box 51.5).

**NEOPLASMS OF THE THYROID**

Thyroid neoplasms are classified in Table 51.7 and the relative incidence of malignancies in Table 51.8.

**Benign tumours**

Follicular adenomas present as clinically solitary nodules (Figure 51.35) and the distinction between a follicular carcinoma and an adenoma can only be made by histological examination; in the adenoma there is no invasion of the capsule or of pericapsular blood vessels. Treatment is, therefore, by wide excision, i.e. lobectomy. The remaining thyroid tissue is normal so that prolonged follow up is unnecessary. It is doubtful if there is such an entity as a papillary adenoma and all papillary tumours should be considered as malignant even if encapsulated.

**Malignant tumours**

The vast majority of primary malignancies are carcinomas derived from the follicular cells (Table 51.7). Dunhill classified them histologically as differentiated and undifferentiated: and the differentiated carcinomas are subdivided into follicular and papillary. Lymphoma and medullary cancers make up the remainder of primary malignancies. Metastases to the thyroid, most commonly from kidney and breast, are rare. Direct invasion by upper aerodigestive squamous cancer is a rare but lethal event. Lymph node and blood-borne metastases to bone and lung occur and may be the mode of presentation (Figure 51.36).

**Aetiology of malignant thyroid tumours**

The single most important aetiological factor in differentiated thyroid carcinoma, particularly papillary, is irradiation of the cervical lymphoid tissue in childhood. The use of radioactive iodine in the treatment of thyrotoxicosis occasionally causes thyroid carcinoma. In the 1950s the use of chemotherapy in solid tumours was pioneered at the M.D. Anderson Hospital in Texas, USA, and continues to this day.

---

**Figure 51.35** Isolated swelling in upper pole right thyroid lobe.

**Figure 51.36** Metastasis in the humerus from thyroid carcinoma (courtesy of DS Devadatta, Vellore, India).
thyroid cancer in the Ukraine rose from 57 in the five years before the Chernobyl nuclear incident in 1986 to 577 in the subsequent ten years. In the town of Gomel, the incidence rose from <1 per million to 96 per million.

Short latency aggressive papillary cancer is associated with the ret/PTC3 oncogene and later developing, possibly less aggressive, cancers with ret/PTC1. The incidence of follicular carcinoma is high in endemic goitrous areas, possibly due to TSH stimulation. Malignant lymphomas sometimes develop in autoimmune thyroiditis, and the lymphocytic infiltration in the autoimmune process may be an aetiological factor.

Clinical features of thyroid cancers

The annual incidence is about 3.7 per 100,000 of the population and the sex ratio is three females to one male. The overall mortality should be low because most patients are in a low-risk category but older patients have more aggressive disease with a worse prognosis. The most common presenting symptom is a thyroid swelling (Figures 51.35 and 51.37) and a five-year history is far from uncommon in differentiated growths. Enlarged cervical lymph nodes may be the presentation of papillary carcinoma. Recurrent laryngeal nerve paralysis is very suggestive of locally advanced disease.

Anaplastic growths are usually hard, irregular and infiltrating. A differentiated carcinoma may be suspiciously firm and irregular, but is often indistinguishable from a benign swelling. Small papillary tumours may be impalpable, even when lymphatic metastases are present. Pain, often referred to the ear, is frequent in infiltrating growths.

Diagnosis of thyroid neoplasms

Diagnosis is obvious on clinical examination in most cases of anaplastic carcinoma, although Riedel’s thyroiditis (see later) is indistinguishable. The localised forms of granulomatous and lymphocytic thyroiditis may simulate carcinoma. It is not always easy to exclude a carcinoma in a multinodular goitre, and solitary nodules, particularly in the young male, are always suspect. Failure to take up radioiodine is characteristic of almost all thyroid carcinomas (only very rarely will differentiated carcinoma (primary or secondary) take up $^{123}$I in the presence of normal thyroid tissue), but this also occurs in degenerating nodules and all forms of thyroiditis. TSH levels are often raised in carcinoma but this may be clouded by simultaneous elevation antithyroid antibodies. The key role of FNAC in preoperative diagnosis has already been discussed. There is a false-negative rate with all investigations, and lobectomy is appropriate when there is a strong clinical suspicion. Incisional biopsy may cause seeding of cells and local recurrence, and is not advised in a resectable carcinoma. In an anaplastic and obviously irremovable carcinoma, however, incisional or core needle biopsy is justified.

When a preoperative diagnosis is made, imaging with either ultrasound or MRI is required. CT, particularly with iodine containing contrast media, should be avoided. As well as additional information on the extent of the primary, this will give valuable information on nodal involvement (Figures 51.38 and 51.39) to permit preoperative planning for nodal dissection.

Figure 51.37 Follicular neoplasm of thyroid presenting as an isolated swelling.

Figure 51.38 Magnetic resonance imaging scan of papillary cancer with multiple node metastases.

Figure 51.39 Composite ultrasound scan of papillary cancer of right thyroid lobe with extensive nodal metastases. N, enlarged nodes; C, carotid artery; R, primary carcinoma in right thyroid lobe; L, normal left thyroid lobe (courtesy Dr D McAteer, Aberdeen, UK).
Frozen section histology has a limited role in thyroid surgery. It cannot reliably differentiate encapsulated benign from malignant follicular neoplasms and is of more value in confirming whether nodes are involved with papillary cancer and thereby influencing the extent of nodal surgery.

**Papillary carcinoma**

Most papillary tumours contain a mixture of papillary and colloid-filled follicles and, in some, the follicular structure predominates. Nevertheless, if any papillary structure or characteristic cytology is present, the tumour will behave in a predictable fashion as a papillary carcinoma. Histologically the tumour shows papillary projections and characteristic pale, empty nuclei (Orphan Annie-eyed nuclei) (Figure 51.40). Papillary carcinomas are very seldom encapsulated.

Multiple foci may occur in the same lobe as the primary tumour or, less commonly, in both lobes. They may be due to lymphatic spread in the rich intrathyroidal lymph plexus, or to multicentric growth. Spread to the lymph nodes is common, but blood-borne metastases are unusual unless the tumour is extrathyroidal. The term extrathyroidal indicates that the primary tumour has infiltrated through the capsule of the thyroid gland although minimal invasion of the sternothyroid muscle is much less significant than infiltration into the oesophagus or trachea.

**Microcarcinoma (occult carcinoma)**

The reported prevalence of tiny foci of papillary carcinoma is related to the care with which the thyroid is examined histologically. In an autopsy study from Finland in which the thyroid was examined serially in 2-mm slices, an incidence of up to 36 per cent was reported. Clearly, the majority of such tumours never progress to become a clinically significant entity. A small percentage of cancers present with enlarged lymph nodes in the jugular chain or pulmonary metastases with no palpable abnormality of the thyroid. The primary tumour may be no more than a few millimetres in size and is often termed occult. Foci of papillary carcinoma may also be discovered in thyroid tissue resected for other reasons, for example Graves’ disease. The term ‘occult’ was formally applied to all papillary carcinomas less than 1.5 cm in diameter but the preferred terminology now is microcarcinoma for cancers less than 1 cm. These have a uniformly excellent prognosis although those presenting with nodal or distant metastases justify more aggressive therapy.

**Follicular carcinoma**

These appear to be macroscopically encapsulated but, microscopically, there is invasion of the capsule and of the vascular spaces in the capsular region (Figure 51.41). Multiple foci are seldom seen and lymph node involvement is much less common than in papillary carcinoma. Blood-borne metastases are more common and the eventual mortality rate is twice that of papillary cancer (Figure 51.42).

Hürthle cell tumours are a variant of follicular neoplasm in which oxyphil (Hürthle, Askanazy) cells predominate histologically. Hürthle cell cancers are associated with a poorer prognosis and some hold that all Hürthle cell neoplasms are malignant.
Karl Hürthle, 1866–1945, a German histopathologist who first drew attention to these cells. Max Askanazy, 1865–1940, described these cells while working at the Pathological Anatomy Institute, Tübingen, Germany.

Prognosis in differentiated thyroid carcinoma

The prognosis in differentiated thyroid carcinoma compared to most cancers is excellent. Although influenced by histological type, prognosis is much more dependent on age at diagnosis, size of the tumour, metastatic disease and the presence of either extrathyroidal spread (in papillary cancer) or major capsular transgression (in follicular carcinoma). There are a multiplicity of scoring systems all of which identify the group of patients at high (40 per cent at 20 years) or low (1 per cent at 20 years) risk of death (Table 51.9). All patients should be TNM staged and this classification acknowledges the low risk of patients aged less than 45 years at presentation (Table 51.10). Approximately 80 per cent of patients are at a low risk of dying of thyroid cancer but suboptimal treatment, i.e. failure to eradicate all macroscopic disease at the first operation, may lead to increased recurrence and avoidable deaths many years after presentation. It is, however, important to avoid iatrogenic morbidity by overzealous treatment in those patients with a normal life expectancy.

Surgical treatment

Patients with large, locally aggressive or metastatic differentiated thyroid cancer (DTC) require total thyroidectomy, with excision of adjacent involved structures if necessary, and appropriate nodal surgery followed by radioiodine ablation with long-term TSH suppression. Such ‘high risk’ patients however are in the minority and there is continuing disagreement on the most appropriate operation for ‘low risk’ differentiated thyroid carcinoma, particularly with the increase in diagnosis of incidental microcarcinomas of less than 1 cm. Current guidelines advocate routine total thyroidectomy, often necessitating early reoperation and second lobectomy following a diagnostic first lobectomy with routine central compartment node dissection for all tumours greater than 1 cm. Total thyroidectomy facilitates the use of radioiodine for postoperative scanning to detect and subsequently ablate metastases results in lower thyroglobulin levels. An undetectable serum thyroglobulin is increasingly used as a proxy for cure. While this policy may reduce the rate of reoperation for recurrent disease it is unlikely to improve on existing 99 per cent survival in low risk patients and exposes patients to increased risk of RLN injury, hypoparathyroidism and later development of second cancers.

Local recurrence, in either the thyroid bed or contralateral lobe, should be exceptionally rare after total lobectomy, particularly in low risk cases. A randomised trial would have to recruit several thousand patients and take 50 years to resolve this debate. For the foreseeable future, many patients will be overtreated until a reliable method of identifying those who will benefit is established.

It is the author’s current practice when a preoperative diagnosis of DTC has been made, usually on FNAC, to image the neck with ultrasound or MRI (Figures 51.36 and 51.37). The imaging will identify involved lymph node levels and permit

Figure 51.42 Follicular carcinoma of thyroid with skull secondaries.
operative planning. Total thyroidectomy is recommended for tumours greater than 2 cm and those with nodal involvement or metastases and lobectomy for the remainder. Functional selective node dissection of involved node levels is performed as required. Lateral extension of the normal thyroidectomy incision generally gives adequate access to node levels 3–7. If access to level 2 is difficult an additional higher skin crease incision or alternatively a J-shaped utility incision may be made. Surgery should aim to remove all macroscopic disease (Figure 51.43).

There is a practical difference between a ‘diagnostic’ central compartment dissection in patients with no obvious nodal involvement and a ‘therapeutic’ clearance for macroscopic disease. A ‘diagnostic’ dissection can be limited to selective unilateral node dissection often with preservation of the thymus whereas a ‘therapeutic’ dissection requires clearance of all tissue to the level of the innominate vein. Very occasionally, it may be necessary to sacrifice the recurrent laryngeal nerve if it is completely encircled and, on even more rare occasions, extrathyroidal spread may require tracheal, oesophageal or laryngeal resection. Such procedures are not for the occasional surgeon. When the diagnosis of DTC is made after diagnostic lobectomy TSH suppression and review can be recommended with reoperation only for a clear indication. Indications for completion total thyroidectomy are the development of a new swelling or rising thyroglobulin. This is based on analysis of the outcome of thyroid lobectomy in the author’s unit in both ‘low’ and ‘high’ risk patients since 1977.

**Additional measures**

**Thyroxine**

It is standard practice to prescribe thyroxine in a dose of 0.1–0.2 mg daily, to suppress endogenous TSH production, for all patients after operation for differentiated thyroid carcinoma on the basis that most tumours are TSH dependent. Suppression of the TSH level should be confirmed by measurement. Failure of suppression to a level of <0.1 mU/L may indicate an inadequate dose of thyroxine or, more usually, that the patient is non-compliant. There is a trend to manage patients with undetectable thyroglobulin after radical treatment with a TSH level in the normal range because of some concern over the impact of long-term TSH suppression.

Thyroid hormone replacement is obviously necessary after total thyroidectomy and in the majority of patients after near-total thyroidectomy, and is usually given in the form of thyroxine. Patients with potential or actual distant metastases, who may require repeated radioiodine administration for scanning and therapy, should be given tri-iodothyronine (60–80 µg per day) because it is much shorter acting and, on stopping it, increased TSH secretion and thyroid avidity for iodine recovers quickly so that radioiodine may be given after 7 days. The patient is thereby spared the 4 weeks needed to develop thyroid insufficiency after stopping thyroxine before radioiodine may be given. An alternative to thyroxine withdrawal is to administer recombinant synthetic TSH over a 48-hour period to maximise iodine uptake. This is an equally effective but more expensive regime.

**Radioiodine**

If metastases take up radioiodine, they may be detected by scanning and treated with large doses of radioiodine. For effective

scanning, all normal thyroid tissue must have been ablated either by surgery or preliminary radioiodine and the patient must be hypothyroid to improve uptake. Alternatively, synthetic recombinant TSH may be used to stimulate uptake. The indications for scanning after operations for differentiated carcinoma are also disputed, but radioiodine is indicated in patients with unresectable disease, local recurrence or metastatic disease, high-risk patients, and in those with a rising serum thyroglobulin level. A whole body scan can be carried out after empiric treatment with high-dose radioiodine 10 days later to allow decay of activity (Figure 51.44). Unfortunately, the more aggressive and de-differentiated the cancer the more likely it is not to take up radioiodine: those most in need of an effect are least likely to derive benefit.

If metastases have been treated, the serum thyroglobulin level and local protocols will determine when the scan should be repeated and further therapeutic doses of radioiodine given if necessary. Solitary distant metastases may be treated by external radiotherapy.

**Thyroglobulin**

The measurement of serum thyroglobulin is invaluable in the follow up and detection of metastatic disease in patients who have undergone surgery for differentiated thyroid cancer. It can be used after lobectomy, as after total thyroidectomy, provided that endogenous TSH production has been suppressed by \( T_4 \). This measurement reduces the need for serial radioactive iodine scanning but, when a rise occurs, imaging with neck ultrasound is appropriate. Surgery or therapeutic radioiodine is then indicated with a subsequent whole body scan once activity has decayed (Figure 51.45). This will confirm and locate metastatic disease which is iodine avid. The presence of circulating antithyroglobulin antibodies interferes with and invalidates thyroglobulin as a serum marker for recurrence, and occasionally, careful clinical palpation of the neck will be the first indication of local recurrence.

**Undifferentiated (anaplastic) carcinoma**

This occurs mainly in elderly women and is much less often diagnosed now than in the past when many thyroid lymphomas were mistakenly classified histologically as anaplastic carcinomas. Local infiltration is an early feature of these tumours with spread by lymphatics and by the bloodstream. They are extremely lethal tumours and survival is calculated in months. Complete resection is justified if the disease appears confined to the thyroid and possibly the strap muscles and is only possible in a minority of patients. Even then the survival rarely exceeds six months and the median is around three months for the whole group. Some of these aggressive lesions present in an advanced stage with tracheal obstruction and they require urgent tracheal decompression. The trachea may be decompressed and tissue obtained for histology by isthmusectomy. Tracheostomy is best avoided. Radiotherapy should be given in all cases and may provide a worthwhile period of palliation, but there is little evidence to support the use of chemotherapy outwith clinical trials.

**Medullary carcinoma**

These are tumours of the parafollicular (C cells) derived from the neural crest and not from the cells of the thyroid follicle as are other primary thyroid carcinomas. The cells are not unlike those of a carcinoid tumour and there is a characteristic amyloid stroma (Figure 51.46). High levels of serum calcitonin and carcinoembryonic antigen are produced by many medullary tumours. Calcitonin levels fall after resection and rise again with recurrence making it a valuable tumour marker in the follow up of patients with this disease. Diarrhoea is a feature in 30 per cent of cases and this may be due to 5-hydroxytryptamine or prostaglandins produced by the tumour cells.

Some tumours are familial and account for 10–20 per cent of all cases. Medullary carcinoma may occur in combination with
adrenal phaeochromocytoma and hyperparathyroidism (usually due to hyperplasia) in the syndrome known as multiple endocrine neoplasia (MEN) type 2A (MEN-2A). The familial form of the disease frequently affects children and young adults, whereas the sporadic cases occur at any age with no sex predominance. When the familial form is associated with prominent mucosal neuromas involving the lips, tongue and inner aspect of the eyelids, with a Marfanoid habitus, the syndrome is referred to as MEN type 2B (see Chapter 52).

Involvement of lymph nodes occurs in 50–60 per cent of cases of medullary carcinoma and blood-borne metastases are common. As would be expected, tumours are not TSH dependent and do not take up radioactive iodine. The prognosis is variable and depends on the stage at diagnosis. Any nodal involvement virtually eliminates the prospect of cure and, unfortunately, even small tumours confined to the thyroid gland may have spread by the time of diagnosis, particularly in familial cancers. In common with many endocrine tumours the progression of disease may be very slow with a characteristically indolent course and long survival, even in the absence of cure.

**Treatment**

Treatment is by total thyroidectomy and either prophylactic or therapeutic resection of central and bilateral cervical lymph nodes.

Familial cases are now detected by genetic screening for the RET mutations, which identifies individuals who will develop medullary cancer later in life (Figure 51.47). The genetic tests are supplemented by estimating serum calcitonin levels in the basal state and after stimulation by either calcium or pentagastrin. A rise in calcitonin levels under these circumstances should lead to thyroidectomy, but even then the disease may be beyond the preinvasive C-cell hyperplasia stage (Figure 51.48). Prophylactic surgery is recommended for infants with the genetic trait. Detailed preoperative genetic and biochemical analyses permit a tailored approach to nodal surgery and may avoid unnecessarily radical surgery. A recent refinement as a result of preoperative genetic differentiation between sporadic and familial cancers suggests that lobectomy might be adequate treatment for sporadic cases.

In all cases, before embarking upon thyroid surgery, phaeochromocytoma must be excluded by measurement of urinary catecholamine levels.

**Malignant lymphoma**

In the past, many malignant lymphomas were diagnosed as small round-cell anaplastic carcinomas. Response to irradiation is dramatic (Figure 51.49) and radical surgery is unnecessary once the diagnosis is established by biopsy. Although the diagnosis may be made or suspected on FNAC, sufficient material is seldom available for immunocytochemical classification and core needle or open biopsy is usually necessary. In patients with tracheal compression, isthmusectomy is the most appropriate form of biopsy although the response to therapy is so rapid that this should rarely be necessary unless there has been difficulty in making a histological diagnosis. The prognosis is good if there is no involvement of cervical lymph nodes. Rarely, the tumour is part of widespread malignant lymphoma disease, and the prognosis in these cases is worse. Most lymphomas occur against a background of lymphocytic thyroiditis (Summary box 51.6).

THYROIDITIS

Chronic lymphocytic (autoimmune) thyroiditis

This common condition is usually associated with raised titres of thyroid antibodies. Not infrequently there is a family history of other autoimmune disease. It commonly presents as a goitre, which may be diffuse or nodular with a characteristic ‘bosselated’ feel or with established or subclinical thyroid failure. The diagnosis often follows investigation of a discrete swelling. Features of chronic lymphocytic (focal) thyroiditis are commonly present on histological examination in association with other thyroid disease, notably toxic goitre. Primary myxoedema without detectable thyroid enlargement represents the end stage of the pathological process.

Clinical features

The onset, thyroid status and the type of goitre vary profoundly from case to case. The onset may be insidious and asymptomatic, or so sudden and painful that it resembles the acute form of granulomatous thyroiditis. Mild hyperthyroidism may be present initially, but hypothyroidism is inevitable and may develop rapidly or extremely slowly. The goitre is usually lobulated, and may be diffuse or localised to one lobe. It may be large or small, and soft, rubbery or firm in consistency, depending upon the cellularity and the degree of fibrosis. The disease is most common in women at the menopause, but may occur at any age. Papillary carcinoma and malignant lymphoma are occasionally associated with autoimmune thyroiditis (Figure 51.50).

Diagnosis

Biochemical tests of thyroid function vary with the thyroid status and are of diagnostic value only if hypothyroidism is present. Significantly, raised serum levels of one or more thyroid antibodies are present in over 85 per cent of cases. Nevertheless, differential diagnosis from nodular goitre, carcinoma and malignant lymphoma of the thyroid is not always easy. FNAC is the most appropriate investigation although abundant lymphocytes may make the cytological distinction between autoimmune thyroiditis and lymphoma difficult. When there is doubt about neoplastic disease, which may coexist with thyroiditis, diagnostic lobectomy may be necessary.

Treatment

Full replacement dosage of thyroxine should be given for hypothyroidism and if the goitre is large or symptomatic, because some (under TSH stimulation) may subside with hormone therapy. More minor manifestations of the condition such as a small goitre with raised antibody titres, or histological evidence of thyroiditis in association with other thyroid disease, do not justify thyroxine replacement if thyroid function is biochemically normal; however, long-term surveillance is necessary because of
Granulomatous thyroiditis (subacute thyroiditis, de Quervain’s thyroiditis)

This may follow a viral infection. In a typical subacute presentation, there is pain in the neck, fever, malaise, and a firm, irregular enlargement of one or both thyroid lobes. There are raised inflammatory markers, absent thyroid antibodies, the serum T
t is high normal or slightly raised, and the 123I uptake of the gland is low. The condition is self-limiting and, in a few months, the goitre subsides and there may be a period of months of hypothyroidism before eventual recovery. In 10 per cent of cases the onset is acute, the goitre very painful and tender and there may be symptoms of hyperthyroidism. One-third of cases are asymptomatic but for the presence of the goitre. If diagnosis is in doubt, it may be confirmed by FNAC, radioactive iodine uptake and by a rapid symptomatic response to prednisone. The specific treatment for the acute case with severe pain is to give prednisone 10–20 mg daily for 7 days and the dose is then gradually reduced over the next month. If thyroid failure is prominent, treatment with thyroxine may be required until function recovers.

Riedel’s thyroiditis

This is very rare, accounting for 0.5 per cent of goitres. Thyroid tissue is replaced by cellular fibrous tissue, which infiltrates through the capsule into muscles and adjacent structures, including parathyroids, recurrent nerves and carotid sheath. It may occur in association with retroperitoneal and mediastinal fibrosis and is most probably a collagen disease. The goitre may be unilateral or bilateral and is very hard and fixed. The differential diagnosis from anaplastic carcinoma can be made with certainty only by biopsy, when a wedge of the isthmus should also be removed to free the trachea. If unilateral, the other lobe is usually involved later and subsequent hypothyroidism is common. Treatment is with high-dose steroid, tamoxifen and thyroxine replacement. Reduction in size of the goitre and long-term improvement in symptoms are to be expected if treatment is commenced early (Summary box 51.7).

Parathyroid hyperparathyroidism

Primary hyperparathyroidism

Primary hyperparathyroidism is commonly a sporadic rather than familial condition associated with hypercalcaemia and inappropriately raised serum PTH levels due to enlargement of one or more glands and hypersecretion of PTH. The normal response to hypercalcaemia is PTH suppression.

Epidemiology

The prevalence of sporadic primary hyperparathyroidism increases with age and affects women more than men. Approximately 1 per cent of adults are hypercalcaemic on biochemical screening.

Familial hyperparathyroidism occurs as part of the following genetically determined conditions:

- MEN1 (multiple endocrine neoplasia type 1: Werner’s syndrome);
- MEN2A (Sipple syndrome), rarely in MEN2B;
- Familial hyperparathyroidism.

Pathology

The majority (85 per cent) of patients with sporadic primary hyperparathyroidism have a single adenoma, approximately 13 per cent have hyperplasia affecting all four glands and about 1 per cent will have more than one adenoma or a carcinoma. In familial disease, multiple gland enlargement is usual.

There is a weak correlation between the size of an adenoma and the level of PTH (Figure 51.51). The histological differentiation between adenoma and hyperplasia can be difficult and the macroscopic findings are an important determinant in making the diagnosis. A single enlarged gland with three small normal glands is characteristic of a single adenoma regardless of the histology which may show considerable overlap between a hyperplastic and adenomatous gland. Multiple adenomas occur more frequently in older patients.

Parathyroid hyperplasia by definition affects all four glands (Figure 51.52).

Parathyroid carcinomas are large tumours and typically much more adherent or even frankly invasive than large adenomas. Histology demonstrates a florid desmoplastic reaction with dense fibrosis and capsular and vascular invasion.

Parathyroid cysts may be secondary to degeneration in nodules or adenomas, developmental and, while some present as a palpable neck swelling, small cysts are most often noted as
incidental findings during neck exploration. If aspirated preoperatively the diagnosis should be suspected from the watery clear fluid aspirated. The diagnosis is confirmed by a high PTH level.

Clinical presentation
The classic quartet of ‘stones, bones, abdominal groans and psychic moans’ is rarely observed in developed countries when the diagnosis is usually detected on serum calcium estimation well before the full picture of severe bone disease (von Recklinghausen’s disease), renal calculi and calcinosis, pancreatitis and psychiatric disorder. Incidentally detected hypercalcaemia is rarely truly ‘asymptomatic’ and most patients experience an improved sense of well-being after surgery. Careful enquiry into family history is always appropriate and may reveal an index case for familial disease including familial primary HPT, MEN syndromes and familial hypocalciuric hypercalcaemia.

Diagnosis
Although ionised calcium is the physiologically active circulating element, total serum calcium is a satisfactory measure. The effect of binding to serum proteins must be corrected by upward or downward correction to a serum albumin level of 40 g/L. Inappropriate, i.e. elevated or normal PTH levels in the presence of high serum calcium is diagnostic of primary HPT. Hypophosphataemia and elevated urine calcium excretion are confirmatory.

Other causes of hypercalcaemia must be considered and excluded (Table 51.11). Advanced malignancy is the most common cause of hypercalcaemia in hospitalised patients, due to parathyroid hormone-related peptide (PTHrP) or bone metastases. The PTH level is suppressed.

Familial hypocalciuric hypercalcaemia is an autosomal dominant disorder characterised by mild elevation of calcium and PTH levels secondary to a missense mutation in the cell membrane calcium receptor. The low urinary excretion of calcium will discriminate this from HPT. Parathyroidectomy is not required. However, neonatal hyperparathyroidism is rare but is associated with severe hypercalcaemia in homozygous patients and urgent near-total parathyroidectomy is required.

Treatment of primary hyperparathyroidism
At present surgery is the only curative option and should be offered to all patients with significant hypercalcaemia provided they are otherwise fit for the procedure. There are a number of medical strategies and therapies, particularly in mild hyperparathyroidism, which include simple expectant treatment until the calcium level or symptoms reach a level at which surgery becomes more attractive, low calcium diet, withdrawal of drugs (diuretics and lithium) which aggravate hypercalcaemia and, more recently, calcium reducing agents such as bisphosphonates and the calcium receptor agonist cinacalcet.

Occasionally, patients present with a parathyroid crisis and severe hypercalcaemia (serum calcium greater than 3.5 mmol/L). This results in confusion, nausea, abdominal pain, cardiac arrhythmias and hypotension with acute renal failure. Intravenous saline and bisphosphonate therapy (pamidronate) are required to correct the dehydration and hypercalcaemia. This is best done in a high-dependency unit or even intensive therapy unit setting to monitor the major physiological fluxes which result.

Figure 51.52 Parathyroid hyperplasia. (a) Mobilised right thyroid lobe showing enlarged superior and inferior parathyroid glands. Note how the superior gland has migrated posterior and inferior to the inferior thyroid artery. (b) Total parathyroidectomy specimens.
Indications for operation

Conventional indications for operation are shown in Table 51.12, but traditionally, endocrine surgeons have had a lower threshold for recommending operation than physicians. However, the widespread adoption of minimal access techniques for parathyroidectomy has changed many physicians’ attitudes because of the perceived reduction in operative morbidity. There remains a cohort of patients with mild primary HPT and those with significant comorbidity where the decision for operation remains a matter of clinical judgement.

Preoperative localisation

There has been a paradigm shift in the use of preoperative imaging in primary hyperparathyroidism. Until a few years ago the maxim that the ‘only localisation test necessary was to locate a good endocrine surgeon’ (Doppman) was apposite when opinion favoured a conventional bilateral neck exploration. Skilled surgeons can achieve cure rates of the order of 98 per cent, with failure due to an ectopic adenoma not accessible through a cervical incision or, occasionally, failure to recognise multiple gland disease. While there should be minimal morbidity associated with a bilateral neck exploration, an image-guided targeted approach reduces this even further and has become routine in most major centres. Concerns that subtle abnormalities will be missed if all glands are not routinely visualised remain but have not translated into a significant clinical issue to date. There remains a cohort of patients in whom preoperative imaging does not localise an adenoma and the experience of the surgeon remains paramount in achieving a high cure rate.

High frequency neck ultrasound is non-invasive and should identify 75 per cent of enlarged glands. It gives better resolution but reduced penetration and cannot visualise the mediastinum (Figure 51.53). Nodular thyroid disease is a confounding factor.

Technetium-99m (99mTc)-labelled sestamibi (MIBI) isotope scans (Figure 51.54) also identify 75 per cent of abnormal parathyroid glands. The area scanned must include the mediastinum to detect ectopic glands. Single-photon emission computed tomography (SPECT) (Figure 51.55) gives a three-dimensional image which may influence the surgical approach. Concordance between ultrasound and sestamibi scan permits a targeted approach with confidence. However, the size of the adenoma is important and imaging and concordance decline with glands weighing less than 500 mg.

CT, PET and MRI imaging are not indicated prior to first-time neck exploration.

![Ultrasound scan of parathyroid adenoma at upper pole right thyroid lobe. C, carotid artery; A, parathyroid adenoma; T, right thyroid lobe.](image)

![Technetium-sestamibi scans 15 minutes and 3 hours after injection showing retention of isotope in a left inferior parathyroid adenoma.](image)

John L Doppman, contemporary, radiologist, Bethesda, MA, USA.

The noun isotope is derived from the Greek isos = equal and tropos = place, meaning having an equal place on the periodic table.
Consent for surgery
Preoperative discussion must include the possibilities of:
- persistent hyperparathyroidism (5 per cent);
- recurrent laryngeal nerve injury (1 per cent);
- postoperative haemorrhage (1 per cent);
- permanent hypoparathyroidism;
- recurrent hyperparathyroidism.

Operation for primary hyperparathyroidism
There are a number of surgical options available, of which a targeted small incision approach and bilateral exploration using a conventional ‘thyroidectomy’ incision are the most frequently performed. Video-assisted (in which a video endoscope is used to reduce the size of incision and permit bilateral exploration) and totally endoscopic techniques with multiple punctures have not achieved much popularity. Methylene blue infusion to assist in gland identification has largely been abandoned. A gamma probe can be used to guide exploration following preoperative injection of technetium-labelled sestamibi. The short serum half-life of PTH means that intraoperative measurement can be used to confirm that the source of excess PTH production has been excised. This is a more physiological approach than surgical opinion supported by frozen section and is routine in many centres but is not infallible or inexpensive. Serum levels of PTH are measured pre-incision, pre-removal, 5 minutes after removal and 10 minutes after removal. The assay takes 30 minutes and if the percentage drop is not >50 per cent then further exploration is indicated.

Operative strategy and technique of parathyroidectomy
Targeted approach
General or local anaesthesia may be used. A head light and magnifying loupes or alternatively a 5-mm video laparoscope are useful. Confident preoperative localisation permits a 2–3 cm incision located over the site of the adenoma (Figure 51.56). This may be placed to permit extension to a formal bilateral exploration incision if the imaging is suboptimal. The subplatysmal plane is incised and either a midline or lateral approach is indicated. A 2-cm incision over left inferior parathyroid adenoma.

Conversion to a formal neck incision and bilateral exploration should rarely be required if preoperative assessment has been rigorous.

Conventional approach
The patient is positioned in reverse Trendelenburg, with a silicone gel pad transversely under the shoulders to extend the neck with the head supported in a padded ring.

A transverse collar incision is made, the subplatysmal plane developed superiorly and inferiorly and the deep cervical fascia incised in the midline between the strap muscles. The thyroid lobes are mobilised with division of the middle thyroid vein when present. It is not normally necessary to divide the superior thyroid vessels unless the exploration proves difficult. Medial rotation of the thyroid lobe exposes the inferior thyroid artery and recurrent laryngeal nerve (Figures 51.5 and 51.52a). The glands are identified in a systematic manner commencing with the common sites and working sequentially through to the rare locations.

Superior gland:
1. in fat pad on surface of thyroid lobe above the inferior thyroid artery at level of cricothyroid articulation then
2. inferiorly behind the inferior thyroid artery and oesophagus then
3. divide superior thyroid vessels and rotate upper pole anterio-

Inferior gland:
1. along the thyrothymic axis then
2. on or under the capsule of the lower pole of the thyroid then
3. incise the fascia of the upper horn of thymus then
4. extend this down into the accessible mediastinal thymus then
5. within the carotid sheath (usually suggested by a tongue of ectopic thymus) then
6. transcervical thymectomy achieved by gentle upper retrac-

7. within the thyroid lobe which may require thyroid lobectomy.

All abnormal glands are excised and, in the event of sporadic four-gland disease, subtotal parathyroidectomy is carried out, preserving approximately 50 mg of one gland. This must be marked with a non-absorbable suture to facilitate any possible future re-exploration.

In patients with four-gland disease, transcervical thymectomy is recommended to reduce the risk of persistent or recurrent hyperparathyroidism. In patients with MEN-1, total parathyroidectomy reduces the risk of recurrence.

Preoperative imaging will identify the 1 per cent of patients with a mediastinal adenoma and allow a single curative operation (Figure 51.57a and b).
Secondary hyperparathyroidism

Chronic renal failure results in secondary hyperparathyroidism. The kidney cannot convert vitamin D into the physiologically active 1,25-cholecalciferol. Reduced intestinal absorption of calcium resulting in a low serum calcium and elevated phosphate due to renal failure to excrete phosphate increases secretion of parathyroid hormone. Prolonged stimulation results in parathyroid hyperplasia. Initially this is reversible following renal transplantation but when autonomous hyperfunction progresses after transplantation this is termed tertiary hyperparathyroidism.

Secondary hyperparathyroidism also occurs in vitamin D-deficient rickets, malabsorption and pseudohypoparathyroidism.

Clinical and biochemical features

These include bone pain, pruritus, muscle weakness, renal osteodystrophy and soft-tissue calcification (Figure 51.58a and b). Calciphylaxis (calcific uremic arteriolopathy) is the end stage of this condition with arteriolar occlusion resulting in cutaneous ulceration and gangrene. The systemic effects of these changes results in a high mortality and urgent parathyroidectomy may be required if the PTH is excessively high.

Treatment

Medical treatment of secondary hyperparathyroidism includes dietary phosphate restriction, calcium and vitamin D supplementation. Cinacalcet is not recommended except in patients unfit for surgery. Surgery is indicated when there is an excessive rise in the calcium/phosphate product and serum PTH. Patients are prepared with high-dose vitamin D (calcitriol) to reduce the severity of the profound hypocalcaemia which would otherwise follow parathyroidectomy. Preoperative dialysis is obligatory.

Operative strategy

Multiple-gland disease is usual although occasionally hyperparathyroidism secondary to single-gland disease is the cause rather than the consequence of renal failure. Options for management include total parathyroidectomy (Figure 51.52), total parathyroidectomy with autotransplantation of 50 mg parathyroid tissue into the brachioradialis or subtotal parathyroidectomy. The
latter is preferred if renal transplantation is likely. Transcervical thymectomy is indicated. Even after subtotal parathyroidectomy or autotransplantation postoperative hypocalcaemia is inevitable. Preoperative preparation and oral calcitriol and calcium are mandatory. Intravenous calcium and magnesium are often required.

**Parathyroid carcinoma**

Cancer of the parathyroid is rare accounting for 1 per cent of cases of hyperparathyroidism. Typical features are very high calcium and PTH levels often with a palpable neck swelling or occasionally lymphadenopathy. Scanning may support the diagnosis (Figure 51.59). The diagnosis is rarely known at the time of exploration but, if suspected, operation should include excision of the tumour mass with en bloc thyroid lobectomy and node dissection when indicated. The diagnosis is difficult to make histologically and may only become apparent when recurrent disease presents with hypercalcaemia, increased serum PTH and evidence of local recurrence. Adjuvant or palliative radiotherapy may be indicated and overall survival as in most endocrine cancers is reasonable with 85 per cent five-year survival.

**Persistent hyperparathyroidism**

The first operation is the best opportunity to cure hyperparathyroidism surgically and when competently performed should be successful in more than 95 per cent of procedures. If hypercalcaemia persists after a first neck exploration the diagnosis, preoperative investigations, operative findings and pathology must be reviewed carefully. Referral to a specialist centre is prudent. If reoperation is appropriate, further investigation is required to localise the abnormal parathyroid tissue, usually a missed adenoma. This may be readily apparent but can require a combination of ultrasound, sestamibi, CT, MRI, PET, selective angiography (Figure 51.60) and venous sampling for PTH. The latter may be difficult to interpret if normal venous drainage has been disrupted by previous operations.

When the site of an ectopic or missed adenoma is accurately identified, a second operation can be straightforward when performed through intact tissue planes. Re-exploration through previously explored tissues is more difficult and increases the risks to the recurrent laryngeal nerves and of postoperative hypocalcaemia.

**Recurrent hyperparathyroidism**

Recurrent hyperparathyroidism is diagnosed when hypercalcaemia recurs more than 12 months after an initially curative operation. This may occur due to:

- missed pathology at the first operation;
- (rarely) development of a second adenoma;
- hyperplasia in autotransplanted tissue;
- parathyromatosis (disseminated nodules of parathyroid tissue within the soft tissues of the neck and superior mediastinum caused by rupture of abnormal parathyroid tissue at initial surgery).

Reoperative parathyroid surgery is associated with an increased risk of recurrent laryngeal nerve injury and postoperative hypocalcaemia.

**HYPOPARATHYROIDISM**

While there are rare congenital (DiGeorge) and medical (autoimmune polyglandular and Wilson) syndromes causing hypoparathyroidism, for practical purposes postoperative
hypo-parathyroidism is the dominant management issue in surgical practice. This results from removal, trauma or devascularisation of the parathyroid glands which may be deliberate but is more often inadvertent.

**Symptoms and signs**

The symptoms and signs of acute hypoparathyroidism are related to the level of serum calcium and range through mild circumoral and digital numbness and paraesthesia, to tetanic symptoms with carpopedal or laryngeal spasms, cardiac arrhythmia and fits. Chronic hypoparathyroidism can lead to abnormal bone demineralisation, cataracts, calcification in basal ganglia and consequent extrapyramidal disorders.

Percussion of the facial nerve just below the zygoma causes contraction of the ipsilateral facial muscles (Chvostek’s sign). Carpopedal spasm can be induced by occlusion of the arm with a blood pressure cuff for 3 minutes (Trousseau’s sign). Electrocardiogram changes include prolonged QT intervals and QRS complex changes.

**Treatment**

Acute symptomatic hypocalcaemia is a medical emergency and requires urgent correction by intravenous injection of calcium. Magnesium supplements may also be required. Oral calcium supplements (1g three or four times daily) supplemented by 1–3 µg of 1-alpha-vitamin D if necessary should be given with a view to gradual withdrawal over the next 3–12 months. Lesser degrees of asymptomatic hypocalcaemia 1.90–2.10 mmol/L can be treated with oral calcium supplements of 3–4 g calcium per day in divided doses (Summary box 51.8).

**FURTHER READING**

ADRENAL GLANDS

Anatomy
The weight of a normal adrenal gland is approximately 4 g. There are two distinct components to the gland: the inner adrenal medulla and the outer adrenal cortex (Figure 52.1). The adrenal glands are situated near the upper poles of the kidneys, in the retroperitoneum, within Gerota’s capsule. The right adrenal gland is located between the right liver lobe and the diaphragm, close to and partly behind the inferior vena cava. The left adrenal gland lies close to the upper pole of the left kidney and the renal pedicle. It is covered by the pancreatic tail and the spleen (Figure 52.2). The adrenal glands are well supplied by blood vessels. The arterial blood supply branches from the aorta and the diaphragmatic and renal arteries and varies considerably. A large adrenal vein drains on the right side into the vena cava and on the left side into the renal vein.

Embryology
The two functional parts, the cortex and the medulla, arise from different blastodermic layers: mesodermal cells form the adrenal cortex and neuroectodermal cells migrate to the cortex from the neural crest during embryogenesis and form the adrenal medulla.

Histology
The adrenal cortex is arranged in a zonal configuration. The outer zona glomerulosa contains small, compact cells. The central zona fasciculata can be identified by larger, lipid-rich cells, which are arranged in radial columns. Compact and pigmented cells characterise the inner zona reticularis. The adrenal medulla consists of a thin layer of large chromaffin cells, which synthesise, store and secrete catecholamine.

Figure 52.1 Cross-section of a normal adrenal gland. The inner, very thin layer between the two dark lines (zona reticularis) is the adrenal medulla.

Figure 52.2 Position of the adrenal glands (hatched) in the retroperitoneum.
Function of the adrenal glands
The adrenal glands play a pivotal role in the response to stress. Catecholamines are secreted by the adrenal medulla and corticosteroids, aldosterone and cortisol are synthesised in the adrenal cortex. Cells of the adrenal medulla synthesise mainly adrenaline (epinephrine) but also noradrenaline (norepinephrine) and dopamine. These catecholamines act as hormones as they are secreted directly into the circulation. Their effects, which are mediated through α and β receptors on target organs, include the cardiovascular system, resulting in an increase in blood pressure and heart rate; vasoconstriction of vessels in the splanchnic system and vasodilatation of vessels in the muscles; bronchodilatation; and increased glycolysis in liver and muscles: all necessary for the flight/fight response. Cells of the zona glomerulosa produce aldosterone, which regulates sodium–potassium homeostasis. The target organs of aldosterone are the kidneys, the sweat and salivary glands and the intestinal mucosa. Aldosterone promotes sodium retention and potassium excretion. The most important regulators of aldosterone secretion are the renin–angiotensin system and the serum potassium concentration. Renin produced by the juxtaglomerular cells in the kidneys acts on its substrate angiotensinogen to generate angiotensin I. Angiotensin I is converted by angiotensin-converting enzyme (ACE) to the octapeptide angiotensin II, which is modified to angiotensin III. Both stimulate the secretion of aldosterone from the adrenal cortex. A decrease in renal blood flow (haemorrhage, dehydration, salt depletion, orthostasis, renal artery stenosis) or hypernatraemia increases renin secretion and leads to sodium retention, potassium excretion and an increase of plasma volume.

Cells of the zona fasciculata and zona reticularis synthesise cortisol and the adrenal androgens dehydroepiandrosterone (DHEA) and its sulphate (dehydroepiandrosterone sulphate (DHEAS)). DHEA and DHEAS are precursors of androgens and are converted in peripheral tissues such as fat. Cortisol secretion is regulated by adrenocorticotropic hormone (ACTH), which is produced by the anterior pituitary gland. The hypothalamus controls ACTH secretion by secreting corticotropin-releasing hormone (CRH). The serum cortisol level inhibits the release of CRH and ACTH via a closed-loop system (negative feedback loop).

Cortisol has numerous metabolic and immunological effects. It increases gluconeogenesis and lipolysis, decreases peripheral glucose utilisation, immunological response and muscular mass. It affects fat distribution, wound healing and bone mineralisation; and alters mood (euphoria or, rarely, depression) and cortical alertness.

DISORDERS OF THE ADRENAL CORTEX

Incidentaloma
Definition
Incidentaloma is an adrenal mass, detected incidentally by imaging studies conducted for other reasons, not known previously to have been present or causing symptoms.

Incidence
The prevalence of adrenal masses in autopsy studies ranges from 1.4 to 8.7 per cent and increases with age. Incidentalomas may be detected on imaging studies in 1 per cent of patients. More than 75 per cent are non-functioning adenomas but Cushing’s adenomas, phaeochromocytomas, metastases, adrenocortical carcinomas and Conn’s tumours can all be found this way (Table 52.1).

Diagnosis
When an incidentaloma is identified, a complete history and clinical examination are required. Occasionally, a previously occult endocrine disturbance will come to light. A biochemical work-up for hormone excess is needed and sometimes additional imaging studies are also required. The main goal is to exclude a functioning or malignant adrenal tumour.

Hormonal evaluation includes:
- morning and midnight plasma cortisol measurements;
- a 1-mg overnight dexamethasone suppression test;
- 24-hour urinary cortisol excretion;
- 12 or 24-hour urinary excretion of metanephrines or plasma-free metanephrines;
- serum potassium, plasma aldosterone and plasma renin activity;
- serum DHEAS, testosterone or 17-hydroxyestradiol (virilising or feminising tumour).

Computed tomography (CT) or magnetic resonance imaging (MRI) should be performed in all patients with adrenal masses. The likelihood of an adrenal mass being an adrenocortical carcinoma increases with the size of the mass (25 per cent >4 cm). Adrenal metastases are likely in patients with a history of cancer elsewhere and the sole indications for biopsy of an adrenal mass is to confirm a suspected metastasis from a distant primary site (Summary box 52.1).

Summary box 52.1
Adrenal gland biopsy
- Never biopsy an adrenal mass until phaeochromocytoma has been biochemically excluded
- The indication for adrenal gland biopsy is to confirm adrenal gland metastasis

Harvey Williams Cushing. 1869–1939, Professor of Surgery, Harvard University Medical School, Boston, MA, USA.
Treatment
The treatment of functional adrenal tumours is described below. Any non-functioning adrenal tumour greater than 4 cm in diameter and smaller tumours that increase in size over time should undergo surgical resection. Non-functioning tumours smaller than 4 cm should be followed-up after 6, 12 and 24 months by imaging (MRI) and hormonal evaluation.

Primary hyperaldosteronism – Conn’s syndrome
Incidence
Primary hyperaldosteronism (PHA) is defined by hypertension, as a result of hypersecretion of aldosterone. In PHA, plasma renin activity is suppressed. Among patients with hypertension the incidence of PHA is approximately 2 per cent. Recent studies have revealed that up to 12 per cent of hypertensive patients have PHA with normal potassium levels, thus potassium levels are an inconsistent diagnostic feature of this disease, and cannot be relied on to confirm or exclude it.

Pathology
The most frequent cause of PHA with hypokalaemia is a unilateral adrenocortical adenoma (Figure 52.3). In 20–40 per cent of cases, bilateral micronodular hyperplasia is present. Rare causes of PHA are bilateral macronodular hyperplasia, glucocorticoid-suppressible hyperaldosteronism or adrenocortical carcinoma. In the subset of patients with normokalaemic PHA, 70 per cent have hyperplasia and 30 per cent unilateral adenoma.

Clinical features
Most patients are between 30 and 50 years of age with a female predominance. Apart from hypertension, patients complain of non-specific symptoms: headache, muscle weakness, cramps, intermittent paralysis, polyuria, polydypsia and nocturia.

Diagnosis
The key feature of the biochemical diagnosis is the assessment of potassium level and the aldosterone to plasma renin activity ratio. Antihypertensive and diuretic therapy, which cause hypokalaemia and influence the renin–angiotensin–aldosterone system, have to be discontinued. Once the biochemical diagnosis is confirmed, MRI or CT should be performed to distinguish unilateral from bilateral disease. Conn’s adenomas usually measure between 1 and 2 cm and are detected by CT with a sensitivity of 80–90 per cent (Figure 52.4). Micronodular changes and small adenomas are often undiagnosed. An apparent unilateral mass could be a non-functioning tumour in a patient with bilateral micronodular hyperplasia. Selective adrenal vein catheterisation can help before a decision on non-surgical or surgical treatment is made. During selective adrenal vein catheterisation, samples are obtained from the vena cava and from both adrenal veins and the aldosterone to cortisol ratio (ACR) is determined in each sample. A significant difference in the ACR ratio on one side indicates unilateral disease.

Treatment
The first-line therapy for PHA with bilateral hyperplasia is medical treatment with spironolactone. In most cases supplemental antihypertensive medication is necessary.
Unilateral laparoscopic adrenalectomy is an effective therapy in patients with clear evidence of unilateral or asymmetrical bilateral disease. A subtotal resection can be considered in the case of a typical single Conn’s adenoma. In 10–30 per cent of patients who undergo an adrenalectomy, hypertension persists despite adequate diagnostic work-up and treatment, albeit at a lower level, requiring fewer medications to control it.

Cushing’s syndrome
Definition
Hypersecretion of cortisol caused by endogenous production of corticosteroids is known as Cushing’s syndrome. It can be either ACTH-dependent or ACTH-independent in origin. The most common cause (85 per cent) of ACTH-dependent Cushing’s syndrome is Cushing’s disease resulting from a pituitary adenoma that secretes an excessive amount of ACTH. Ectopic ACTH-producing tumours (small cell lung cancer,
foregut carcinoid) and CRH-producing tumours (medullary thyroid carcinoma, neuroendocrine pancreatic tumour) are more infrequent causes of ACTH-dependent Cushing’s syndrome. Excessive or prolonged administration of cortisol-like drugs will produce the same clinical picture.

In about 15 per cent of patients, an ACTH-independent Cushing’s syndrome (low ACTH levels) is caused by a unilateral adrenocortical adenoma. Adrenocortical carcinoma and bilateral macronodular or micronodular hyperplasia represent rare causes of hypercortisolism.

**Clinical symptoms**

The clinical features of Cushing’s syndrome are shown in Summary box 52.2. The typical patient is characterised by a facial plethora, a buffalo hump and a moon face in combination with hypertension, diabetes and central obesity (Figures 52.5 and 52.6). However, clinical signs can be minimal or absent in patients with subclinical Cushing’s syndrome.

### Summary box 52.2

**Clinical features of Cushing’s syndrome**

- Weight gain/central obesity
- Diabetes
- Hirsutism
- Hypertension
- Skin changes (abdominal striae, facial plethora, ecchymosis, acne)
- Muscle weakness
- Menstrual irregularity/impotence
- Depression/mania
- Osteoporosis
- Hypokalaemia

---

**Diagnosis**

- Morning and midnight plasma cortisol levels are elevated, possibly with loss of diurnal rhythm.
- Dexamethasone fails to suppress 24-hour urinary cortisol excretion.
- Serum ACTH levels discriminate ACTH-dependent from ACTH-independent disease.

Elevated or normal ACTH levels provide evidence for an ACTH-producing pituitary tumour (85 per cent) or ectopic ACTH production. Therefore, in patients with elevated ACTH, MRI of the pituitary gland must be performed. If MRI is negative and additional venous sampling from the inferior petrosal sinus has excluded a pituitary microadenoma, a CT scan of the chest and abdomen is warranted to detect an ectopic ACTH-producing tumour. In patients with suppressed ACTH levels, a CT or MRI scan is performed to assess the adrenal glands.

Subclinical Cushing’s syndrome is diagnosed if clinical symptoms are absent in the face of abnormal cortisol secretion.

**Treatment**

Medical therapy with metyrapone or ketoconazole reduces steroid synthesis and secretion and can be used to prepare patients with severe hypercortisolism preoperatively or if surgery is not possible. ACTH-producing pituitary tumours are treated by trans-sphenoidal resection or radiotherapy. If an ectopic ACTH source is localised, resection will correct hypercortisolism.

A unilateral adenoma is treated by adrenalectomy. In cases of bilateral ACTH-independent disease (Figure 52.7), bilateral adrenalectomy is the primary treatment. Patients with an ectopic ACTH-dependent Cushing’s syndrome and an irremovable or unlocalised primary tumour should be considered for bilateral adrenalectomy as this controls hormone excess. Subclinical Cushing’s syndrome caused by unilateral adenoma is treated by unilateral adrenalectomy.

**Preoperative management**

Patients with Cushing’s syndrome are at an increased risk of hospital-acquired infection, thromboembolic and myocardial...
Complications. Therefore, prophylactic anticoagulation and the use of prophylactic antibiotics are essential. Cushing-associated diseases (diabetes, hypertension) must be controlled by medical therapy preoperatively.

Postoperative management

After unilateral adrenalectomy supplemental cortisol should be given postoperatively because the contralateral gland will be suppressed. In total, 15 mg/hour is required parenterally for the first 12 hours followed by a daily dose of 100 mg for 3 days, which is gradually reduced thereafter. After unilateral adrenalectomy, the contralateral suppressed gland needs up to one year to recover adequate function. In 10 per cent of patients with Cushing’s disease who undergo a bilateral adrenalectomy after failed pituitary surgery, the pituitary adenoma causes Nelson’s syndrome due to continued ACTH secretion at high levels, causing hyperpigmentation as a result of chemical synergies between ACTH and melanocyte-stimulating hormone.

Adrenal metastases

Adrenal metastases are discovered at autopsy in one-third of patients with malignant disease (less frequently during life). In declining frequency, the most common primary tumours are breast, lung, renal, gastric, pancreatic, ovarian and colorectal cancer. In selected circumstances an adrenalectomy is appropriate, for example if it is the sole site of metastatic disease.

Adrenocortical carcinoma

Incidence

Adrenocortical carcinoma is a rare malignancy with an incidence of 1–2 cases per 1,000,000 population per year and a variable but generally poor prognosis. A slight female predominance is observed (1.5:1). The age distribution is bimodal with a first peak in childhood and a second between the fourth and fifth decades.

Pathology

The differentiation between benign and malignant adrenal tumours is challenging, even in the hands of an experienced pathologist. Criteria for malignancy are tumour size, the presence of necrosis or haemorrhage and microscopic features such as capsular or vascular invasion. These should be assessed in terms of a microscopic diagnostic score. Additional information is provided by immunohistochemistry. The macroscopic features are commonly multinodularity and heterogeneous structure (see Figure 52.8) with haemorrhage and necrosis.

Clinical presentation

Approximately 60 per cent of patients present with evidence of cortisol excess (Cushing’s syndrome). Patients with non-functioning tumours frequently complain of abdominal discomfort or back pain caused by large tumours. However, with increasing use of abdominal imaging, a growing number of adrenocortical carcinomas are detected incidentally. Adrenal tumours secreting more than one hormone in excess, or feminising/masculanising steroids are likely to be malignant.

Diagnosis

The diagnostic work-up should include measurements of DHEAS, cortisol and catecholamines to exclude a phaeochromocytoma and a dexamethasone suppression test. MRI and CT are equally effective in imaging adrenocortical carcinoma (Figure 52.9). MRI angiography is useful to exclude tumour thrombus in the vena cava. As distant metastases are frequently present, a CT scan of the lungs is recommended. The World Health Organization classification of 2004 is based on the McFarlane classification and defines four stages: tumours <5 cm (stage I) or >5 cm (stage II), locally invasive tumours (III) or tumours with distant metastases (IV). Functioning tumours tend to do worse than non-functioning, but have the advantage of a serum marker which can be used for follow up and disease monitoring.

Treatment

Complete tumour resection (R0) is associated with favourable survival and should be attempted whenever possible. In order to prevent tumour spillage and implantation metastases, the capsule must not be damaged. En bloc resection with removal of locally involved organs is often required and in case of tumour thrombus in the vena cava thrombectomy is needed. Laparoscopic adrenalectomy is associated with a high incidence of local recurrence.

Figure 52.7 Bilateral asymmetrical hyperplasia of the adrenal glands (arrows) in a patient with Cushing’s syndrome.

Figure 52.8 Adrenocortical carcinoma that caused Cushing’s syndrome and virilisation in a female patient.
and cannot be recommended. Tumour debulking plays a role in functioning tumours to control hormone excess.

Patients can be treated postoperatively with mitotane alone or in combination with etoposide, doxorubicin and cisplatin. Adjuvant radiotherapy may reduce the rate of local recurrence. After surgery, restaging every three months is required as the risk of tumour relapse is high. Prognosis depends on the stage of disease and complete removal of the tumour. Patients with stage I or II disease have a five-year survival rate of 25 per cent whereas patients with stage III and stage IV disease have five-year survival rates of 6 and 0 per cent, respectively.

**Congenital adrenal hyperplasia (adrenogenital syndrome)**

Virilisation and adrenal insufficiency in children are pathognomonic of congenital adrenal hyperplasia (CAH). This is an autosomal recessive disorder caused by a variety of enzymatic defects in the synthetic pathway of cortisol and other steroids from cholesterol. The most frequent defect (95 per cent) is the 21-hydroxylase deficiency, which has an incidence of 1 in 5000 live births. Excessive ACTH secretion is caused by the loss of cortisol and this leads to an increase in androgenic precursors and to ACTH secretion and is caused by therapeutic glucocorticoid administration, brain tumour or irradiation.

**Acute adrenal insufficiency**

Acute adrenal insufficiency usually presents as shock in combination with fever, nausea, vomiting, abdominal pain, hypoglycaemia and electrolyte imbalance. The Waterhouse–Friderichsen syndrome is a bilateral adrenal infarction associated with meningococcal sepsis and is rapidly fatal unless immediately treated. Because of intestinal symptoms and fever, the so-called Addisonian crisis is often misdiagnosed as an acute abdominal condition.

**Chronic adrenal insufficiency**

When symptoms develop over time, patients present with anorexia, weakness and nausea. As a result of negative feedback, ACTH and pro-opiomelanocortin (POMC) levels increase and cause hyperpigmentation of the skin and oral mucosa. Hypotension, hyponatraemia, hyperkalaemia and hypoglycaemia are commonly observed. The diagnosis of adrenal insufficiency is made using the ACTH stimulation test. Basal ACTH levels are found to be high with cortisol levels decreased. There is no rise in cortisol levels following the exogenous administration of ACTH (synacthen test).

**Treatment**

If a patient displays features of adrenal insufficiency, treatment must immediately be commenced, before awaiting the biochemical diagnosis. Initial blood samples can be used for later determinations of ACTH and cortisol levels. In addition to intravenous administration of hydrocortisone, 100 mg every 6 hours, 3 litres of saline is given in 6 hours under careful cardiovascular monitoring. Concomitant infections, which are frequently present, require treatment.

Chronic adrenal insufficiency is treated by replacement therapy with daily oral hydrocortisone (10 mg/m² body surface area) and fludrocortisone (0.1 mg). Patients must be advised about the need to take lifelong glucocorticoid and mineralocorticoid replacement therapy. To prevent an Addisonian crisis, patients must be aware of the need to increase the dose in case of illness or stress. If patients with adrenal insufficiency are scheduled for surgery, appropriate steroid cover must be administered.

DISORDERS OF THE ADRENAL MEDULLA AND NEURAL CREST-DERIVED TISSUE

Phaeochromocytoma and paraganglioma

**Definition**
These are tumours of the adrenal medulla and sympathetic ganglia which are derived from chromaffin cells and which produce catecholamines.

**Aetiology**
The prevalence of phaeochromocytoma in patients with hypertension is 0.1–0.6 per cent with an overall prevalence of 0.05 per cent in autopsy series. In total, 4 per cent of incidentalomas are phaeochromocytomas. Sporadic phaeochromocytomas occur around the fourth decade whereas patients with hereditary forms are diagnosed earlier. Phaeochromocytoma is known as the '10 per cent tumour' as 10 per cent of tumours are inherited, 10 per cent are extra-adrenal, 10 per cent are malignant, 10 per cent tumour' as 10 per cent of tumours are inherited, 10 per cent in patients with hyperplasia, sometimes bilateral. Phaeochromocytoma is rarely malignant in MEN 2.

Hereditary phaeochromocytomas occur in several tumour syndromes:
- **Multiple endocrine neoplasia type 2 (MEN 2):** an autosomal dominant inherited disorder that is caused by activating germline mutations of the RET proto-oncogene.
- **Familial paraganglioma (PG) syndrome:** glomus tumours of the carotid body and extra-adrenal paraganglioma are characteristic in this hereditary tumour syndrome, which is caused by germline mutations within the succinate dehydrogenase complex subunit B (SDHB) SDHD and SDHC genes.
- **von Hippel–Lindau (VHL) syndrome:** those affected can develop early-onset bilateral kidney tumours, phaeochromocytomas, cerebellar and spinal haemangioblastomas and pancreatic tumours. Patients have a germline mutation in the VHL gene.
- **Neurofibromatosis (NF) type 1:** phaeochromocytomas in combination with fibromas on the skin and mucosae (café-au-lait skin spots) are indicative of a germline mutation in the NF1 gene.

![Gross appearance of a phaeochromocytoma.](image)

**Pathology**
Phaeochromocytomas are greyish-pink on the cut surface and are usually highly vascularised. Areas of haemorrhage or necrosis are often observed (Figure 52.10). Microscopically, tumour cells are polygonal but the configuration varies considerably. The differentiation between malignant and benign tumours is difficult, except if metastases are present. An increased PASS (phaeochromocytoma of the adrenal gland scale score), a high number of Ki-67-positive cells, vascular invasion or a breached capsule all lean more towards malignant rather than benign.

Phaeochromocytomas may also produce calcitonin, ACTH, vasoactive intestinal polypeptide (VIP) and parathyroid hormone-related protein (PTHrP). In patients with MEN 2, the onset of phaeochromocytoma is preceded by adrenomedullary hyperplasia, sometimes bilateral. Phaeochromocytoma is rarely malignant in MEN 2.

**Clinical features**
Symptoms and signs are caused by catecholamine excess and are typically intermittent (Table 52.2). In total, 90 per cent of patients with the combination of headache, palpitations and sweating have a phaeochromocytoma. Paroxysms may be precipitated by physical training, induction of general anaesthesia and numerous drugs and agents (contrast media, tricyclic antidepressive drugs, metoclopramide and opiates). Hypertension may occur continuously, be intermittent or absent. A subset of patients are asymptomatic. More than 20 per cent of apparently sporadic phaeochromocytomas are caused by germline mutations in the RET, SDHB, SDHC, SDHD and NF1 genes; genetic testing for these genes is therefore recommended, particularly in those aged under 50 years.

**Diagnosis**
The first step in the diagnosis of a phaeochromocytoma is the determination of adrenaline and noradrenaline breakdown products, metanephrine and normetanephrine level, in a 12- or 24-hour urine collection. Levels that exceed the normal range by 2–40 times will be found in affected patients. Determination of plasma-free metanephrine and normetanephrine levels also
Disorders of the adrenal medulla and neural crest-derived tissue 785

has a high sensitivity. Biochemical tests should be performed at least twice. The biochemical diagnosis is followed by the localisation of the phaeochromocytoma. MRI is preferred because contrast media used for CT scans can provoke paroxysms. Classically, phaeochromocytomas show a 'Swiss cheese' configuration (Figure 52.11). \(^{131}\)I-MIBG (metaiodobenzylguanidine) single-photon emission computed tomography (SPECT) will identify about 90 per cent of primary tumours and is essential for the detection of multiple extra-adrenal tumours and metastases (Figure 52.12). PET scanning using FDG PET or DOPA PET is yet more sensitive in detecting metastatic foci.

**Treatment**

Laparoscopic resection is now routine in the treatment of phaeochromocytoma. If the tumour is larger than 8–10 cm or radiological signs of malignancy are detected, an open approach should be considered.

**Preoperative**

Once a phaeochromocytoma has been diagnosed, an α-adrenoreceptor blocker (phenoxybenzamine) is used to block catecholamine excess and its consequences during surgery. With adequate medical pretreatment, the perioperative mortality rate has decreased from 20–45 per cent to less than 3 per cent. A dose of 20 mg of phenoxybenzamine initially should be increased daily by 10 mg until a daily dose of 100–160 mg is achieved and the patient reports symptomatic postural hypotension. Additional β-blockade is required if tachycardia or arrhythmias develop; this should not be introduced until the patient is α-blocked.

With adequate α-blockade preoperatively, anaesthesia should not be more hazardous than in patients with a non-functioning adrenal tumour; however, in some patients, dramatic changes in heart rate and blood pressure may occur and require sudden administration of pressor or vasodilator agents. A central venous catheter and invasive arterial monitoring are used. Special attention is required when the adrenal vein is ligated as a sudden drop in blood pressure may occur. The infusion of large volumes of fluid or administration of noradrenaline can be necessary to correct postoperative hypotension in the presence of unopposed α-blockade.

**Postoperative**

Patients should be observed for 24 hours in the intensive care or high dependency unit as hypovolaemia and hypoglycaemia may occur. Lifelong yearly biochemical tests should be performed to identify recurrent, metastatic or metachronous phaeochromocytoma (Summary box 52.4).

---

**Malignant phaeochromocytoma**

**Definition**

Approximately 10 per cent of phaeochromocytomas are malignant. This rate is higher in extra-adrenal tumours (paragangliomas). The diagnosis of malignancy implies metastases of chromaffin tissue, most commonly to lymph nodes, bone and liver.

**Treatment**

Surgical excision is the only chance for cure. Even in patients with metastatic disease, tumour debulking can be considered to reduce the tumour burden and to control the catecholamine excess. Symptomatic treatment can be obtained with α-blockers. Mitotane should be started as adjuvant or palliative treatment. Treatment with \(^{131}\)I-MIBG or combination chemotherapy has resulted in a partial response in 30 per cent and an improvement of symptoms in 80 per cent of patients. The natural history is highly variable with a five-year survival rate of less than 50 per cent.

**Phaeochromocytoma in pregnancy**

Phaeochromocytomas in pregnancy may imitate an amniotic infection syndrome or pre-eclampsia. Without adequate α-blockade,

---

**Summary box 52.4**

**Phaeochromocytoma**

- Obtain a secure biochemical diagnosis
- Exclude family history
- Diagnosis confirmed, treat with α-blockers
- Plan surgical excision
- Yearly lifelong follow up

**Malignant phaeochromocytoma**

**Definition**

Approximately 10 per cent of phaeochromocytomas are malignant. This rate is higher in extra-adrenal tumours (paragangliomas). The diagnosis of malignancy implies metastases of chromaffin tissue, most commonly to lymph nodes, bone and liver.

**Treatment**

Surgical excision is the only chance for cure. Even in patients with metastatic disease, tumour debulking can be considered to reduce the tumour burden and to control the catecholamine excess. Symptomatic treatment can be obtained with α-blockers. Mitotane should be started as adjuvant or palliative treatment. Treatment with \(^{131}\)I-MIBG or combination chemotherapy has resulted in a partial response in 30 per cent and an improvement of symptoms in 80 per cent of patients. The natural history is highly variable with a five-year survival rate of less than 50 per cent.

**Phaeochromocytoma in pregnancy**

Phaeochromocytomas in pregnancy may imitate an amniotic infection syndrome or pre-eclampsia. Without adequate α-blockade,
mother and unborn child are threatened by hypertensive crisis during delivery. In the first and second trimesters, the patient should be scheduled for laparoscopic adrenalectomy after adequate β-blockade; the risk of a miscarriage during surgery is high. In the third trimester, elective Caesarean with consecutive adrenalectomy should be performed. The maternal mortality rate is 30 per cent when a phaeochromocytoma remains undiagnosed.

**Neuroblastoma**

**Definition**
A neuroblastoma is a malignant tumour that is derived from the sympathetic nervous system in the adrenal medulla (38 per cent) or from any site along the sympathetic chain in the paravertebral sites of the abdomen (30 per cent), chest (20 per cent) and, rarely, the neck or pelvis.

**Pathology**
Neuroblastomas have a pale and grey surface, are encapsulated and show areas with calcification. With increased tumour size, necrosis and haemorrhage may be detected. They are characterised by the presence of immature cells derived from the neuroectoderm of the sympathetic nervous system. Mature cells are found only in ganglioneuroblastomas.

**Clinical features**
Predominantly, newborn infants and young children (<5 years of age) are affected. Symptoms are caused by tumour growth or by bone metastases. Patients present with a mass in the abdomen, neck or chest, proptosis, bone pain, painless bluish skin metastases, weakness or paralysis. Metastatic disease is present in 70 per cent of patients at presentation.

**Diagnosis**
Biochemical evaluation should include urinary excretion (24-hour urine) of vanillylmandelic acid (VMA), homovanillic acid (HVA), dopamine and noradrenaline, as increased levels are present in about 80 per cent of patients. Accurate staging requires CT/MRI of the chest and abdomen, a bone scan, bone marrow aspiration and core biopsies as well as an MIBG scan. Staging is established according to the International Neuroblastoma Staging System (INSS).

**Treatment**
Prognosis can be predicted by the tumour stage and the age at diagnosis. Patients are classified as low, intermediate or high risk. Low-risk patients are treated by surgery alone (the addition of 6–12 weeks of chemotherapy is optional) whereas intermediate-risk patients are treated by surgery with adjuvant multiagent chemotherapy (carboplatin, cyclophosphamide, etoposide, doxorubicin). High-risk patients receive high-dose multiagent chemotherapy followed by surgical resection in responding tumours and myeloablative stem cell rescue. Patients assigned to the low-risk, intermediate-risk and high-risk groups have overall three-year survival rates of 90, 70–90 and 30 per cent, respectively.

**Ganglioneuroma**

**Definition**
A ganglioneuroma is a benign neoplasm that arises from neural crest tissue. Ganglioneuromas can occur in the adrenal medulla and are characterised by mature sympathetic ganglion cells and Schwann cells in a fibrous stroma.

**Clinical features**
Ganglioneuroma is found in all age groups but is more common before the age of 60. Ganglioneuromas occur anywhere along the paravertebral sympathetic plexus and in the adrenal medulla (30 per cent). Most often they are identified incidentally by CT or MRI performed for other indications.

**Treatment**
Treatment is by surgical excision, laparoscopic when adrenalectomy is indicated.

**SURGERY OF THE ADRENAL GLANDS**

Since its introduction in the 1990s, laparoscopic or retroperitoneoscopic adrenalectomy has become the ‘gold standard’ in the resection of adrenal tumours, except for tumours with signs of malignancy. The more popular approach is the laparoscopic transperitoneal approach, which offers a better view of the adrenal region than open surgery. The advantage of the retroperitoneoscopic approach is the minimal dissection required by this extra-abdominal procedure. In the case of small, bilateral tumours or in patients with hereditary tumour syndromes a subtotal resection is warranted, to avoid steroid dependence. The mortality rate ranges from 0 to 2 per cent in specialised centres.

An open approach should be considered if radiological signs, distant metastases, large tumours (>8–10 cm) or a distinct hormonal pattern suggest malignancy.

**Laparoscopic adrenalectomy**
Knowledge of the anatomy of the adrenal region is essential as anatomical landmarks guide the surgeon during operation. If these landmarks are respected, injury to the vena cava or renal vein, the pancreatic tail or the spleen can be avoided. Careful haemostasis is essential as small amounts of blood can impair the surgeon’s view. To prevent tumour spillage, direct grasping of the adrenal tissue/tumour has to be avoided.

**Right adrenalectomy**
Position the patient right side up, with table brake. Use three ports to start. The dissection starts at the level of the periadrenal fat using careful coagulation and the peritoneum should be divided 2 cm below the edge of the liver from medial (inferior vena cava) to the lateral abdominal wall (Figure 52.13). This flap of peritoneum can then be used to retract the liver up and off the adrenal. A fourth port may be useful to hold the liver up. Identify the gland and mobilise gently, securing the vein with a clip or using one of the available energy devices, and remove the gland in a plastic catch bag.

**Left adrenalectomy**
With the patient positioned on his or her right side, mobilisation of the spleen will displace the pancreatic tail medially. The incision of Gerota’s fascia is followed by identification of the adrenal vein, which runs into the renal vein in the space between the medial aspect of the kidney and the posterior aspect of the pancreatic tail. The resection is completed by mobilising...
the adrenal gland at the level of the periadrenal fat. Remove the gland in a bag and close the three port sites after infiltrating each with local anaesthesia.

**Retroperitoneoscopic adrenalectomy**

The first port is placed at the distal end of the 12th rib with the patient in the prone position. After a digital dissection into the retroperitoneum, Gerota’s fascia is displaced ventrally. The right adrenal vein is covered by the retrocaval posterior aspect of the adrenal gland. The left adrenal vein is usually located at the medial inferior pole of the adrenal gland. High inflation pressures allow bloodless dissection effectively tamponading the veins. Being outside the abdominal cavity affords an excellent view.

**Open adrenalectomy**

An open adrenalectomy is almost exclusively performed when a malignant adrenal tumour is suspected. On the right side, the hepatic flexure of the colon is mobilised and the right liver lobe is cranially retracted to achieve an optimal exposure of the inferior vena cava and the adrenal gland. On the left side, the adrenal gland can be exposed after mobilisation of the splenic flexure of the colon, through the transverse mesocolon or through the gastrocolic ligament. The remaining dissection is the same as in laparoscopic adrenalectomy. A resection of regional lymph nodes is recommended in malignant adrenal tumours and should include resection of the tissue between the renal pedicle and the diaphragm.

**PANCREATIC ENDOCRINE TUMOURS**

**Introduction**

Pancreatic endocrine tumours (PET) represent an important subset of pancreatic neoplasms. They account for 5 per cent of all clinically detected pancreatic tumours. They consist of single or multiple, benign or malignant neoplasms and are associated in 10–20 per cent of cases with multiple endocrine neoplasia type 1 (MEN 1). They present as either functional tumours, causing specific hormonal syndromes, or non-functional tumours, with symptoms similar to those in patients with pancreatic adenocarcinoma. This section focuses on insulinomas, gastrinomas and non-functioning tumours because they represent 90 per cent of all PET (Table 52.3).

**Function of the endocrine pancreas**

The endocrine cells of the pancreas are grouped in the islets of Langerhans, which constitute approximately 1–2 per cent of the mass of the pancreas (Figure 52.14). There are about one million islets in a healthy adult human pancreas and their combined weight is 1–1.5 g. There are four main types of cell in the islets of Langerhans, which can be classified according to their secretions:

1. beta cells producing insulin (65–80 per cent of the islet cells);
2. alpha cells producing glucagon (15–20 per cent);
3. delta cells producing somatostatin (3–10 per cent);
4. pancreatic polypeptide (PP) cells containing polypeptide (1 per cent).

**Insulinoma**

**Definition**

This is an insulin-producing tumour of the pancreas causing the clinical scenario know as Whipple’s triad, i.e. symptoms of hypoglycaemia after fasting or exercise, plasma glucose levels ≤2.8 mmol/L and relief of symptoms on intravenous administration of glucose.

George Hoyt Whipple, 1878–1976, Professor of Pathology, University of Rochester, Rochester, NY, USA, described this disease in 1907. He shared the 1934 Nobel Prize for Physiology or Medicine with George Richards Minot and William Paryy Murphy for their discoveries concerning liver therapy against anaemias.
Incidence
Insulinomas are the most frequent of all the functioning PETs with a reported incidence of 2–4 cases per million population per year. Insulinomas have been diagnosed in all age groups with the highest incidence found in the fourth to the sixth decades. Women seem to be slightly more frequently affected.

Pathology
The aetiology and pathogenesis of insulinomas are unknown. No risk factors have been associated with these tumours. Virtually all insulinomas are located in the pancreas and tumours are equally distributed within the gland. Approximately 90 per cent are solitary and about 10 per cent are multiple and associated with MEN 1 syndrome.

Prognosis and predictive factors
No markers are available that reliably predict the biological behaviour of an insulinoma. Approximately 10 per cent are malignant. Insulinomas of <2 cm in diameter without signs of vascular invasion or metastases are considered benign.

Clinical features
Insulinomas are characterised by fasting hypoglycaemia and neuroglycopenic symptoms. The episodic nature of the hypoglycaemic attacks is caused by intermittent insulin secretion by the tumour. This leads to central nervous system symptoms such as diplopia, blurred vision, confusion, abnormal behaviour and amnesia. Some patients develop loss of consciousness and coma. The release of catecholamines produces symptoms such as sweating, weakness, hunger, tremor, nausea, anxiety and palpitations.

Biochemical diagnosis
A fasting test that may last for up to 72 hours is regarded as the most sensitive test. Usually, insulin, proinsulin, C-peptide and blood glucose are measured in 1- to 2-hour intervals to demonstrate inappropriately high secretion of insulin in relation to blood glucose. About 80 per cent of insulinomas are diagnosed by this test, most of them in the first 24 hours. Elevated C-peptide levels demonstrate the endogenous secretion of insulin and exclude factitious hypoglycaemia caused by insulin injection.

Differential diagnosis
The differential diagnosis of hypoglycaemia includes hormonal deficiencies, hepatic insufficiency, medication, drugs and enzyme defects. Occasionally, differentiating insulinoma from other causes of hypoglycaemia can be difficult. Nesidioblastosis is a rare disorder, mainly encountered in children, which is characterised by replacement of normal pancreatic islets by diffuse hyperplasia of islet cells.

Medical treatment of insulinoma
Medical management is reserved only for patients who are unable or unwilling to undergo surgical treatment or for unresectable metastatic disease. Diazoxide suppresses insulin secretion by direct action on the beta cells and offers reasonably good control of hypoglycaemia in approximately 50 per cent of patients. When surgical options to treat malignant insulinomas cannot be applied, chemotherapeutic options include doxorubicin and streptozotocin.

Surgical treatment of insulinoma
Indications for operation
After a positive fasting test and exclusion of diffuse abdominal metastases by ultrasound or CT scan, all patients should be advised to undergo surgical excision of insulinoma.

Preoperative localisation studies
Intraoperative exploration of the pancreas is the best method to use for localisation of insulinoma, yet the operating surgeon will need preoperative localisation! Insulinomas are detected in about 65 per cent of cases by endoscopic ultrasound (EUS), 33 per cent of cases by CT scan and abdominal ultrasound and 15 per cent of cases by magnetic resonance tomography. Intraoperative ultrasound (IOUS) of the pancreas is a vital tool.
Pancreatic endocrine tumours

Emil Theodor Kocher, 1841–1917, Professor of Surgery, Berne, Switzerland. In 1909 he was awarded the Nobel Prize for Physiology or Medicine for his work on the thyroid.

Robert Milton Zollinger, 1903–1992, Professor of Surgery, Ohio State University, Columbus, OH, USA.

Edwin Homer Ellison, 1918–1970, Professor of Surgery, Marquette University, WI, USA.

Zollinger and Ellison described this condition in a joint paper in 1955 when they were both working at Ohio State University.

after mobilisation of the gland. For preoperative localisation of an insulinoma, EUS has the highest sensitivity and should be used if laparoscopic resection is considered. If no lesion is identified and one can rely on the biochemical tests for diagnosis, laparotomy should follow, using IOUS.

Benign insulinoma

Surgical cure rates in patients with the biochemical diagnosis of insulinoma range from 90 to 100 per cent. At open surgery an extended Kocher manoeuvre and mobilisation of the head and then the distal pancreas is performed to explore the whole gland. IOUS should then be used to confirm the presence of a tumour, to find non-palpable lesions and also to identify the relation of the tumour to the pancreatic duct (Figure 52.15a). Tumour enucleation is the technique of choice (Figure 52.15b).

For superficial tumours, laparoscopic enucleation is undertaken (Figure 52.16). Tumours located deep in the body or tail of the pancreas and those in close proximity to the pancreatic duct require distal pancreatectomy. Postoperatively, blood sugar levels begin to rise in most patients within the first few hours after removal of the tumour. To preserve pancreatic function and reduce the risk of iatrogenic diabetes mellitus, patients in whom tumour localisation is not successful at operation should not undergo blind resection.

Malignant insulinoma

Aggressive attempts at resection are recommended as these tumours are much less virulent than adenocarcinomas.

Gastrinoma (Zollinger–Ellison syndrome)

Definition

Zollinger–Ellison syndrome (ZES) is a condition that includes: (1) fulminating ulcer diathesis in the stomach, duodenum or atypical sites; (2) recurrent ulceration despite ‘adequate’ therapy; and (3) non-beta islet cell tumours of the pancreas (gastrinoma).

Incidence

Gastrinomas account for about 20 per cent of PETs, second in frequency to insulinomas. Approximately 0.1 per cent of patients with duodenal ulcers have evidence of ZES. The reported incidence is between 0.5 and 4 cases per million population per year. ZES is more common in males than in females. The mean age at the onset of symptoms is 38 years, and the range is 7–83 years.

Pathology

The aetiology and pathogenesis of sporadic gastrinomas are unknown. At the time of diagnosis more than 60 per cent of tumours are malignant. Pancreatic gastrinomas are mainly found in sporadic disease; most are found in the head of the pancreas. More than 70 per cent of the gastrinomas in MEN 1 syndrome and most sporadic gastrinomas are located in the first and second part of the duodenum. Therefore, the anatomical area comprising the head of the pancreas, the superior and descending portion of the duodenum and the relevant lymph nodes has been called the ‘gastrinoma triangle’ because it harbours the vast majority of these tumours (Figure 52.17). All patients with gastrinomas should be tested for MEN 1 syndrome.

Prognosis and predictive factors

In general, the progression of gastrinomas is relatively slow with a five-year survival rate of 65 per cent and a ten-year survival rate of 51 per cent. Patients with complete tumour resection have excellent five- and ten-year survival rates (90–100 per cent). Patients with pancreatic tumours have a worse prognosis than those with primary tumours in the duodenum. There is no established marker to predict the biological behaviour of gastrinoma.

Clinical and biochemical features

Over 90 per cent of patients with gastrinomas have peptic ulcer disease, often multiple or in unusual sites. Diarrhoea is another
common symptom, caused by the large volume of gastric acid secretion. Abdominal pain from either peptic ulcer disease or gastro-oesophageal reflux disease (GORD) remains the most common symptom, occurring in more than 75 per cent of patients.

**Biochemical diagnosis**
If the patient presents with a gastric pH below 2.5 and a serum gastrin concentration above 1000 pg/mL (normal <100 pg/mL) then the diagnosis of ZES is confirmed. Unfortunately, the majority of patients have serum gastrin concentrations between 100 and 500 pg/mL and in these patients a secretin test should be performed. The secretin test is considered positive if an increase in serum gastrin of >200 pg/mL over the pretreatment value is obtained; this also rules out other causes of hypergastrinaemia (e.g. atrophic gastritis).

**Differential diagnosis**
The most common misdiagnoses are idiopathic peptic ulcer disease, chronic idiopathic diarrhoea and GORD. Other reasons for hypergastrinaemia are chronic atrophic gastritis, gastric outlet stenosis and retained antrum after gastric resection.

**Medical treatment of gastrinoma**
In most patients with ZES, gastric hypersecretion can be treated effectively with proton pump inhibitors. Octreotide can also help to control acid hypersecretion. Systemic chemotherapy is utilised in patients with diffuse metastatic gastrinomas. Streptozotocin in combination with 5-fluorouracil or doxorubicin is the first-line treatment.

**Surgical treatment of gastrinoma**

**Indications for operation**
Surgical exploration should be performed in all patients without diffuse metastases, to remove known malignant gastrinomas or benign ones.

**Preoperative localisation studies**
Pancreatic gastrinomas are often larger than 1 cm in diameter whereas gastrinomas of the duodenum are usually smaller. Therefore, it is nearly impossible to identify duodenal gastrinomas by preoperative imaging. Pancreatic gastrinomas are detected by EUS in about 80–90 per cent of cases, by CT in 39 per cent of cases and by MRI in 46 per cent of cases. In approximately one-third of patients, the results of conventional imaging studies are negative. On the basis of recent studies, either EUS or CT and somatostatin receptor scintigraphy (SRS) should be performed preoperatively for staging.

**Pancreatic gastrinomas**
Most pancreatic gastrinomas are solitary, located in the head of the gland or uncinate process, and can be identified at operation. Enucleation with peripancreatic lymph node dissection is the procedure of choice. Rarely, tumours are situated in the body or tail and should be treated by enucleation or distal resection. Even if a tumour is found in the pancreas, duodenotomy is recommended to detect additional tumours, if the patient has MEN 1.

**Duodenal gastrinomas**
The duodenum should be opened with a longitudinal incision and the posterior and anterior walls palpated separately (Figure 52.18). Duodenal tumours smaller than 5 mm can be enucleated with the overlying mucosa; larger tumours are excised with full-thickness excision of the duodenal wall.

**Non-functional endocrine pancreatic tumours**

**Definition**
PETs are clinically classified as non-functioning PETs (NF-PETs) when they do not cause a clinical syndrome.

**Incidence**
NF-PETs account for 30–50 per cent of all PETs. They are most often diagnosed in the fifth to sixth decades of life.

**Pathology**
NF-PETs cannot be differentiated from functional tumours by immunocytochemistry because they may also express hormones such as gastrin, insulin, etc. They usually stain positively for
chromogranin A and synaptophysin. The tumours are usually large (>3 cm) and unifocal except in MEN 1 syndrome. They are distributed throughout the pancreas with a head to body to tail ratio of 7:1:1.5.

Prognosis and predictive factors
About 70 per cent of all NF-PETs are malignant. Overall five- and ten-year survival rates of 65 and 49 per cent, respectively, have been described. When comparing NF-PETs with functioning PETs, the NF-PETs have a worse prognosis.

Clinical features
Patients usually present late because of the lack of a clinical/hormonal marker of tumour activity. Therefore, in contrast to functioning PETs, patients with NF-PETs present with various non-specific symptoms, including jaundice, abdominal pain, weight loss and pancreatitis. In some cases liver metastases are the first presentation.

Biochemical diagnosis
Increased levels of chromogranin A have been reported in 50–80 per cent of NF-PETs; the level of chromogranin A sometimes correlates with the tumour burden. The combination of elevated chromogranin A and PP measurements increases the sensitivity of diagnosis from 84 to 96 per cent in NF-PETs.

Differential diagnosis
Differentiation from the more aggressive pancreatic adenocarcinoma is extremely important (Table 52.4). Recognition of NF-PETs is imperative because of their resectability and excellent long-term survival compared with their exocrine counterparts.

Medical treatment of non-functioning islet cell tumours
When surgical excision is not possible, chemotherapeutic options include streptozotocin, octreotide and interferon.

Surgical treatment of non-functioning islet cell tumours
Indications for operation
An aggressive surgical approach should be considered in malignant NF-PETs, even in the presence of distant metastases.

Preoperative localisation studies
Preoperative ultrasound or CT scan are the procedures of choice as these tumours are relatively large. Also, SRS should be performed to differentiate endocrine from non-endocrine pancreatic tumours.

Operative procedures
The major goal is a potentially curative resection. This may require partial pancreaticoduodenectomy as well as the synchronous or metachronous resection of liver metastases. Using an aggressive approach, curative resections are possible in up to 62 per cent of cases and overall five-year survival rates of around 65 per cent can be achieved. Repeated resections for recurrent recurrences or metastases are justified to improve survival.

NEUROENDOCRINE TUMOURS OF THE STOMACH AND SMALL BOWEL

Definition and physiology
Neuroendocrine tumours (NET) of the gut and the pancreas arise from the diffuse neuroendocrine cell system, which can be found as single or clustered cells in the mucosa of the bronchi, stomach, gut, biliary tree, urogenital system and in the pancreas (see Chapters 71, 69 and 72 for NET of the appendix, colon and rectum, respectively). This cell system was first recognised as the ‘clear cell system’ by Feyrer in the 1930s and is identical to the APUD (amine precursor uptake and decarboxylation) system described by Pearse in 1970. All cells of the system secrete different neuroendocrine markers, such as synaptophysin, chromogranin A and neuron-specific enolase (NSE), and produce peptide hormones that are stored in granules, e.g. serotonin, somatostatin, PP or gastrin. In clinical practice chromogranin A is utilised as a tumour marker. The main functional test for NET of the jejunum and ileum (the NET that are most often encountered) is the measurement of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in urine.

Pathology
Neuroendocrine cells can form hyperplasias or tumours. In 1907, Oberndorfer coined the term ‘carcinoids’ for tumours arising from these cells. Although the term carcinoid continues to be used in clinical practice, these tumours do not always grow in a well-differentiated pattern reflecting the rather benign ‘carcinoma-like’, i.e. ‘carcinoid’, tumour. They can show different growth patterns, from benign tumours to high-grade undifferentiated carcinomas having a poor prognosis (neuroendocrine carcinomas). Therefore, they should always be addressed as NET, including a description of their histological pattern (benign, low- or high-grade malignant) and their anatomical site (e.g. stomach, ileum) according to the World Health Organization classification (2000). The relative distribution of NET in different organs is given in Table 52.5. Another classification based on embryological principles classifies NET as foregut (lung, stomach, pancreas), midgut (small bowel and appendix) and hindgut (colon and rectum) tumours.

Neuroendocrine tumours of the stomach
These tumours are rare. They comprise about 5 per cent of all NET of the gastrointestinal tract and have an incidence of

approximately 0.2 cases per 100,000 population per year. There are four different types of gastric NET (Table 52.6). Types 1 and 2 are small benign tumours that arise from the enterochromaffin-like (ECL) cells in the gastric mucosa and grow in either a linear or a nodular pattern (Figure 52.19). Hypergastrinaemia may cause symptoms and the treatment of choice is endoscopic resection. Types 3 and 4 are almost always malignant and surgical resection should be undertaken if possible.

Pathogenesis, diagnosis and treatment

Type 1 tumours (ECLomas) are the most frequent NET of the stomach (approximately 80 per cent); they occur mostly in elderly women. Chronic hypergastrinaemia is the result of chronic atrophic gastritis and achlorhydria, the alkaline pH being the stimulus for hypersecretion of gastrin. They do not cause symptoms and are usually detected during gastroscopy for other reasons. Endoscopic resection is the treatment of choice. Antrectomy and resection of ECLomas should be undertaken only if there is recurrent disease and multiple (more than six) tumours, with at least one measuring >1 cm and infiltration of at least one into the submucosa.

The pathogenesis, diagnosis and treatment of type 2 tumours is similar to that of type 1. The only difference is the cause of the hypergastrinaemia, which in type 2 tumours is the result of MEN 1 syndrome, with multiple gastrinomas in the duodenum or, rarely, in the pancreas.

Type 3 tumours are rare, sporadic and solitary tumours of unknown origin. Serum gastrin is normal; upper gastrointestinal bleeding is the usual symptom that leads to endoscopy. Type 3 tumours are usually larger than 2 cm and often have lymph node and liver metastases at the time of diagnosis. Gastrectomy and lymph node dissection and resection of liver metastases is the treatment of choice. Liver metastases can also be treated by chemoembolisation.

Type 4 tumours present as large ulcerating malignancies similar to adenocarcinomas and should be treated accordingly. The prognosis of types 3 and 4 is poor (Table 52.6).

**Neuroendocrine tumours of the small bowel**

*Introduction*

These are the tumours that are most commonly referred to as 'carcinoid' tumours, as most NET of the gastrointestinal tract are found in the small bowel. They are also called 'midgut' tumours (together with NET of the appendix and the right colon). These tumours produce serotonin and cause the 'carcinoid' syndrome, but only in patients who have a large volume of liver metastases or if there is advanced local tumour growth draining into the

inferior vena cava and thereby bypassing the liver. NET of the duodenum (gastrinomas in MEN 1 syndrome, somatostatinomas and others) are very rare and are not discussed further.

**Pathology**

NET of the jejunum and ileum arise from a subgroup of cells of the diffuse neuroendocrine system, the enterochromaffin (EC) cells, which secrete serotonin and substance P. They are either solitary or more often multiple, are almost always malignant and metastasise early to the regional lymph nodes and the liver depending on the location of the primary tumour(s) (Figure 52.20).

**Clinical symptoms**

Symptoms that lead to the diagnosis are caused by either the primary tumour or its lymph node metastases. Acute or chronic, recurrent or persistent abdominal pain, ileus or, rarely, lower gastrointestinal bleeding may occur. Symptoms may be due to liver metastases, such as sudden painful reddening of the face and chest ('flushing'), diarrhoea or bronchospasm. These symptoms constitute ‘carcinoid’ syndrome. About 60 per cent of patients eventually develop cardiac symptoms because of stenosis and insufficiency of the pulmonary and, more rarely, the tricuspid valve, with enlargement and thickening of the wall of the right atrium. The aetiology is unknown but local effects of serotonin and kinins may contribute.

Abdominal symptoms are caused either by obstruction of the appendix by an appendiceal NET (leading to appendectomy) or by obstruction of the mesentery or the bowel lumen by growth of lymph node metastases in the mesentery near the bowel. Pain is caused by chronic ischaemia of the bowel (Figure 52.21), resulting not only from mesenteric lymph node metastases but also from constriction of mesenteric arteries and fibrosis of the mesentery by a so-called desmoplastic reaction.

Primary tumours in the jejunum and ileum rarely cause symptoms such as bleeding or intussusception as they usually only measure from a few millimetres up to 1 cm or at the most 2 cm in diameter (Figure 52.22). A polypoid NET of the terminal ileum may, however, cause ileocaecal intussusception.

**Diagnosis**

The diagnosis of NET of the small bowel is made by history, physical examination of the abdomen, imaging and an assessment of 5-HIAA in a 24-hour urine sample. It is positive in larger tumours only if metastases are present. Cross-sectional imaging, sonography, CT scan and MRI may show the primary tumour, mesenteric lymph node and liver metastases.

The best method for staging of NET is an octreotide (SRS) scan. This will show all tumour deposits provided that they are large enough and have a high somatostatin receptor density (Figure 52.23).

**Surgical procedure**

Surgery should be undertaken as soon as the diagnosis is made, even in the presence of liver metastases. The main goal is resection of the bowel primary tumour(s) and mesenteric lymph node metastases. This may entail resection of large amounts of bowel (100 cm or more), particularly if stage III or IV lymph node masses are found in the mesentery (Figure 52.24). In the presence of liver metastases, extrahepatic disease should be resected whenever possible. Metastatic disease in the mesenteric root will lead to long-term pain in the abdomen or back and to a poor quality of life, whereas liver metastases can be treated by chemotherapy or embolisation.

PART 8
BREAST AND ENDOCRINE

THE ADRENAL GLANDS AND OTHER ABDOMINAL ENDOCRINE DISORDERS

794

Paul Wermer, 1898–1975, physician, The Presbyterian Hospital, New York, NY, USA, described this condition in 1954.

Somatostatin and its analogues provide symptomatic treatment of the 'carcinoid' syndrome caused by a large volume of liver metastases. These drugs may also have an antiproliferative effect. Surgery to remove liver metastases is possible in approximately 10 per cent of patients. In others, embolisation, chemoembolisation, SRS using radioactively labelled octreotide, chemotherapy, biotherapy and also liver transplantation can be performed.

MULTIPLE ENDOCRINE NEOPLASIAS

Introduction

Multiple endocrine neoplasias (MEN) are inherited syndromes characterised by a combination of benign and malignant tumours in different endocrine glands. There are two main types, type 1 (MEN 1) and type 2 (MEN 2). The mode of inheritance is autosomal dominant in both.

MEN 1 is characterised by the triad of tumours in the anterior pituitary gland, mostly presenting as prolactinomas or non-functioning tumours, hyperplasia of the parathyroids causing primary hyperparathyroidism (pHPT) and pancreaticoduodenal endocrine tumours. The syndrome was first described by Wermer in 1954 and is therefore also called Wermer’s syndrome. It is caused by germline mutations in the menin gene, located on chromosome 11.

MEN 2 is divided into three subtypes: familial medullary thyroid carcinoma (FMTC), MEN 2a and MEN 2b. Medullary thyroid carcinoma (MTC) plays the key role in all subtypes. MEN 2 is caused by germline mutations in the RET proto-oncogene, located on chromosome 10. MEN 2a is characterised by the combination of MTC, pHPT and mostly bilateral phaeochromocytomas. MTC combined with phaeochromocytoma alone is called Sipple’s syndrome. FMTC is characterised by distinct mutations in RET and MTC alone as the clinical manifestation. MEN 2b comprises MTC, phaeochromocytoma and characteristic facial and oral mucosal neuromas and intestinal ganglioneuromatosis accompanied by a Marfanoid habitus (Figure 52.25).

The most important difference between MEN 1 and MEN 2, besides the different clinical pictures, is that MEN 2 is characterised by a well-understood genotype–phenotype correlation. This means that depending on the particular mutation in the RET proto-oncogene, the phenotypic appearance and the onset of endocrine tumours will be different and can be predicted from the type of mutation. This is not the case in MEN 1 syndrome.
Multiple endocrine neoplasia type 1

**Epidemiology**

The prevalence of the syndrome is estimated to be around 0.04–0.2 cases per 1000 population per year. The penetrance is high with almost 100 per cent of mutation carriers developing the syndrome. The disease is equally distributed between men and women.

**Clinical presentation**

The clinical presentation depends on the affected organs. Tumours can occur synchronously (Table 52.7). Most of the mutation carriers identified in screening programmes are asymptomatic.

**Parathyroids**

In total, 90–100 per cent of patients suffering from MEN 1 develop pHPT and it is usually the first manifestation of the disease. MEN 1 pHPT is characterised by multiglandular disease so that all four parathyroids become hyperplastic in the course of the disease. The clinical presentation of MEN 1 pHPT is similar to that of the sporadic disease. Few patients have asymptomatic disease; most common in symptomatic disease is nephrolithiasis. Diagnosis is established by determination of parathyroid hormone (PTH) and calcium in serum and urine.

**Endocrine pancreas**

PETs occur in around 50–60 per cent of MEN 1 patients. In such patients taking part in screening programmes, 70–90 per cent are found to have non-functioning and functioning PETs. This high rate of detection of PETs is the result of the improvement in diagnostic procedures in the last decade, including EUS. MEN 1 PETs are the most common syndrome-associated cause of death. They are mostly multiple and often recur after surgery. Although most patients have multiple tumours, one hormone syndrome is usually dominant. The most common functional tumour is gastrinoma followed by insulinoma. VIPomas, glucagonomas and somatostatinomas are extremely rare. Non-functioning tumours can be asymptomatic for many years.

The diagnostic work-up is similar to that for sporadic PETs and includes hormone measurements, e.g. gastrin, insulin, PP, etc., and imaging.

**Anterior pituitary gland**

Tumours of the anterior pituitary gland are found in 30–60 per cent of patients with MEN 1. These are mostly microadenomas that present as prolactinomas or non-functioning tumours. Most prolactinomas can be treated with medication, thus avoiding operation.

**Adrenal tumours and other organ manifestations**

Adrenal involvement is common in MEN 1 patients and affects nearly 40–50 per cent of patients. Mostly non-functioning adenomas are found. Very rarely, adrenocortical carcinomas or phaeochromocytomas may develop.

Although very rare, manifestations of MEN 1 include NET of the lung, thymus, stomach, duodenum and small bowel. It is important to check for NETs of the thymus, as they are mostly malignant.

**Genetic screening**

Identification of the MEN 1 (menin) gene in 1997 formed the basis for direct mutational analysis of the gene and for family screening. After genetic counselling of the index patient, family members can be screened. Mutation carriers can then be included in screening programmes that make early detection of mutation carriers possible.
endocrine tumours possible. Screening programmes should follow the consensus guidelines published by Brandi et al. in 2001. In cases of apparently sporadic endocrine tumours in patients younger than 40 years, genetic testing for MEN 1 is advised.

**Operative therapy**

**Parathyroids**

The indications for surgery in MEN 1 pHPT follow the same criteria as in sporadic disease but the choice of procedure is different. As multiglandular disease is present in all cases, resection follows the same rules as in secondary HPT. Therefore, the most common procedures are total parathyroidectomy, including cervical thymectomy or 3/2-gland resection, leaving approximately 50 mg of parathyroid tissue behind, and cervical thymectomy. Selective resection of enlarged glands is obsolete because of the high rates of recurrence.

**Endocrine pancreas**

Indications for surgery and its extent are controversial. Most experts agree that MEN 1 gastrinoma and insulinoma have to be operated on to prevent liver metastases and to control hormonal excess, provided that diffuse liver metastases are not present. MEN 1 gastrinomas are often located in the duodenum as multiple small tumours than in the pancreas. For gastrinomas located in the duodenum or pancreatic head (gastrinoma triangle, Figure 52.17), pylorus-preserving partial pancreaticoduodenectomy is recommended. In rare cases, the gastrinoma is located in the body or tail of the pancreas. In such cases, distal pancreatectomy with excision of tumours in the pancreatic head is the procedure of choice. In MEN 1 insulinoma the standard operative procedure is distal pancreatectomy with enucleation of tumours in the pancreatic head. Non-functioning PETs are operated on if they reach a size of 1 cm. Careful palpation and IUS are essential in every pancreatic procedure for MEN 1 PETs.

**Anterior pituitary gland**

The indications for surgery in tumours of the anterior pituitary gland are the presence of symptomatic non-functional tumours or if medical therapy of prolactinoma fails. Most procedures can be performed through a trans-sphenoidal approach.

**Adrenal tumours**

Functional adrenal tumours in MEN 1 are rare and have to be operated on. Non-functioning tumours should be resected if they reach a size of 4 cm. Pre- and perioperative management follows the same rules as in sporadic adrenal tumours; therefore, phaeochromocytoma has to be ruled out in every patient. In most cases, a laparoscopic or retroperitoneoscopic approach can be used. If there is evidence for a malignant tumour, open surgery is preferred.

---

**Multiple endocrine neoplasia type 2**

In most patients with MEN 2a, the disease is caused by mutations of the RET proto-oncogene in codon 634. MTC is almost always the first manifestation of the syndrome. If phaeochromocytoma and pHPT do not occur, one must suspect the presence of the MTC subtype. Patients with MEN 2b do not develop pHPT and in 95 per cent of cases mutations in codon 918 of the RET proto-oncogene are causative (Table 52.8).

**Medullary thyroid carcinoma**

MTC is characterised by multicentricity and is often accompanied by C-cell hyperplasia. These characteristics should lead to molecular diagnostic work-up (mutational analysis of the RET proto-oncogene) in patients with apparently ‘sporadic’ MTC. In contrast to sporadic MTC, the diagnosis in families with known mutation of the RET gene is mostly made much earlier, possibly as the result of mutational screening and calcitonin measurements. MTC is most aggressive in MEN 2b. It occurs in early childhood, much earlier than in MEN 2a, with lymph node metastases present in the early stages. Preventative surgery is advised around the age of one year.

**Primary hyperparathyroidism**

pHPT in MEN 2a is less common and has a milder clinical course than MEN 1 pHPT. It occurs in about 20–30 per cent of patients with MEN 2a. Most patients are asymptomatic but all parathyroid glands can become hyperplastic, mostly synchronously. The disease develops after the third decade of life typically.

**Phaeochromocytoma**

The frequency of phaeochromocytoma in MEN 2 is around 10–50 per cent and tumours can be bilateral. This can occur synchronously or metachronously. The tumours are almost always benign. Diagnostic work-up includes measurement of urinary catecholamines, abdominal CT or MRI, and 131I-MIBG scintigraphy (see above).

**Operative therapy**

**Medullary thyroid carcinoma**

Operative therapy for MEN 2 MTC in patients detected by genetic screening is a good example of efficient prophylactic surgery, as the likelihood of developing MTC is 100 per cent for most mutations. The mutation carriers can be operated on with no evidence of tumour in the thyroid, protecting them from MTC for the rest of their lives. Different RET mutations are associated with early or late onset of the disease. Risk groups have been defined to determine the appropriate age for thyroidectomy (Table 52.9).

FMTC, familial medullary thyroid cancer; MEN 2a, multiple endocrine neoplasia type 2a; MEN 2b, multiple endocrine neoplasia type 2b; MTC, medullary thyroid cancer; PCC, phaeochromocytoma; pHPT, primary hyperparathyroidism; RET, RET proto-oncogene (RET = rearranged during transfection).
Phaeochromocytoma
The operative approach is laparoscopy or retroperitoneoscopy. Unilateral or bilateral subtotal resection may be feasible, which retains the healthy part of the gland and prevents postoperative dependence on cortisol and mineralocorticoid supplementation (see above) (Figure 52.26). Further phaeos can develop in the remnants that are left so continued surveillance is required.

Primary hyperparathyroidism
The clinical situation in MEN 2 pHPT is even more difficult than in MEN 1 pHPT because of the association with MTC in MEN 2. During neck surgery for MTC in a eucalcaemic patient, enlarged parathyroid glands should be removed. In cases in which neck surgery has already been performed for MTC, the surgical approach to MEN 2a pHPT should be more tailored to the individual patient. For example, in an older patient after thyroidectomy for MTC with mild asymptomatic hypercalcaemia, localisation procedures and a targeted approach may be appropriate.

FURTHER READING
The protuberant part of the human breast is generally described as overlying the second to the sixth ribs and extending from the lateral border of the sternum to the anterior axillary line. Actually, a thin layer of mammary tissue extends considerably further, from the clavicle above to the seventh or eighth ribs below and from the midline to the edge of the latissimus dorsi posteriorly. This fact is important when performing a mastectomy, the aim of which is to remove the whole breast. The anatomy of the breast is illustrated in Figure 53.1.

The axillary tail of the breast is of surgical importance. In some normal subjects it is palpable and, in a few, it can be seen premenstrually or during lactation. A well-developed axillary tail is sometimes mistaken for a mass of enlarged lymph nodes or a lipoma.

The lobule is the basic structural unit of the mammary gland. The number and size of the lobules vary enormously; they are most numerous in young women. From 10 to over 100 lobules empty via ductules into a lactiferous duct, of which there are 15–20. Each lactiferous duct is lined with a spiral arrangement of contractile myoepithelial cells and is provided with a terminal ampulla, a reservoir for milk or abnormal discharges.

The ligaments of Cooper are hollow conical projections of fibrous tissue filled with breast tissue; the apices of the cones are attached firmly to the superficial fascia and thereby to the skin overlying the breast. These ligaments account for the dimpling of the skin overlying a carcinoma.

The areola contains involuntary muscle arranged in concentric rings as well as radially in the subcutaneous tissue. The areolar epithelium contains numerous sweat glands and sebaceous glands, the latter of which enlarge during pregnancy and serve to lubricate the nipple during lactation (Montgomery’s tubercles).

The nipple is covered by thick skin with corrugations. Near its apex lie the orifices of the lactiferous ducts. The nipple contains smooth muscle fibres arranged concentrically and longitudinally; thus, it is an erectile structure, which points outwards.

The lymphatics of the breast drain predominantly into the axillary and internal mammary lymph nodes. The axillary nodes receive approximately 85 per cent of the drainage and are arranged in the following groups:

- lateral, along the axillary vein;
- anterior, along the lateral thoracic vessels;
- posterior, along the subscapular vessels;
- central, embedded in fat in the centre of the axilla;
- interpectoral, a few nodes lying between the pectoralis major and minor muscles;
- apical, which lie above the level of the pectoralis minor tendon in continuity with the lateral nodes and which receive the efferents of all the other groups.

Sir Astley Paston Cooper, 1768–1841, surgeon, Guy’s Hospital, London, UK, described these ligaments in 1845. He received a baronetcy and one thousand guineas for successfully removing an infected wen from the head of King George IV at Brighton in 1821. He described scrofulous swellings in the bosoms of young women, most of whom suffered from tuberculous cervical adenitis.

William Fetherston Montgomery, 1797–1859, obstetrician, Dublin, Ireland described these tubercles in 1837. He was instrumental in establishing the Chair of Obstetrics at the Irish College of Physicians.
The apical nodes are also in continuity with the supraclavicular nodes and drain into the subclavian lymph trunk, which enters the great veins directly or via the thoracic duct or jugular trunk. The sentinel node is defined as the first lymph node draining the tumour-bearing area of the breast. The importance of the sentinel node is described later.

The internal mammary nodes are fewer in number. They lie along the internal mammary vessels deep to the plane of the costal cartilages, drain the posterior third of the breast and are not routinely dissected although they were at one time biopsied for staging.

INVESTIGATION OF BREAST SYMPTOMS

Although an accurate history and clinical examination are important methods of detecting breast disease, there are a number of investigations that can assist in the diagnosis. Examination precedes palpation and requires careful observation of the patient both with the arms at rest and also elevated to lift the breast. Small lesions may betray their presence by dimpling or minor distortions when the patient moves.

Mammography

Soft tissue radiographs are taken by placing the breast in direct contact with ultrasensitive film and exposing it to low-voltage, high amperage x-rays (Figure 53.2). The dose of radiation is approximately 0.1 cGy and, therefore, mammography is a very safe investigation. The sensitivity of this investigation increases with age as the breast becomes less dense. In total, 5 per cent of breast cancers are missed by population-based mammographic screening programmes; even in retrospect, such carcinomas are not apparent. Thus, a normal mammogram does not exclude the presence of carcinoma. Digital mammography is being introduced, which allows manipulation of the images and computer-aided diagnosis. Tomo-mammography is also being assessed as a more sensitive diagnostic modality.

Ultrasound

Ultrasound is particularly useful in young women with dense breasts in whom mammograms are difficult to interpret, and in distinguishing cysts from solid lesions (Figures 53.3 and 53.4). It can also be used to localise impalpable areas of breast pathology.

Gy is short for Gray, the SI unit for the absorbed dose of ionizing radiation.

Louis Harold Gray, 1905–1965, Director, The British Empire Cancer Campaign Research Unit in Radiobiology, Mount Vernon Hospital, Northwood, Middlesex, UK.
It is not useful as a screening tool and remains operator dependent. Increasingly, ultrasound of the axilla is performed when a cancer is diagnosed with guided percutaneous biopsy of any suspicious glands.

**Magnetic resonance imaging**

Magnetic resonance imaging (MRI) is of increasing interest to breast surgeons in a number of settings:

- It can be useful to distinguish scar from recurrence in women who have had previous breast conservation therapy for cancer (although it is less accurate within nine months of radiotherapy because of abnormal enhancement).
- It is becoming the standard of care when a lobular cancer is diagnosed to assess for multifocality and multicentricity and can be used to assess the extent of DCIS (ductal carcinoma in situ).
- It is the best imaging modality for the breasts of women with implants.
- It has proven to be useful as a screening tool in high-risk women (because of family history).
- It is less useful than ultrasound in the management of the axilla in both primary breast cancer and recurrent disease (Figure 53.5).

Although biopsies can be performed with MRI guidance this is complicated because of the configuration of the imaging system. With improved ultrasound equipment, an MRI-detected lesion can often be found on a second-look ultrasound and biopsied using this modality.

**Needle biopsy/cytology**

Histology can be obtained under local anaesthesia using a spring-loaded core needle biopsy device (Figure 53.6). Cytology is obtained using a 21G or 23G needle and 10-ml syringe with multiple passes through the lump with negative pressure in the syringe. The aspirate is then smeared on to a slide, which is air dried or fixed (Figure 53.7). Fine-needle aspiration cytology (FNAC) is the least invasive technique of obtaining a cell diagnosis and is rapid and very accurate if both operator and cytologist are experienced. However, false negatives do occur, mainly through sampling error, and invasive cancer cannot be distinguished from in situ disease. A histological specimen taken by core biopsy allows a definitive preoperative diagnosis, differentiates between duct carcinoma in situ and invasive disease and also allows the tumour to be stained for receptor status. This is important before commencing neoadjuvant therapy.

**Large-needle biopsy with vacuum systems**

The sampling error decreases as the biopsy volume increases and using 8G or 11G needles allows more extensive biopsies to be
taken. This is useful in the management of microcalcifications or in the complete excision of benign lesions such as fibroadenomas.

**Triple assessment**

In any patient who presents with a breast lump or other symptoms suspicious of carcinoma, the diagnosis should be made by a combination of clinical assessment, radiological imaging and a tissue sample taken for either cytological or histological analysis (Figure 53.8), the so-called triple assessment. The positive predictive value (PPV) of this combination should exceed 99.9 per cent.

**THE NIPPLE**

Absence of the nipple is rare and is usually associated with amastia (congenital absence of the breast).

Supernumerary nipples not uncommonly occur along a line extending from the anterior fold of the axilla to the fold of the groin (Figure 53.9). This constitutes the milk line of lower mammals. Rarely, there is duplication of the nipple on a normal areola.

**Nipple retraction**

This may occur at puberty or later in life. Retraction occurring at puberty, also known as simple nipple inversion, is of unknown aetiology (benign horizontal inversion). In about 25 per cent of cases it is bilateral. It may cause problems with breastfeeding and infection can occur, especially during lactation, because of retention of secretions. Recent retraction of the nipple may be of considerable pathological significance. A slit-like retraction of the nipple may be caused by duct ectasia and chronic periductal mastitis (Figure 53.10a), but circumferential retraction, with or without an underlying lump, may well indicate an underlying carcinoma (Figure 53.10b).

**Treatment**

Treatment is usually unnecessary and the condition may spontaneously resolve during pregnancy or lactation.

Simple cosmetic surgery can produce an adequate correction but has the drawback of dividing the underlying ducts. Mechanical suction devices have been used to evert the nipple, with some effect.
Cracked nipple
This may occur during lactation and be the forerunner of acute infective mastitis. If the nipple becomes cracked during lactation, it should be rested for 24–48 hours and the breast should be emptied with a breast pump. Feeding should be resumed as soon as possible.

Papilloma of the nipple
Papilloma of the nipple has the same features as any cutaneous papilloma and should be excised with a tiny disc of skin. Alternatively, the base may be tied with a ligature and the papilloma will spontaneously fall off.

Retention cyst of a gland of Montgomery
These glands, situated in the areola, secrete sebum and if they become blocked a sebaceous cyst forms.

Eczema
Eczema of the nipples is a rare condition and is often bilateral; it is usually associated with eczema elsewhere on the body. It is treated with 0.5 per cent hydrocortisone (not a stronger steroid preparation).

Paget’s disease
Paget’s disease of the nipple must be distinguished from eczema. The former is caused by malignant cells in the subdermal layer and is usually associated with a carcinoma within the breast. Eczema tends to occur in younger people who have signs of eczema elsewhere (look at the antecubital fossae).

Discharges from the nipple
Discharge can occur from one or more lactiferous ducts. Management depends on the presence of a lump (which should always be given priority in diagnosis and treatment) and the presence of blood in the discharge or discharge from a single duct. Mammography is rarely useful except to exclude an underlying impalpable mass. Cytology may reveal malignant cells but a negative result does not exclude a carcinoma or in situ disease.

- A clear, serous discharge may be “physiological” in a parous woman or may be associated with a duct papilloma or mammary dysplasia. Multiduct, multicoloured discharge is physiological and the patient may be reassured.
- A blood-stained discharge may be caused by duct ectasia, a duct papilloma or carcinoma. A duct papilloma is usually single and situated in one of the larger lactiferous ducts; it is sometimes associated with a cystic swelling beneath the areola.
- A black or green discharge is usually the result of duct ectasia and its complications (Summary box 53.1).

Treatment
Treatment must first be to exclude a carcinoma by occult blood test and cytology. Simple reassurance may then be sufficient but, if the discharge is proving intolerable, an operation to remove the affected duct or ducts can be performed (microdochectomy).

Microdochectomy
It is important not to express the blood before the operation as it may then be difficult to identify the duct in theatre. A lacrimal probe or length of stiff nylon suture is inserted into the duct from which the discharge is emerging. A tennis racquet incision can be made to encompass the entire duct or a periareolar incision used and the nipple flap dissected to reach the duct. The duct is then excised. A papilloma is nearly always situated within 4–5 cm of the nipple orifice.

Ductoscopy (inspection of the internal structure of the duct system) using microendoscopes is technically feasible but generally disappointing. The affected duct may not be visualised and biopsy systems are currently rudimentary.

Cone excision of the major ducts (after Hadfield) (subareolar resection)
When the duct of origin of nipple bleeding is uncertain or when there is bleeding or discharge from multiple ducts, the entire major duct system can be excised for histological examination without sacrifice of the breast form. A periareolar incision is made and a cone of tissue is removed with its apex just deep to the surface of the nipple and its base on the pectoral fascia. The resulting defect may be obliterated by a series of purse-string sutures although a temporary suction drain will reduce the chance of long-term deformity. It is vital to warn the patient that she will be unable to breastfeed after this and may experience altered nipple sensation.

Sir James Paget, 1874–1899, surgeon, St Bartholomew’s Hospital, London, UK, described this disease of the nipple in 1874 and osteitis deformans in 1877.

Geoffrey John Hadfield, surgeon, Stoke Mandeville Hospital, Aylesbury, Buckinghamshire, UK.
Benign breast disease

This is the most common cause of breast problems; up to 30 per cent of women will suffer from a benign breast disorder requiring treatment at some time in their lives. The most common symptoms are pain, lumpiness or a lump. The aim of treatment is to exclude cancer and, once this has been done, to treat any remaining symptoms.

Congenital abnormalities

Amazia

Congenital absence of the breast may occur on one (Figure 53.11) or both sides. It is sometimes associated with absence of the sternal portion of the pectoralis major (Poland's syndrome). It is more common in males.

Polymazia

Accessory breasts (Figure 53.12) have been recorded in the axilla (the most frequent site), groin, buttok and thigh. They have been known to function during lactation.

Mastitis of infants

Mastitis of infants is at least as common in boys as in girls. On the third or fourth day of life, if the breast of an infant is pressed lightly, a drop of colourless fluid can be expressed; a few days later, there is often a slight milky secretion, which disappears during the third week. This is popularly known as 'witch's milk' and is seen only in full-term infants. It is caused by stimulation of the fetal breast by prolactin in response to the drop in maternal oestrogens and is essentially physiological. True mastitis is uncommon and is predominately caused by Staphylococcus aureus.

Diffuse hypertrophy

Diffuse hypertrophy of the breasts occurs sporadically in otherwise healthy girls at puberty (benign virginal hypertrophy) and, much less often, during the first pregnancy. The breasts attain enormous dimensions and may reach the knees when the patient is sitting. The condition is rarely unilateral. This tremendous overgrowth is apparently caused by an alteration in the normal sensitivity of the breast to oestrogenic hormones and some success in treating it with anti-oestrogens has been reported. Treatment is otherwise by reduction mammoplasty.

Injuries of the breast

Haematoma

Haematoma, particularly a resolving haematoma, gives rise to a lump, which, in the absence of overlying bruising, is difficult to diagnose correctly unless it is biopsied.

Traumatic fat necrosis

Traumatic fat necrosis may be acute or chronic and usually occurs in stout, middle-aged women. Following a blow, or even indirect violence (e.g. contraction of the pectoralis major), a lump, often painless, appears. This may mimic a carcinoma, even displaying skin tethering and nipple retraction, and biopsy is required for diagnosis. A history of trauma is not diagnostic as this may merely have drawn the patient's attention to a pre-existing lump. A seatbelt may transect the breast with a sudden deceleration injury, as in a road traffic accident.

Acute and subacute inflammations of the breast

Bacterial mastitis

Bacterial mastitis is the most common variety of mastitis and is associated with lactation in the majority of cases.

Aetiology

Lactational mastitis is seen far less frequently than in former years. Most cases are caused by S. aureus and, if hospital acquired, are likely to be penicillin resistant. The intermediary is usually the infant; after the second day of life, 50 per cent of infants harbour staphylococci in the nasopharynx.

Although ascending infection from a sore and cracked nipple may initiate the mastitis, in many cases the lactiferous ducts will first become blocked by epithelial debris leading to stasis; this theory is supported by the relatively high incidence of mastitis in women with a retracted nipple. Once within the ampulla of the duct, staphylococci cause clotting of milk and, within this clot, organisms multiply.
Clinical features
The affected breast, or more usually a segment of it, presents the classical signs of acute inflammation. Early on this is a generalised cellulitis but later an abscess will form.

Treatment
During the cellulitic stage the patient should be treated with an appropriate antibiotic, for example flucloxacillin or co-amoxiclav. Feeding from the affected side may continue if the patient can manage. Support of the breast, local heat and analgesia will help to relieve pain.

If an antibiotic is used in the presence of undrained pus, an ‘antibioma’ may form. This is a large, sterile, brawny oedematous swelling that takes many weeks to resolve.

It used to be recommended that the breast should be incised and drained if the infection did not resolve within 48 hours or if after being emptied of milk there was an area of tense induration or other evidence of an underlying abscess. This advice has been replaced with the recommendation that repeated aspirations under antibiotic cover (if necessary using ultrasound for localisation) be performed. This often allows resolution without the need for an incision scar and will also allow the patient to carry on breastfeeding.

The presence of pus can be confirmed with needle aspiration and the pus sent for bacteriological culture. In contrast to the majority of localised infections, fluctuation is a late sign. Usually, the area of induration is sector-shaped and, in early cases, about one-quarter of the breast is involved (Figure 53.13); in many late cases the area is more extensive (Figure 53.14). When in doubt, an ultrasound scan may clearly define an area suitable for drainage.

Operative drainage of a breast abscess
This is less commonly needed as prompt commencement of antibiotics and repeated aspiration is usually successful. Incision of a lactational abscess is necessary if there is marked skin thinning and can usually be performed under local anaesthesia if an analgesic cream such as EMLA (lidocaine) is applied 30 minutes before surgery.

The usual incision is sited in a radial direction over the affected segment, although if a circumareolar incision will allow adequate access to the affected area this is preferred because it gives a better cosmetic result. The incision passes through the skin and the superficial fascia. A long artery forceps is then inserted into the abscess cavity. Every part of the abscess is palpated against the point of the artery forceps and its jaws are opened. All loculi that can be felt are entered.

Finally, the artery forceps having been withdrawn, a finger is introduced and any remaining septa are disrupted. The wound may then be lightly packed with ribbon gauze or a drain inserted to allow dependent drainage.

Chronic intramammary abscess
A chronic intramammary abscess, which may follow inadequate drainage or injudicious antibiotic treatment, is often a very difficult condition to diagnose. When encapsulated within a thick wall of fibrous tissue the condition cannot be distinguished from a carcinoma without the histological evidence from a biopsy.

Tuberculosis of the breast
Tuberculosis of the breast, which is comparatively rare, is usually associated with active pulmonary tuberculosis or tuberculous cervical adenitis.

Tuberculosis of the breast (Figure 53.15) occurs more often in parous women and usually presents with multiple chronic abscesses and sinuses and a typical bluish, attenuated appearance

Figure 53.13 Intramammary breast abscess.

Figure 53.14 Large breast abscess.

Figure 53.15 Tuberculosis of the breast with secondary suppurating axillary lymph nodes (courtesy of Professor AK Toufeeq, Lahore, Pakistan).
of the surrounding skin. The diagnosis rests on bacteriological and histological examination. Treatment is with anti-tuberculous chemotherapy. Healing is usual, although often delayed, and mastectomy should be restricted to patients with persistent residual infection.

**Actinomycosis**
Actinomycosis of the breast is rarer still. The lesions present the essential characteristics of faciocervical actinomycosis.

**Mondor’s disease**
Mondor’s disease is thrombophlebitis of the superficial veins of the breast and anterior chest wall (Figure 53.16), although it has also been encountered in the arm.

In the absence of injury or infection, the cause of thrombophlebitis (like that of spontaneous thrombophlebitis in other sites) is obscure. The pathognomonic feature is a thrombosed subcutaneous cord, usually attached to the skin. When the skin over the breast is stretched by raising the arm, a narrow, shallow subcutaneous groove alongside the cord becomes apparent. The differential diagnosis is lymphatic permeation from an occult carcinoma of the breast. The only treatment required is restricted arm movements and, in any case, the condition subsides within a few months without recurrence, complications or deformity. There are case reports of Mondor’s disease being associated with subsequent development of malignancy although this has been unsubstantiated by others and is thought to be coincidental.

**Duct ectasia/periductal mastitis**

**Pathology**
This is a dilatation of the breast ducts, which is often associated with periductal inflammation. The pathogenesis is obscure and almost certainly not uniform in all cases, although the disease is much more common in smokers.

The classical description of the pathogenesis of duct ectasia asserts that the first stage in the disorder is a dilatation in one or more of the larger lactiferous ducts, which fill with a stagnant brown or green secretion. This may discharge. These fluids then set up an irritant reaction in surrounding tissue leading to periductal mastitis or even abscess and fistula formation (Figures 53.17 and 53.18). In some cases, a chronic indurated mass forms beneath the areola, which mimics a carcinoma. Fibrosis eventually develops, which may cause slit-like nipple retraction.

An alternative theory suggests that periductal inflammation is the primary condition and, indeed, anaerobic bacterial infection is found in some cases. A marked association between recurrent periductal inflammation and smoking has been demonstrated. This was thought by some to indicate that arteriopathy is a contributing factor in its aetiology although others believe that smoking increases the virulence of the commensal bacteria. It is certainly clear that cessation of smoking increases the chance of a long-term cure.

**Clinical features**
Nipple discharge (of any colour), a subareolar mass, abscess, mammary duct fistula and/or nipple retraction are the most common symptoms.
Treatment
In the case of a mass or nipple retraction, a carcinoma must be excluded by obtaining a mammogram and negative cytology or histology. If any suspicion remains the mass should be excised.

Antibiotic therapy may be tried, the most appropriate agents being co-amoxiclav or flucloxacillin and metronidazole. However, surgery is often the only option likely to bring about cure of this notoriously difficult condition; this consists of excision of all of the major ducts (Hadfield’s operation). It is particularly important to shave the back of the nipple to ensure that all terminal ducts are removed. Failure to do so will lead to recurrence.

Aberrations of normal development and involution

Nomenclature
The nomenclature of benign breast disease is confusing. This is because over the last century a variety of clinicians and pathologists have chosen to describe a mixture of physiological changes and disease processes according to a variety of clinical, pathological and aetiological terminology. As well as leading to confusion, patients were often unduly alarmed or overtreated by ascribing a pathological name to a variant of physiological development. To address this confusion, a concept (aberrations of normal development and involution (ANDI)) has been developed and described by the Cardiff Breast Clinic.

Aetiology
The breast is a dynamic structure that undergoes changes throughout a woman’s reproductive life and, superimposed upon this, cyclical changes throughout the menstrual cycle. This is illustrated in Figure 53.19. The pathogenesis of ANDI involves disturbances in the breast physiology extending from a perturbation of normality to well-defined disease processes. There is often little correlation between the histological appearance of the breast tissue and the symptoms.

Pathology
The disease consists essentially of four features that may vary in extent and degree in any one breast:
1. **Cyst formation.** Cysts are almost inevitable and very variable in size.
2. **Fibrosis.** Fat and elastic tissues disappear and are replaced with dense white fibrous trabeculae. The interstitial tissue is infiltrated with chronic inflammatory cells.
3. **Hyperplasia** of epithelium in the lining of the ducts and acini may occur, with or without atypia.
4. **Papillomatosis.** The epithelial hyperplasia may be so extensive that it results in papillomatous overgrowth within the ducts.

Clinical features
The symptoms of ANDI are many as the term is used to encompass a wide range of benign conditions, but often include an area of lumpiness (seldom discrete) and/or breast pain (mastalgia).

- A benign discrete lump in the breast is commonly a cyst or fibroadenoma. True lipomas occur rarely.
- Lumpiness may be bilateral, commonly in the upper outer quadrant or, less commonly, confined to one quadrant of one breast. The changes may be cyclical, with an increase in both lumpiness and often tenderness before a menstrual period.
- Non-cyclical mastalgia is more common in perimenopausal than postmenopausal women. It may be associated with ANDI or with periductal mastitis. It should be distinguished from referred pain, for example a musculoskeletal disorder. ‘Breast’ pain in postmenopausal women not taking hormone replacement therapy (HRT) is usually derived from the chest wall, back or neck.

About 5 per cent of breast cancers exhibit pain at presentation, but rarely as the sole presenting feature.

Treatment of lumpy breasts
If the clinician is confident that he or she is not dealing with a discrete abnormality (and clinical confidence is supported by mammography and/or ultrasound scanning if appropriate), then initially the woman can be offered firm reassurance. It is perhaps worthwhile reviewing the patient at a different point in the menstrual cycle, for example 6 weeks after the initial visit, and often the clinical signs will have resolved by that time. There is a tendency for women with lumpy breasts to be rendered unnecessarily anxious and to be submitted to multiple random biopsies because the clinician lacks the courage of his or her convictions. Rapid referral into the secondary health-care system often means patients are assessed without an intervening menstrual cycle and this may lead to additional concerns.

Treatment of mastalgia
Pronounced cyclical mastalgia may become a significant clinical problem if the pain and tenderness interfere with the woman’s life, disturb her sleep and impair sexual activity. Initially, firm reassurance that the symptoms are not associated with cancer will help the majority of women. Acknowledgement that this is a real symptom, a non-dismissive attitude and an explanation of the aetiology are all helpful in managing this condition.

In the first instance, an appropriately fitting and supportive bra should be worn throughout the day and a soft bra (such as a sports bra) worn at night. Avoiding caffeine drinks is said to help, although the author remains unconvinced.

A patient symptom diary will help her to chart the pattern of pain throughout the month and thus determine whether this is cyclical mastalgia. This allows the majority of patients to adjust to the concept of a cyclical nature of their problem.
but, if reassurance is inadequate, then a planned escalation of treatment (Table 53.1) could be advised. Oil of evening primrose, in adequate doses given over three months, will help more than half of these women. It appears to achieve higher response rates in those over 40 years of age rather than younger women. For those with intractable symptoms, an anti-gonadotrophin, such as danazol, or a prolactin inhibitor, such as bromocriptine, may be tried. Very rarely, it is necessary to prescribe an anti-oestrogen, for example tamoxifen, or a luteinising hormone-releasing hormone (LHRH) agonist to deprive the breast epithelium of oestrogenic drive. Ablative surgery should never be contemplated for breast pain and any patient seeking this treatment should be referred to a psychiatrist. For non-cyclical mastalgia it is important to exclude extramammary causes such as chest wall pain. This is common in postmenopausal women who are not on HRT and the neck and shoulders are common sites of referred pain. It is seldom necessary these days to carry out a biopsy on a very localised tender area that might be harbouring a subclinical cancer as imaging is so much better. Treatment may be with non-steroidal analgesics or by injection with local anaesthetic on a ‘trigger spot’.

**Breast cysts**
These occur most commonly in the last decade of reproductive life as a result of a non-integrated involucrum of stroma and epithelium. They are often multiple, may be bilateral and can mimic malignancy. Diagnosis can be confirmed by aspiration and/or ultrasound. They typically present suddenly and cause great alarm; prompt diagnosis and drainage provides immediate relief.

**Treatment**
A solitary cyst or small collection of cysts can be aspirated. If they resolve completely, and if the fluid is not blood-stained, no further treatment is required. However, 30 per cent will recur and require reaspiration. Cytological examination of cyst fluid is no longer practised routinely. If there is a residual lump or if the fluid is blood-stained, a core biopsy or local excision for histological diagnosis is advisable, which is also the case if the cyst reforms repeatedly. This will exclude cystadenocarcinoma, which is more common in elderly women.

**Galactocele**
Galactocele, which is rare, usually presents as a solitary, subareolar cyst and always dates from lactation. It contains milk and in long-standing cases its walls tend to calcify.

**Fibroadenoma**
These usually arise in the fully developed breast between the ages of 15 and 25 years, although occasionally they occur in much older women. They arise from hyperplasia of a single lobe and usually grow up to 2–3 cm in size. They are surrounded by a well-marked capsule and can thus be enucleated through a cosmetically appropriate incision. A fibroadenoma does not require excision unless associated with suspicious cytology, it becomes very large or the patient expressly desires the lump to be removed.

Giant fibroadenomas occasionally occur during puberty. They are over 5 cm in diameter and are often rapidly growing but, in other respects, are similar to smaller fibroadenomas and can be enucleated through a submammary incision. They are more common in the Afro-Caribbean population.

**Phyllodes tumour**
These benign tumours, previously sometimes known as serocystic disease of Brodie or cystosarcoma phyllodes, usually occur in women over the age of 40 years but can appear in younger women. They present as a large, sometimes massive, tumour with an unevenly bossedated surface. Occasionally, ulceration of overlying skin occurs because of pressure necrosis. Despite their size they remain mobile on the chest wall. Histologically, there is a wide variation in their appearance, with some of low malignant potential resembling a fibroadenoma and others having a higher mitotic index, which are histologically worrying. The latter may recur locally but, despite the name of cystosarcoma phyllodes, they are rarely cystic and only very rarely develop features of a sarcomatous tumour. These may metastasise via the bloodstream.

**Treatment**
Treatment for the benign type is enucleation in young women or wide local excision. Massive tumours, recurrent tumours and those of the malignant type will require mastectomy (Summary box 53.2).

**When the diagnosis of carcinoma is in doubt**
There will always be cases when the clinician cannot be sure whether a particular lump in the breast is an area of mammery dysplasia, a benign tumour or an early carcinoma.

If there is doubt on clinical, cytological or radiological examination, it is essential to obtain a tissue diagnosis. This is often

possible by needle biopsy. In the event of a negative result, open biopsy of the mass or large-gauge vacuum biopsy is necessary. Because of the possibility of reporting errors and because the histology is likely to be more difficult (if a diagnosis has not already been made), the author suggests that frozen-section reporting should be used rarely and certainly should not form the basis for a decision to undertake a mastectomy. Table 53.2 gives an algorithm for investigating any breast lump.

### Risk of malignancy developing in association with benign breast pathology

The relative risks of malignancy developing according to different histological features found at biopsy are illustrated in Table 53.3.

These were elucidated 30 years ago but remain pertinent and a recent single-centre review reinforces the conclusion that the histological classification of the benign lesion in combination with a family history of breast cancer are important predictors of risk.

### CARCINOMA OF THE BREAST

Breast cancer is the most common cause of death in middle-aged women in Western countries. In 2010, approximately one and three-quarter million new cases were diagnosed worldwide. In England and Wales, 1 in 12 women will develop the disease during their lifetime. The incidence is expected to continue rising as the population ages although more slowly than previously thought as the use of HRT has reduced in the USA and UK.

### Aetiological factors

#### Geographical

Carcinoma of the breast occurs commonly in the Western world, accounting for 3–5 per cent of all deaths in women. In developing countries it accounts for 1–3 per cent of deaths.

#### Age

Carcinoma of the breast is extremely rare below the age of 20 years but, thereafter, the incidence steadily rises so that by the age of 90 years nearly 20 per cent of women are affected.

#### Gender

Less than 0.5 per cent of patients with breast cancer are male.

#### Genetic

It occurs more commonly in women with a family history of breast cancer than in the general population. Breast cancer related to a specific mutation accounts for about 5 per cent of breast cancers yet has far-reaching repercussions in terms of counselling and tumour prevention in these women. This will be discussed more fully in a subsequent section (see under Familial breast cancer).

#### Diet

Because breast cancer so commonly affects women in the ‘developed’ world, dietary factors may play a part in its causation. There is some evidence that there is a link with diets low in phyto-oestrogens. A high intake of alcohol is associated with an increased risk of developing breast cancer.

#### Endocrine

Breast cancer is more common in nulliparous women and breast-feeding in particular appears to be protective. Also protective is having a first child at an early age, especially if associated with late menarche and early menopause. It is known that in postmenopausal women, breast cancer is more common in the obese. This is thought to be because of an increased conversion of steroid hormones to oestradiol in the body fat. Recent studies have clarified the role of exogenous hormones, in particular the oral contraceptive pill and HRT, in the development of breast cancer. For most women the benefits of these treatments will far outweigh the small putative risk; however, long-term exposure to the combined preparation of HRT does significantly increase the risk of developing breast cancer. The recent fall in use of HRT in USA and UK has seen a reduction in the incidence of breast cancer in the 50- to 60-year-old cohort.

#### Previous radiation

This was considered to be of historical interest, as the majority of women exposed to the atomic bombs at Hiroshima and

Nagasaki have now died. It is, however, a real problem in women who have been treated with mantle radiotherapy as part of the management of Hodgkin’s disease, in which significant doses of radiation to the breast are received. The risk appears about a decade after treatment and is higher if radiotherapy occurred during breast development. A surveillance programme has been organised in the UK with MRI and mammographic screening.

Pathology
Breast cancer may arise from the epithelium of the duct system anywhere from the nipple end of the major lactiferous ducts to the terminal duct unit, which is in the breast lobule. The disease may be entirely in situ, an increasingly common finding with the advent of breast cancer screening, or may be invasive cancer. The degree of differentiation of the tumour is usually described using three grades: well differentiated, moderately differentiated or poorly differentiated. Commonly, a numerical grading system based on the scoring of three individual factors (nuclear pleomorphism, tubule formation and mitotic rate) is used, with grade III cancers roughly equating to the poorly differentiated group.

Previously, descriptive terms were used to classify breast cancer (‘scirrhous’, meaning woody, or ‘medullary’, meaning brain-like). More recently, histological descriptions have been used. These have been shown to have clinical correlations in the way that the tumour behaves and are likely to be used for the near future. However, with the increasing application of molecular markers there will be a change in the way that breast cancers are classified and it is likely that much more information about an individual tumour will be routinely reported, such as its likelihood of metastasis and to which therapeutic agents it will be susceptible. Gene array analysis of breast cancers has identified five subtypes. Some of these correlate with known markers such as oestrogen receptor status. There are specific gene signatures that are said to correlate with response to chemotherapy or poor prognosis; trials based upon these differences are planned. A commercial test is now available to patients with oestrogen-positive tumours to assess their risk of recurrence. This is based on analysis of 21 genes and may allow selection of patients in whom more aggressive therapy is indicated.

Current nomenclature
Ductal carcinoma is the most common variant with lobular carcinoma occurring in up to 15 per cent of cases. There are subtypes of lobular cancer including the classical type, which carries a better prognosis than the pleomorphic type. Occasionally, the picture may be mixed with both ductal and lobular features. There are different patterns of spread depending on histological type. If there is doubt whether a tumour is predominantly lobular in type, immunohistochemical analysis using the e-cadherin antibody, which reacts positively in lobular cancer, will help in diagnosis.

Rarer histological variants, usually carrying a better prognosis, include colloid or mucinous carcinoma, whose cells produce abundant mucin, medullary carcinoma, with solid sheets of large cells often associated with a marked lymphocytic reaction, and tubular carcinoma. Invasive lobular carcinoma is commonly multifocal and/or bilateral, hence the increasing use of MRI for assessment. Cases detected via the screening programme are often smaller and better differentiated than those presenting to the symptomatic service and are of a special type.

Inflammatory carcinoma is a fortunately rare, highly aggressive cancer that presents as a painful, swollen breast, which is warm with cutaneous oedema. This is the result of blockage of the subdermal lymphatics with carcinoma cells. Inflammatory cancer usually involves at least one-third of the breast and may mimic a breast abscess. A biopsy will confirm the diagnosis and

| Relative risk of invasive breast carcinoma based on pathological examination of benign breast tissue [American College of Pathologists Consensus Statement] |
| No increased risk | Adenosis, sclerosing or florid |
| Apocrine metaplasia |

| Moderately increased risk (5 times) | Atypical hyperplasia (ductal or lobular) |
| Insufficient data to assign a risk | Solitary papilloma of lactiferous sinus |
| Radial scar lesion |

*A combination with positive family history significantly increases the risks shown above.
After Page and Dupont (1978) by kind permission of the Journal of the National Cancer Institute, USA.
show undifferentiated carcinoma cells. It used to be rapidly fatal but with aggressive chemotherapy and radiotherapy and with salvage surgery the prognosis has improved considerably.

In situ carcinoma is preinvasive cancer that has not breached the epithelial basement membrane. This was previously a rare, usually asymptomatic, finding in breast biopsy specimens but is becoming increasingly common because of the advent of mammographic screening; it now accounts for over 20 per cent of cancers detected by screening in the UK. In situ carcinoma may be ductal (DCIS) or lobular (LCIS), the latter often being multifocal and bilateral. Both are markers for the later development of invasive cancer, which will develop in at least 20 per cent of patients. Although mastectomy is curative, this constitutes overtreatment in many cases. The best treatment for in situ carcinoma is the subject of a number of ongoing clinical trials. DCIS may be classified using the Van Nuys system, which combines the patient’s age, type of DCIS and presence of microcalcification, extent of resection margin and size of disease. Patients with a high score benefit from radiotherapy after excision, whereas those of low grade, whose tumour is completely excised, need no further treatment.

Staining for oestrogen and progesterone receptors is now considered routine, as their presence will indicate the use of adjuvant hormonal therapy with tamoxifen or an aromatase inhibitor (Figure 53.20). Tumours are also stained for c-erbB2 (also known as HER-2/neu) (a growth factor receptor) as patients who are positive can be treated with the monoclonal antibody trastuzumab (Herceptin®), either in the adjuvant or relapse setting.

The pathologist is an important member of the breast cancer team and will increasingly help decide which adjuvant therapies will be appropriate.

**Paget’s disease of the nipple**

Paget’s disease of the nipple (Figure 53.21a and b) is a superficial manifestation of an underlying breast carcinoma. It presents as an eczema-like condition of the nipple and areola, which persists despite local treatment. The nipple is eroded slowly and eventually disappears. If left, the underlying carcinoma will sooner or later become clinically evident. Nipple eczema should be biopsied if there is any doubt about its cause. Microscopically, Paget’s disease is characterised by the presence of large, ovoid cells with abundant, clear, pale-staining cytoplasm in the Malpighian layer of the epidermis.

**The spread of breast cancer**

**Local spread**

The tumour increases in size and invades other portions of the breast. It tends to involve the skin and to penetrate the pectoral muscles and even the chest wall if diagnosed late.

**Lymphatic metastasis**

Lymphatic metastasis occurs primarily to the axillary and the internal mammary lymph nodes. Tumours in the posterior one-third of the breast are more likely to drain to the internal mammary nodes. The involvement of lymph nodes has both biological and chronological significance. It represents not only an evolutional event in the spread of the carcinoma but is also a marker for the metastatic potential of that tumour. Involvement of supraclavicular nodes and of any contralateral lymph nodes represents advanced disease.

**Spread by the bloodstream**

It is by this route that skeletal metastases occur, although the initial spread may be via the lymphatic system. In order of
frequency, the lumbar vertebrae, femur, thoracic vertebrae, rib and skull are affected and these deposits are generally osteolytic. Metastases may also commonly occur in the liver, lungs and brain and, occasionally, the adrenal glands and ovaries; they have, in fact, been described in most body sites.

**Clinical presentation**

Although any portion of the breast, including the axillary tail, may be involved, breast cancer is found most frequently in the upper outer quadrant (Figures 53.22 and 53.23). Most breast cancers will present as a hard lump, which may be associated with indrawing of the nipple. As the disease advances locally there may be skin involvement with peau d’orange (Figure 53.24) or frank ulceration and fixation to the chest wall (Figure 53.25). This is described as cancer-en-cuirasse when the disease progresses around the chest wall. About 5 per cent of breast cancers in the UK will present with either locally advanced disease or symptoms of metastatic disease. This figure is much higher in the developing world. These patients must then undergo a staging evaluation so that the full extent of their disease can be ascertained. This will include a careful clinical examination, chest radiograph, computed tomography (CT) of the chest and abdomen and an isotope bone scan (Figure 53.26). This is important for both prognosis and treatment; a patient with widespread visceral metastases may obtain an increased length and quality of survival from systemic hormone therapy or chemotherapy but is unlikely to benefit from surgery as she will die from her metastases before local disease becomes a problem. In contrast, patients with relatively small tumours (<2 cm in diameter) confined to the breast and ipsilateral lymph nodes rarely need staging beyond a good clinical examination as the pick-up rate for distant metastases is so low. Currently, a chest radiograph, full blood count and liver function tests are all that are recommended for screening of patients with early-stage breast cancer.

**Staging of breast cancer**

Classical staging of breast cancer by means of the TNM (tumour–node–metastasis) or UICC (Union Internationale Contre le Cancer) criteria is used less often as we gain more knowledge of the biological variables that affect prognosis. It is becoming increasingly clear that it is these factors (discussed in more detail below) rather than anatomical mapping that influence outcome and treatment. Perhaps a more pragmatic approach would be to classify patients according to the treatment that they require (Table 53.4). Treatment recommendations are summarised in consensus statements such as those from the American Society of Clinical Oncology (ASCO) and the St Gallen Conference.

**Prognosis of breast cancer**

The best indicators of likely prognosis in breast cancer remain tumour size, grade and lymph node status; however, it is realised that some large tumours will remain confined to the breast

DCIS, duct carcinoma in situ.
Peau d'orange is French for ‘orange skin’.

for decades whereas some very small tumours are incurable at diagnosis. Hence, the prognosis of a cancer depends not on its chronological age but on its invasive and metastatic potential. In an attempt to define which tumours will behave aggressively, and thus require early systemic treatment, a host of prognostic factors have been described. These include the histological grade of the tumour, hormone receptor status, measures of tumour proliferation such as S-phase fraction, growth factor analysis and oncogene or onco-gene product measurements. Many others are under investigation but have proved of little practical value in patient management. Prognostic indices (such as the Nottingham prognostic index) have combined these factors to allow subdivision of patients into discrete prognostic groups. More recently, computer-aided programs (adjuvant online; www.adjuvantonline.com or in the UK Predict; www.predict.nhs.uk) have been developed, which incorporate the putative benefits of treatment allowing oncologist and patient to visualise the benefits of therapy.

Treatment of cancer of the breast

The two basic principles of treatment are to reduce the chance of local recurrence and the risk of metastatic spread. Treatment of early breast cancer will usually involve surgery with or without radiotherapy. Systemic therapy such as chemotherapy or hormone therapy is added if there are adverse prognostic factors such as lymph node involvement, indicating a high likelihood of metastatic relapse. At the other end of the spectrum, locally advanced or metastatic disease is usually treated by systemic therapy to palliate symptoms, with surgery playing a much smaller role. An algorithm for the management of breast cancer is shown in Summary box 53.3.

The multidisciplinary team approach

As in all branches of medicine, good doctor–patient communication plays a vital role in helping to alleviate patient anxiety. Participation of the patient in treatment decisions is of particular importance in breast cancer when there may be uncertainty as

Figure 53.24 Peau d’orange of the breast.

Figure 53.25 Ulcerated carcinoma of the right breast.

Figure 53.26 Skeletal isotope bone scan showing multiple ‘hot-spots’ due to metastases.
Summary box 53.3

Algorithm for management of operable breast cancer

- Achieve local control
- Appropriate surgery
  - Wide local excision (clear margins) and radiotherapy, or
  - Mastectomy & radiotherapy (offer reconstruction – immediate or delayed)
- Combined with axillary procedure (see text)
- Await final pathology and receptor measurements
- Use risk assessment tool; stage if appropriate
- Treat risk of systemic disease
  - Offer chemotherapy if prognostic factors poor; include Herceptin if Her-2 positive
  - Radiotherapy as decided above
  - Hormone therapy if oestrogen receptor or progesterone receptor positive

Summary box 53.4

Treatment of early breast cancer

The aims of treatment are:

- ‘Cure’: likely in some patients but late recurrence is possible
- Control of local disease in the breast and axilla
- Conservation of local form and function
- Prevention or delay of the occurrence of distant metastases

Surgery

Surgery still has a central role to play in the management of breast cancer but there has been a gradual shift towards more conservative techniques, backed up by clinical trials that have shown equal efficacy between mastectomy and local excision followed by radiotherapy.

It was initially hoped that avoiding mastectomy would help to alleviate the considerable psychological morbidity associated with breast cancer, but recent studies have shown that over 30 per cent of women develop significant anxiety and depression following both radical and conservative surgery. After mastectomy women tend to worry about the effect of the operation on their appearance and relationships, whereas after conservative surgery they may remain fearful of a recurrence.

Mastectomy is indicated for large tumours (in relation to the size of the breast), central tumours beneath or involving the nipple, multifocal disease, local recurrence or patient preference. The radical Halsted mastectomy, which included excision of the breast, axillary lymph nodes and pectoralis major and minor muscles, is no longer indicated as it causes excessive morbidity with no survival benefit. The modified radical (Patey) mastectomy is more commonly performed and is thus described below.

Simple mastectomy involves removal of only the breast with no dissection of the axilla, except for the region of the axillary tail of the breast, which usually has attached to it a few nodes low in the anterior group.

Patey mastectomy

The breast and associated structures are dissected en bloc (Figure 53.27) and the excised mass is composed of:

- the whole breast;
- a large portion of skin, the centre of which overlies the tumour but which always includes the nipple;
- all of the fat, fascia and lymph nodes of the axilla.

The pectoralis minor muscle is either divided or retracted to gain access to the upper two-thirds of the axilla. The axillary vein and nerves to the serratus anterior and latissimus dorsi (the thoracodorsal trunk) should be preserved. The intercostal brachial nerves are usually divided in this operation and the patient should be warned about sensation changes postoperatively.

The wound is drained using a wide-bore suction tube. Early mobilisation of the arm is encouraged and physiotherapy helps normal function to return very quickly; most patients are able to resume light work or housework within a few weeks.

Conservative breast cancer surgery

This is aimed at removing the tumour plus a rim of at least 1 cm of normal breast tissue. This is commonly referred to as a wide local excision. The term lumpectomy should be reserved for an operation in which a benign tumour is excised and in which a large amount of normal breast tissue is not resected. A quadrantectomy involves removing the entire segment of the breast that contains the tumour. Both of these operations are usually combined with axillary surgery, usually via a separate incision in the axilla. There are various options that can be used to deal with the axilla, including sentinel node biopsy, sampling, removal of the nodes behind and lateral to the pectoralis minor (level II) or a full axillary dissection (level III).

There is a somewhat higher rate of local recurrence following conservative surgery, even if combined with radiotherapy, but the long-term outlook in terms of survival is unchanged. Local recurrence is more common in younger women and in those with high-grade tumours and involved resection margins. Patients whose margins are involved should have a further local excision (or a mastectomy) before going on to radiotherapy. Excision of a breast cancer without radiotherapy leads to an unacceptable local recurrence rate.

The role of axillary surgery is to stage the patient and to treat...
the axilla. The presence of metastatic disease within the axillary lymph nodes remains the best single marker for prognosis; however, treatment of the axilla does not affect long-term survival, suggesting that the axillary nodes act not as a ‘reservoir’ for disease but as a marker for metastatic potential. It used to be accepted that only premenopausal women should have their axilla staged by operation as there was a good case for giving chemotherapy to lymph node-positive patients; however, it is now clear that postmenopausal women also benefit from chemotherapy and so all patients require axillary surgery. In postmenopausal patients, tamoxifen was once given regardless of axillary lymph node status, but it is now known that only hormone receptor-positive patients, irrespective of age, benefit from this. Axillary surgery should not be combined with radiotherapy to the axilla because of excess morbidity. Removal of the internal mammary lymph nodes is unnecessary.

**Sentinel node biopsy**

This technique has become the standard of care in the management of the axilla in patients with clinically node-negative disease. The sentinel node is localised peroperatively by the injection of patent blue dye (Figure 53.28) and radioisotope-labelled albumin in the breast. The recommended site of injection is in the subdermal plexus around the nipple although some still inject on the axillary side of the cancer. The marker passes to the primary node draining the area and is detected visually and with a hand-held gamma camera. Peropererative diagnosis allows completion axillary clearance if nodal disease is detected. This may be achieved with frozen-section analysis, touch imprint cytology (TIC) or by molecular methods. These involve homogenising the node and detection of a gene such as cytokeratin 19 or mammoglobin. In some cases there are only subcapsular micrometastases that are missed at frozen section. In patients in whom there is no tumour involvement of the sentinel node, further axillary dissection can be avoided. A nomogram outlining the chances of further axillary node positivity has been developed by the group at Memorial Sloan Kettering Hospital, New York, and is available on their website (www.mskcc.org/mskcc/html/15938.cfm). Recent trial results have called into question the utility of completion axillary clearance after a positive sentinel node has been detected but, at present, this remains controversial.

**Radiotherapy**

Radiotherapy to the chest wall after mastectomy is indicated in selected patients in whom the risks of local recurrence are high. This includes patients with large tumours and those with large numbers of positive nodes or extensive lymphovascular invasion. There is some evidence that postoperative chest wall radiotherapy improves survival in women with node-positive breast cancer. It is conventional to combine conservative surgery with radiotherapy to the remaining breast tissue. Recurrence rates are too high for treatment by local excision alone except in special cases (small node-negative tumours of a special type). Trials are under way to investigate whether radiotherapy can be given intraoperatively at one sitting or as an accelerated postoperative course. This would have considerable advantages in making conservative surgery available in areas where radiotherapy is not currently used. It would also relieve the burden of the current demand for radiotherapy, which accounts for up to 40 per cent of activity in some departments.

Extrapolation from the Oxford overviews of systemic therapy

---

**Figure 53.27** Radical mastectomy with pectoralis removed; the modified radical approach leaves the pectoralis major muscle intact.
annual rate of recurrence by 25 per cent, with a 17 per cent
increase in breast cancer. Its efficacy as an adjuvant therapy was
appropriate to give hormone therapy to women who do not have
letrozole and exemestane) if postmenopausal. It is no longer
if premenopausal or the newer aromatase inhibitors (anastrozole,
which is now widely accepted that the outcomes of treatment are pre-
determined by the extent of micrometastatic disease at the time
of diagnosis. Variations in the radical extent of local therapy
might influence local relapse but probably do not alter long-term
mortality from the disease. However, systemic therapy targeted
at these putative micrometastases might be expected to delay
relapse and prolong survival. As a result of many international
clinical trials and recent world overview analyses, it can be stated
with statistical confidence that the appropriate use of adjuvant
therapy or hormone therapy will improve relapse-free survival by approximately 30 per cent, which ultimately translates
into an absolute improvement in survival of the order of 10 per
cent at 15 years. Bearing in mind how common the disease is in
northern Europe and the USA, these figures are of major public
health importance.

Who to treat and with what are still questions for which abso-
lute answers have yet to be found, but the data from the over-
views of recent trials show that lymph node-positive and many
higher risk node-negative women should be recommended adju-
vant combined chemotherapy. Women with hormone receptor-
positive tumours will obtain a worthwhile benefit from about
five years of endocrine therapy, either 20 mg daily of tamoxifen
if premenopausal or the newer aromatase inhibitors (anastrozole,
letrazole and exemestane) if postmenopausal. It is no longer
appropriate to give hormone therapy to women who do not have
oestrogen or progesterone receptor-positive disease.

Hormone therapy
Tamoxifen has been the most widely used ‘hormonal’ treat-
ment in breast cancer. Its efficacy as an adjuvant therapy was
first reported in 1983 and it has now been shown to reduce the
annual rate of recurrence by 25 per cent, with a 17 per cent
reduction in the annual rate of death. The beneficial effects of
tamoxifen in reducing the risk of tumours in the contralateral
breast have also been observed, as has its role as a preventative
agent (IBIS-I and NSABP-P1 trials). Trials studying the optimal
duration of treatment suggest that five years of treatment is pref-
erable to two years.

Other hormonal agents that are also beneficial as adjuvant
therapy have been developed. These include the LHRH agonists,
which induce a reversible ovarian suppression and thus have the
same beneficial effects as surgical or radiation-induced ovarian
ablation in premenopausal receptor-positive women, and the
oral aromatase inhibitors (AIs) for postmenopausal women. The
latter group of compounds are now licensed for treatment of
recurrent disease, in which they have been shown to be superior
to tamoxifen. A large trial comparing anastrozole to tamoxifen
in the adjuvant setting has shown a beneficial effect for the aro-
matase inhibitor in terms of relapse-free survival, although no
benefit for overall survival. There is an additional reduction in
contralateral disease, which makes this drug suitable for a study
of prevention, and the side-effect profile is different from that of
tamoxifen. The AIs have been more expensive than tamoxifen
but are all coming off patent protection and generic copies may
allow more widespread use. There is an increase in bone density
loss with patients on an AI and a bone density scan is advised
prior to commencement with treatment of underlying osteope-
nia or osteoporosis.

Chemotherapy
Chemotherapy using a first-generation regimen such as a six-
monthly cycle of cyclophosphamide, methotrexate and 5-fluor-
ouracil (CMF) will achieve a 25 per cent reduction in the risk
of relapse over a 10- to 15-year period. It is important to under-
stand that this 25 per cent reduction refers to the likelihood of
an event happening. For example, a woman with a 96 per cent
chance of survival at, say, five years only has a 4 per cent chance
of death over this time and the absolute benefit from chem-
otherapy would be an increase in survival rate of 1 per cent, to
97 per cent. This would not be a sufficient gain to offset the side
effects of this potentially toxic therapy. However, for a woman
with a 60 per cent chance of dying (40 per cent survival rate)
a 25 per cent reduction in risk would increase her likelihood of
survival to 55 per cent and thus treatment would be worthwhile.
CMF is no longer considered adequate adjuvant chemotherapy
and modern regimens include an anthracycline (doxorubicin or
epirubicin) and the newer agents such as the taxanes.

Chemotherapy was once confined to premenopausal women
with a poor prognosis (in whom its effects are likely to be the
result, in part, of a chemical castration effect) but is being
increasingly offered to postmenopausal women with poor prog-
nosis disease as well. Chemotherapy may be considered in node-
negative patients if other prognostic factors, such as tumour
grade, imply a high risk of recurrence. The effect of combing
hormone and chemotherapy is additive although hormone
therapy is started after completion of chemotherapy to reduce
side effects.

High-dose chemotherapy with stem cell rescue for patients
with heavy lymph node involvement has now been shown in
controlled trials to offer no advantage and has been abandoned.

Primary chemotherapy (neoadjuvant) is being used in many
centres for large but operable tumours that would tradition-
ally require a mastectomy (and almost certainly postoperative
adjuvant chemotherapy). The aim of this treatment is to shrink
the tumour to enable breast-conserving surgery to be performed. This approach is successful in up to 80 per cent of cases but is not associated with improvements in survival compared with conventionally timed chemotherapy. For older patients with breast cancers strongly positive for hormone receptors, a similar effect can be seen with three months of endocrine treatment.

Newer ‘biological’ agents will be used more frequently as molecular targets are identified — the first of these, trastuzumab (Herceptin), is active against tumours containing the growth factor receptor c-erbB2. Other agents currently available include bevacizumab, a vascular growth factor receptor inhibitor, and lapatinib, an oral combined growth factor receptor inhibitor. It is unclear how and when these agents will be used, whether in combination or instead of standard chemotherapy agents.

**Follow up of breast cancer**

Patients with breast cancer used to be followed for life to detect recurrence and dissemination. This led to large clinics with little value for either patient or doctor. It is current practice to arrange yearly or two-yearly mammography of the treated and contralateral breast. There is a move to return the patient early to the care of the general practitioner with fast-track access back to the breast clinic if suspicious symptoms appear. There is currently no routine role for repeated measurements of tumour markers or imaging other than mammography.

**Phenomena resulting from lymphatic obstruction in advanced breast cancer**

**Peau d’orange**

Peau d’orange is caused by cutaneous lymphatic oedema. Where the infiltrated skin is tethered by the sweat ducts it cannot swell, leading to an appearance like orange skin. Occasionally, the same phenomenon is seen over a chronic abscess (Figure 53.24).

Late oedema of the arm is a troublesome complication of breast cancer treatment, fortunately seen less often now that radical axillary dissection and radiotherapy are rarely combined. However, it does still occur occasionally after either mode of treatment alone and appears at any time from months to years after treatment. There is usually no precipitating cause but recurrent tumour should be excluded because neoplastic infiltration of the axilla can cause arm swelling as a result of both lymphatic and venous blockage. This neoplastic infiltration is often painful because of brachial plexus nerve involvement.

An oedematous limb is susceptible to bacterial infections following quite minor trauma and these require vigorous antibiotic treatment. Antibiotics may need to be given for much longer than is normal and patients at risk of infection should have antibiotics readily available to enable treatment to be started promptly. Treatment of late oedema is difficult but limb elevation, elastic arm stockings and pneumatic compression devices can be useful.

**Cancer-en-cuirasse**

The skin of the chest is infiltrated with carcinoma and has been likened to a coat. It may be associated with a grossly swollen arm. This usually occurs in cases with local recurrence after mastectomy and is occasionally seen to follow the distribution of irradiation to the chest wall. The condition may respond to palliative systemic treatment but prognosis in terms of survival is poor.

**Lymphangiosarcoma**

Lymphangiosarcoma is a rare complication of lymphoedema with an onset many years after the original treatment. It takes the form of multiple subcutaneous nodules in the upper limb and must be distinguished from recurrent carcinoma of the breast. The prognosis is poor but some cases respond to cytotoxic therapy or irradiation. Interscapulothoracic (forequarter) amputation is rarely indicated.

**Breast reconstruction**

Despite an increasing trend towards conservative surgery, up to 50 per cent of women still require, or want, a mastectomy. These women can now be offered immediate or delayed reconstruction of the breast. Few contraindications to breast reconstruction exist. Even those with a limited life expectancy may benefit from the improved quality of life; however, patients do require counselling before this procedure so that their expectations of cosmetic outcome are not unrealistic.

The easiest type of reconstruction is using a silicone gel implant under the pectoralis major muscle. This may be combined with prior tissue expansion using an expandable saline prosthesis first (or a combined device), which creates some ptosis of the new breast. If the skin at the mastectomy site is poor (e.g. following radiotherapy) or if a larger volume of tissue is required, a musculocutaneous flap can be constructed either from the latissimus dorsi muscle (an LD flap) (Figure 53.29) or using the transversus abdominis muscle (a TRAM flap as shown in Figure 53.30). The latter gives an excellent cosmetic result in experienced hands but is a lengthy procedure and requires careful patient selection. It is now usually performed as a free transfer using microvascular anastomosis, although the pedicled TRAM from the contralateral side is still used. Variations on the TRAM flap requiring less muscle harvesting, such as the DIEP flap (based on deep inferior epigastric vessels), are increasingly being used.

The timing of reconstruction is difficult. Impediments to immediate reconstruction include insufficient theatre time and a lack of experienced reconstructive surgeons. In addition, if a patient is likely to need postoperative radiotherapy then a delayed reconstruction using a flap often gives a better result. Radiotherapy onto a prosthesis often leads to a high incidence of capsular contracture and unacceptable results.

![Figure 53.29 Reconstructive Surgery with latissimus dorsi flap.](image-url)
the quality of breast cancer services but a number of questions remain unanswered, including the value of screening women under 50 years and the ideal interval between screenings. The psychological consequences of false alarms or false reassurances still need to be addressed and self-examination programmes that have failed to show any benefit for the population in terms of earlier detection of or decreased mortality from breast cancer remain controversial. The opponents of screening rightly point out that some women will have disease detected and treated that might never harm them in their lifetime. However, until we can identify this group and separate them from those in whom prompt diagnosis and treatment will be beneficial, we will continue to treat everyone.

MRI is used to screen those at very high risk or where radiation might be hazardous (Li–Fraumeni syndrome). There is no place for thermography as a screening (or diagnostic) tool.

**Familial breast cancer**

Recent developments in molecular genetics and the identification of a number of breast cancer predisposition genes (BRCA1, BRCA2 and p53) have done much to stimulate interest in this area. Yet women whose breast cancer is due to an inherited genetic change actually account for less than 5 per cent of all cases of breast cancer, that is about 1250 cases per year in the UK and 9000 cases in the USA. A much larger number of women will have a risk that is elevated above normal because of an as yet unspecified familial inheritance. These women have a risk of developing breast cancer that is 2–10 times above baseline. The risks associated with family history are summarised in Table 53.5.

Table 53.5 Likelihood of genetic mutation with family history.

<sup>a</sup>BRCA1 is also associated with ovarian and, to a lesser extent, colorectal and prostate cancer.
<sup>b</sup>BRCA2 is associated with familial male breast cancer.

The BRCA1 gene has been associated with an increased incidence of breast (and ovarian) cancer and is located on the long arm of chromosome 17 (17q). The gene frequency in the population is approximately 0.0006. It does, however, occur with greater frequency in certain populations such as Ashkenazi Jews, in whom there is often a common (founder) mutation. BRCA2 is located on chromosome 13q and there is an association with male breast cancer. Women who are thought to be gene carriers may be offered breast screening (and ovarian screening in the case of BRCA1, which is known to impart a 50 per cent lifetime risk of ovarian cancer), usually as part of a research programme, or genetic counselling and mutation analysis. Those who prove to be ‘gene positive’ have a 50–80 per cent risk of developing breast cancer, predominantly while premenopausal. Many will opt for prophylactic mastectomy. Although this does

Nipple reconstruction is a relatively simple procedure that can be performed under a local anaesthetic. Many different types of nipple reconstruction are described but the majority lose height with time. Tattooing of the reconstructed nipple is often required. Alternatively, the patient can be fitted with a prosthetic nipple. To achieve symmetry the opposite breast may require a cosmetic procedure such as reduction or augmentation mammoplasty, or mastopexy. A breast reconstructive service can be offered by a suitably trained breast surgeon, a plastic surgeon or, ideally, using a combined oncoplastic approach. The patient needs to be warned that breast reconstruction is seldom, if ever, one operation.

External breast prostheses that fit within the bra are the most common method of restoring volume fill and should be available for all women who do not have an immediate reconstruction.

**Screening for breast cancer**

Because the prognosis of breast cancer is closely related to stage at diagnosis it would seem reasonable to hope that a population screening programme that could detect tumours before they come to the patient’s notice might reduce mortality from breast cancer. Indeed, a number of studies have shown that breast screening by mammography in women over the age of 50 years will reduce cause-specific mortality by up to 30 per cent. Following the publication in 1987 of the Forrest report, the National Health Service in the UK launched a programme of three-yearly mammographic screening for women between the ages of 50 and 64 years (now increased to 70 years). The introduction of this programme has undoubtedly improved the ages of 50 and 64 years (now increased to 70 years). The introduction of this programme has undoubtedly improved

Ashkenazi Jews are Jews of Eastern or Central European descent.
not completely eliminate the risk, it does reduce it considerably. This work should be carried out in specialist centres.

For the great majority of women with a positive family history, who are unlikely to be carriers of a breast cancer gene, there are no currently proven breast cancer screening manoeuvres, although this is under investigation. Tamoxifen given for five years appears to reduce the risk of breast cancer by 30–50 per cent, and newer agents are currently under trial. Thus, these women are best served by being assessed and followed-up, preferably in a properly organised family history clinic.

**Pregnancy**

The effects of pregnancy on breast cancer are not well studied but it is thought that breast cancer presenting during pregnancy or lactation tends to be at a later stage, presumably because the symptoms are masked by the pregnancy; however, in other respects it behaves in a similar way to breast cancer in a non-pregnant young woman and should be treated accordingly. Thus, treatment is similar with some provisos: radiotherapy should be avoided during pregnancy, making mastectomy a more frequent option than breast conservation surgery; chemotherapy should be avoided during the first trimester but appears safe subsequently; most tumours are hormone receptor negative and so hormone treatment, which is potentially teratogenic, is not required. Becoming pregnant subsequent to a diagnosis of breast cancer appears not to alter the likely outcome, but women are usually advised to wait at least two years as it is within this time that recurrence most often occurs. The risk of developing breast cancer with oral contraceptive use is only slight, and disappears ten years after stopping the oral contraceptive pill.

**Hormone replacement therapy**

HRT does increase the risk of developing breast cancer if taken for prolonged periods and in certain high-risk groups. HRT may also prolong symptoms of benign breast disorders such as cysts and mastalgia and make mammographic appearances more difficult to interpret.

Patients who develop breast cancer while on HRT appear to have a more favourable prognosis. The consequences in terms of recurrence in women using HRT following breast cancer are unknown.

**Treatment of advanced breast cancer**

Breast cancer may occasionally present as metastatic disease without evidence of a primary tumour (that is with an occult primary). The diagnosis is made partly by exclusion of another site for the primary tumour and may be confirmed by histology with special immunohistological stains of the metastatic lesions. Management should be aimed at palliation of the symptoms and treatment of the breast cancer, usually by endocrine manipulation with or without radiotherapy.

**Locally advanced inoperable breast cancer**

Locally advanced inoperable breast cancer, including inflammatory breast cancer, is usually treated with systemic therapy, either chemotherapy or hormone therapy.

Occasionally, ‘toilet mastectomy’ or radiotherapy is required to control a fungating tumour but often incision through microscopically permeated tissues results in a worse outcome.

---

**Metastatic carcinoma of the breast**

Metastatic carcinoma of the breast will also require palliative systemic therapy to alleviate symptoms. Hormone manipulation is often the first-line treatment because of its minimal side effects. It is particularly useful for bony metastases. However, only about 30 per cent of these tumours will be hormone responsive and, unfortunately, in time, even these will become resistant to treatment. First-line hormone therapy for postmenopausal women is now anastrazole or one of the other third-generation aromatase inhibitors. Tamoxifen, ovarian suppression by surgery (for premenopausal women), radiotherapy and medical treatment are all in common use. When resistance to these has developed, other hormonal agents can prove useful, with about one-half of the response rate seen in the first-line therapy. The newer agents such as anti-progestins, pure anti-oestrogens and growth factor tyrosine kinase inhibitors are all candidates for this role.

Cytotoxic therapy is used particularly in younger women or those with visceral metastases and rapidly growing tumours. A variety of regimens is available and, although none prolongs survival, contrary to expectations, quality of life and symptom control is often better with more aggressive treatments, with responses being seen in up to 70 per cent of patients.

Local treatment may also prove useful for some metastatic disease, such as radiotherapy for painful bony deposits and internal fixation of pathological fractures.

---

**THE MALE BREAST**

**Gynaecomastia**

**Idiopathic**

Hypertrophy of the male breast may be unilateral or bilateral. The breasts enlarge at puberty and sometimes present the characteristics of female breasts.

**Hormonal**

Enlargement of the breasts often accompanied stilbestrol therapy for prostate cancer, now rarely used. It may also occur as a result of a teratoma of the testis, in anorchism and after castration. Rarely, it may be a feature of ectopic hormonal production in bronchial carcinoma and in adrenal and pituitary disease. Bodybuilders may use steroids to improve their physique, which may cause gynaecomastia. Some even go so far as to take tamoxifen to mask this symptom.

**Associated with leprosy**

Gynaecomastia is very common in men suffering from leprosy. This is possibly because of bilateral testicular atrophy, which is a frequent accompaniment of leprosy.

**Associated with liver failure**

Gynaecomastia sometimes occurs in patients with cirrhosis as a result of failure of the liver to metabolise oestrogens. It is associated with drugs that interfere with the hepatic metabolism of oestrogens. It is also seen with certain drugs such as cimetidine, digitalis and spironolactone.

**Associated with Klinefelter syndrome**

Gynaecomastia may occur in patients with Klinefelter’s syndrome, a sex chromosome anomaly having 47XXY trisomy.

---

*Harry Fitch Klinefelter Jr, born 1912, physician of Baltimore, MD, USA, described this syndrome in 1942.*
Treatment
Provided that the patient is healthy and comparatively young, reassurance may be sufficient. If not, mastectomy with preservation of the areola and nipple can be performed. The patient must be warned about the side effects of this procedure, which are common and a cause of many medicolegal complaints in the UK.

Carcinoma of the male breast
Carcinoma of the male breast (Figure 53.31) accounts for less than 0.5 per cent of all cases of breast cancer. The known predisposing causes include gynaecomastia and excess endogenous or exogenous oestrogen. As in the female, it tends to present as a lump and is most commonly an infiltrating ductal carcinoma.

Treatment
Stage for stage the treatment is the same as for carcinoma in the female breast and prognosis depends upon stage at presentation. Adequate local excision, because of the small size of the breast, should always be with a ‘mastectomy’.

OTHER TUMOURS OF THE BREAST

Lipoma
A true lipoma is very rare.

Sarcoma of the breast
Sarcoma of the breast is usually of the spindle-cell variety and accounts for 0.5 per cent of malignant tumours of the breast. Some of these growths arise in an intracanalicular fibroadenoma or may follow previous radiotherapy, e.g. for Hodgkin’s lymphoma, many years previously. It may be impossible to distinguish clinically a sarcoma of the breast from a medullary carcinoma, but areas of cystic degeneration suggest a sarcoma and on incising the neoplasm it is pale and friable. Sarcoma tends to occur in younger women between the ages of 30 and 40 years. Treatment is by simple mastectomy followed by radiotherapy. The prognosis depends on the stage and histological type.

Metastases
On rare occasions cancer elsewhere may present with a metastasis in the breast. The breast is also occasionally infiltrated by Hodgkin’s disease and other lymphomas.

PART 9

Cardiothoracic

54 Cardiac surgery
55 The thorax
INTRODUCTION

In 1925, Sir Henry Souttar reported the first mitral commissurotomy in the British Medical Journal. He wrote that the heart should be as amenable to surgery as any other organ. He saw the main problem as being maintenance of blood flow, particularly to the brain, while surgery was being performed.

The first real advances occurred in the late 1940s and early 1950s, driven by surgeons who had gained confidence and experience under the pressures and opportunities provided by war, followed by the development of cardiopulmonary bypass in the mid-1950s. Recently, the well-being and lifespan of patients with congenital, valvular and degenerative heart disease has improved drastically due to the advances in the range, complexity, and technical expertise in cardiac surgery.

CARDIOPULMONARY BYPASS

Cardiopulmonary bypass (CPB) was first used successfully in 1953 by Gibbon and has since revolutionised cardiac surgery. It can be employed in any procedure in which the heart and lungs need to be stopped temporarily and their function replaced artificially. Before Gibbon’s work, valve surgery under direct vision would not have been possible nor would the precise reconstructions needed to treat extensive coronary artery disease. Much of the success of modern CPB is attributable to the development of new biomaterials and sophisticated oxygenating devices, as well as a greater understanding of the pathophysiological consequences of CPB (Summary box 54.1).

Surgical approach to the heart

The heart is approached mainly by a median sternotomy. An incision is made from the jugular or suprasternal notch to the lower end of the xiphisternum. The sternum is divided and retracted to expose the thymus superiorly and the pericardium inferiorly. The thymus, although atrophic in adults, often remains relatively vascular. The thymus and pleurae are dissected from the pericardium, and the pericardium is opened. Before cannulation for CPB, the patient is fully heparinised. Other incisions which can be used include left anterolateral thoracotomy.

Initiating cardiopulmonary bypass

Arterial cannulation

Conventionally, the great vessels are exposed and an aortic perfusion cannula is inserted into the ascending aorta, held in place by the purse-string suture. Air is excluded and the cannula connected to the bypass circuit. Alternatively, when it is inadvisable (aortic dissection), impractical (aortic root surgery) or impossible (severe adhesions) to cannulate the aorta, alternative arterial cannulation sites can be used, such as the femoral artery or the axillary artery.

Venous cannulation

A second purse-string suture is inserted into the right atrium by the appendage. A single ‘two-stage’ venous cannula placed in the right atrium establishes venous drainage. The venous pipe has end holes that sit in the inferior vena cava and side holes that sit in the right atrium (to take the drainage from the superior vena cava). Alternatively, the superior and inferior

Summary box 54.1

Alternative uses of CPB
- Rewarming from profound hypothermia
- Resuscitation in severe respiratory failure
- As an adjunct in pulmonary embolectomy
- In single- and double-lung transplantation
- In cardiopulmonary trauma
- In certain non-cardiac surgical procedures (e.g. resection of highly vascular tumours and tumours invading large blood vessels)
vena cavae may be cannulated separately to gain better control over the venous return and to facilitate surgery within the right atrium. Venous drainage from the femoral vein can offer an alternative, particularly during thoracic aortic procedures.

**Cardiopulmonary bypass circuit**

Once the circuit is connected (Figure 54.1), the CPB machine (the ‘pump’) gradually takes over the processes of circulation and ventilation. Once full flow is established (the required cardiac output depends on the body surface area of the patient), the ventilator is stopped and the heart can be isolated from the rest of the circulation. Blood is pumped from a venous reservoir and oxygenated using an oxygenator that allows gas exchange across its membrane.

The core systemic temperature can be lowered by passing the returning blood through a heat exchanger which can reduce the metabolic demands of the tissues. The degree of cooling is according to the severity and complexity of the surgical procedure, as well as the surgeon’s preference.

The blood is also filtered to remove particulate emboli and returned to the systemic arterial circulation via a pump. Suction pumps can be employed to keep the area around the heart clear of blood, and to decompress the heart when used as vents.

**Myocardial protection**

Once CPB has been established, the ascending aorta is usually cross-clamped to obtain a bloodless operative field. The heart ceases to eject and becomes anoxic due to inhibition of coronary blood flow. Permanent myocardial damage can develop within 15–20 minutes, therefore most cardiac operations require some form of myocardial protection. Techniques of myocardial protection and the operative management of the myocardium have had a significant impact on the complexity of cardiac surgery. The methods of myocardial protection include intracoronary infusion of a cardioplegic solution, intermittent cross-clamp fibrillation and total circulatory arrest.

Cardioplegic solutions vary in terms of temperature, pH, arresting agent, osmolality, and the presence of red cells and other factors. Most solutions contain potassium as the arresting agent. Potassium arrests the heart in diastole by depolarisation of the membrane. Cold (4–10°C) isotonic crystalloid or blood solutions aid myocardial protection by reducing metabolic requirements through local hypothermia. Warm cardioplegic solutions, on the other hand, may facilitate better myocardial repair recovery postoperatively by aiding intramyocardial enzyme activation.

Intermittent cross-clamp fibrillation is a technique in which intermittent ventricular fibrillation is induced by a small electrical charge. The heart does not eject and is relatively still, but not bloodless. The aorta is cross-clamped to render the heart ischaemic. The heart can tolerate short periods (10–20 minutes) of intermittent ischaemia, providing the heart is reperfused when the cross-clamp is released and allowed to beat following cardioversion for short periods during the operation.

Total circulatory arrest becomes necessary when visibility and clarity of the operative area is crucial, as in paediatric surgery or in surgery of the ascending aorta and arch of the aorta. CPB is instituted and the core body temperature reduced to 15–18°C (profound hypothermia). The metabolic rate of all organs of the body is reduced by 50 per cent with every 7°C drop in temperature. Using this technique, circulatory arrest can be tolerated for 20–30 minutes. Additional cerebral protection can be provided with ice packs placed around the head, pharmacological agents, and cerebral perfusion techniques.

**Discontinuing cardiopulmonary bypass**

At the end of the procedure, air must be meticulously excluded from the cardiac chambers. Once perfusion is restored to the coronary arteries (by removing the cross-clamp) the heart may beat spontaneously. If ventricular fibrillation is present, cardioversion may be required. Epicardial pacing wires may be placed to treat postoperative bradycardia or heart block. The patient is rewarmed, acidosis and hypokalaemia are corrected, and ventilation is restarted. The heart gradually takes over the circulation while the arterial flow from the CPB machine is reduced. When the blood pressure is acceptable and the surgeon is confident that the heart function is adequate, CPB is discontinued. The cannulae are removed and the anticoagulation is reversed by using protamine.

**Complications of cardiopulmonary bypass**

CPB is a complex technique and requires careful management between surgeon, anaesthetist and perfusionist to ensure that the patient remains safe. Difficulties can occur during cannulation (arterial tear), at the start of CPB (oxygenator failure) and at the end of CPB (coagulopathy). A summary is given in Summary box 54.2. Many complications can occur following blood exposure to the non-physiological surface of the CPB circuit. This leads to the activation of inflammatory cascades giving rise to a post-CPB systemic inflammatory response syndrome (SIRS) that can ultimately lead to multiorgan failure.

Recent developments include ‘off-pump’ surgery where the surgery is performed on the beating heart with the aid of stabilisers and minimal (mini) bypass, where all the elements of
Coronary artery bypass surgery

Introduction

Before the 1950s, surgical attempts to treat coronary artery disease (CAD) through augmentation of non-coronary flow to the myocardium via the creation of pericardial or omental adhesions had limited success. From the 1960s, the importance of aorto-coronary saphenous vein grafts and the value of the internal mammary (internal thoracic artery) were increasingly recognised. The outcomes of coronary artery bypass graft (CABG) surgery were carefully monitored from the beginning and by the 1970s multiple large, prospectively randomised, multicentre trials were conducted. All showed that a subset of patients had improved survival after surgery. With the advent of percutaneous coronary intervention (PCI) in the 1980s, the patient population undergoing CABG has changed, becoming progressively sicker but often with the most to gain. Over the last decade, there have been major advances in PCI including the use of bare metal stents and the development of drug-eluting stents in an effort to reduce restenosis. The role of CABG in the treatment of ischaemic heart disease is continually questioned and less invasive therapies are being sought. A recent large multicentred trial compared CABG to PCI with drug-eluting stents and showed that CABG is still the ‘gold standard’ in certain groups of patients (Summary box 54.3).

Summary box 54.3

Randomised controlled trials have confirmed improvement in survival following CABG for certain groups of patients

Coronary artery anatomy

The coronary arteries are branches of the ascending aorta, arising from ostia in the aortic sinuses above the aortic valve, the right from the anterior sinus and the left from the left posterior sinus (Figure 54.2).

Left coronary artery

The left main coronary artery, which arises from the aortic root, can be the site of significant stenosis (‘left main stem disease’) and carries the worst prognosis in terms of survival without surgery. The artery is inaccessible at its origin and therefore grafts are anastomosed to its branches, the left anterior descending artery (LAD).
descending (LAD) artery or anterior interventricular artery and obtuse/marginal (OM) branches of the circumflex artery. The LAD is the most frequently diseased coronary artery and most often bypassed during CABG surgery.

**Right coronary artery**

The right coronary artery (RCA) passes from its origin anteriorly between the right atrial appendage and the pulmonary trunk and courses in the atrioventricular groove around the margin of the right ventricle. It continues as the posterior descending artery or interventricular artery. Common sites of stenosis of the RCA are in its proximal portion or at the bifurcation or crux. In the presence of disease at the bifurcation, a graft can be placed distally to the posterior descending artery.

The question of anatomical dominance is determined by the artery that supplies the posterior descending artery. In approximately 90 per cent of cases, the posterior descending artery arises from the RCA, a pattern referred to as ‘right dominance’. The posterior descending artery can also arise from the circumflex artery, a pattern referred to as ‘left dominance’, which occurs in approximately 10 per cent of cases. A balanced pattern is one in which two posterior descending arteries, one arising from the right coronary artery and one from the circumflex artery, can exist (Figure 54.2).

**Ischaemic heart disease**

Ischaemic heart disease (IHD) is a major cause of morbidity and mortality in developed countries. The underlying pathology is mainly atherosclerosis of the coronary arteries.

**Pathophysiology**

Atherosclerosis is the process underlying the formation of focal obstructions or plaques in large- and medium-sized arteries. It is accepted that atherosclerosis is a chronic inflammatory process resulting from interactions between plasma lipoproteins, leukocytes (monocyte/macrophages, T lymphocytes), vascular endothelial cells, and smooth muscle cells. Atherosclerotic lesions can histologically be found at different stages in blood vessels including:

- **The fatty streak.** The first evidence of atherosclerosis can be found in children 10–14 years of age. This appears as a yellow streak running along the major arteries. The streak consists of smooth muscle cells, which are filled with cholesterol, and foam cells.

- **Fibrous plaque.** A fibrous plaque consists of large numbers of smooth muscle cells, foam cells, and leukocytes. As the fibrous plaque grows, it projects into vessels leading to narrowing of the lumen, which in turn can lead to ischaemia or infarction.

- **Complicated lesion.** This occurs when the fibrous plaque ruptures, provoking activation of the coagulation cascade and the formation of thrombi.

**Clinical manifestations**

The principal symptoms of IHD are chest pain or angina, breathlessness, fatigue, swelling, palpitations and syncope. Severity of symptoms and the extent to which the symptoms interfere with everyday activities form a significant part of the clinical history. An assessment of risk factors should be included (Summary box 54.4). Clinical examination follows and, although often normal, any evidence of myocardial ischaemia or stigmata of associated disease, such as diabetes or peripheral vascular disease, should be noted.

**Investigations**

**Non-invasive methods of diagnosis**

**Resting electrocardiography**

As a baseline test, a 12-lead resting electrocardiogram (ECG) often provides the first indication of ischaemic cardiac disease and is essential in the acute clinical setting. However, it is not necessarily abnormal even in the presence of severe multivessel coronary heart disease. Evidence of previous myocardial infarction is seen commonly as Q waves and/or non-specific ST and T-wave changes.

**Troponin and cardiac isoenzymes**

These are useful in assessing patients with an acute coronary syndrome (ACS) when the diagnosis is in doubt. Standard enzyme measurement such as Troponin, creatine kinase MB (CKMB), and lactate dehydrogenase (LDH) can aid diagnosis, as well as having prognostic implications.

**Exercise tolerance testing**

Exercise tolerance testing (ETT) is a valuable technique for assessing myocardial ischaemia, both for diagnostic purposes and as a prognostic tool. However, an abnormal exercise test must be interpreted in the light of the probability of coronary artery disease and the physiological response to exercise as measured by the percentage of the maximum predicted heart rate achieved. A positive test with evidence of ischaemia on the ECG (ST depression of ≤2 mm) does not always indicate IHD, and a negative test does not always exclude its presence.

**Echocardiography**

Performed either through a transthoracic or transoesophageal approach, it is valuable for the evaluation of ventricular function and regional wall motion abnormalities, as well as valvar lesions.

Stress echocardiography can detect regional wall motion abnormalities brought on by exercise or the use of dobutamine or diprydramole. It is a reliable method of identifying viable myocardium. Impaired but recoverable myocardium possesses a functional reserve that allows it to be temporarily recruited into action, whereas scar tissue does not. The development of
real time three-dimensional ECHO (RT3DE) with the ability to carry out valve construction from different surfaces has recently revolutionised preoperative surgical planning in patients with complex valvular diseases.

**Radionuclide studies and cardiac magnetic resonance imaging**

The two main types of radionuclide study available are perfusion and blood pool studies. They allow an assessment of the perfusion and cellular integrity of viable myocardium. Cardiac magnetic resonance imaging (MRI) can be performed to evaluate the structure and function of the heart and blood vessels and offers an alternative to angiography.

**Positron emission tomography**

Positron emission tomography (PET) provides information on myocardial perfusion, metabolism and cell membrane function. Positron-emitting isotopes are used to label physiological substances, after which the regional distribution of these substances can be measured. PET is valuable in the diagnosis of coronary artery disease, particularly when the more widely available imaging modalities are inconclusive. It can identify injured but viable myocardium that is potentially salvageable by revascularisation.

**Computed tomography**

With the development of the latest computed tomography (CT) scanners, which have the ability to correct for respiratory and cardiac movements, multislice high-resolution CT scanning may become an alternative to coronary angiography. It allows for the assessment of coronary disease, particularly proximal coronary artery disease, and gives some information about the degree of coronary artery calcification.

**Invasive methods of diagnosis**

**Coronary angiography**

Selective coronary angiography provides the means of accurately diagnosing the presence and extent of coronary artery disease and remains the 'gold standard' diagnostic technique (Figure 54.3).

In spite of the availability of newer imaging techniques, such as cardiac MRI, selective coronary angiography provides high image quality, demonstrating the extent, severity and location of coronary artery stenoses and the quality and size of the distal coronary arteries. Any stenosis in an artery of >70 per cent of the diameter (90 per cent reduction on cross-sectional area) is considered 'severe'. In addition, it allows assessment of ventricular function and provides the cardiac surgeon with information to determine operability, operative risk and probability of operative result. This test only outlines the coronary anatomy, does not demonstrate ischaemia and carries an overall complication rate of less than 1 per cent (Summary box 54.5).

**Summary box 54.5**

**Coronary angiography**

- 'Gold standard' for imaging of anatomy
- Demonstrates extent, severity and location of stenoses
- Reduction in diameter of >70 per cent is considered severe (90 per cent reduction in cross-sectional area)
- Demonstrates quality and size of distal arterial tree
- Aids diagnosis of ischaemia
- Evaluates suitability for surgery
- Aids in prognostic assessment

**Indications for surgery**

The decision to offer CABG is based on the balance between the expected benefit and the risks that the patient faces. The two issues to be addressed when deciding if a patient is suitable to have surgery are the appropriateness of revascularization, and the relative merits of CABG versus PCI.

Current best evidence shows that revascularization can be readily justified on symptomatic grounds in patients with persistent limiting symptoms (angina or angina equivalent) despite optimal medical therapy and/or on prognostic grounds in certain anatomical patterns of disease.

Recent guidelines on myocardial revascularization have been released by the Task Force on Myocardial Revascularization of the European Society of Cardiology (ESC) and the European Association for Cardio-Thoracic Surgery (EACTS) and identified patients with certain angiographic features who can benefit from surgery (Summary box 54.6).

**Summary box 54.6**

**Indication for surgery**

- >50 per cent stenosis of the left main stem ('critical left main stem disease')
- >50 per cent stenosis of the proximal left anterior interventricular artery
- Two or three main coronary arteries diseased ('triple-vessel disease')
- Poor ventricular function associated with multi-vessel disease

**Chronic stable angina**

Although PCI is increasingly being used for the treatment of stable angina, CABG is still indicated in the presence of...
certain angiographic features. Angina can be relieved by surgical revascularisation in most patients and symptomatic improvement can be expected for over ten years.

**Acute coronary syndromes**

A recently published meta-analysis showed substantial benefit with an early invasive strategy mainly in high risk patients. An invasive strategy always starts with angiography. After defining the anatomy and its associated risk features, a decision about the type of intervention can be made. The angiography in combination with ECG changes often identifies the culprit lesion and PCI, if desirable, can be recommended to treat the culprit lesion. Angiography should be performed urgently for diagnostic purposes in patients at high risk and in whom the differential diagnosis of other acute clinical situations is unclear. In stabilized patients after an episode of ACS, surgical indications are similar to those with stable chronic disease.

The optimal timing of revascularization is different for PCI and for CABG. While the benefit from PCI in patients with NSTE-ACS (non-ST-segment elevation acute coronary syndrome) is related to its early performance, the benefit from CABG is greatest when patients can undergo surgery after several days of medical stabilization.

**Surgery for the complications of myocardial infarction**

Myocardial infarction (MI) leads to myocyte necrosis, which may heal to form scar tissue or rupture if the ventricular wall gives way. Free rupture of the ventricle is usually fatal despite treatment. Ventricular septal rupture typically presents 3–7 days after infarction with pulmonary oedema, a pansystolic murmur and hypotension. The diagnosis is usually confirmed with echocardiography. Repair is with a pericardial or artificial Dacron patch. Papillary muscle necrosis causes acute mitral regurgitation, a pansystolic murmur and pulmonary oedema. Diagnosis is made by echocardiography and right heart catheterisation (showing large V waves). Mitral valve replacement is usually necessary, but the mortality rate is higher than in valve replacement for rheumatic heart disease as a result of the associated coronary artery disease. Ventricular aneurysm occurs following partial-thickness necrosis of the ventricular wall if the free wall is replaced with non-contractile fibrous tissue. Left ventricular function is affected because the fibrous wall balloons out during systole and reduces the actual stroke volume. Repair is undertaken using CPB, and CABG is undertaken at the same time if necessary combined with valve replacement.

Patients undergoing valve replacement usually have coronary bypass surgery to any significant coronary lesions. However, several variables need to be carefully evaluated when considering the choice of a combined procedure and the overall operative risk: these include age >70 years, female sex and poor left ventricular function, as well as what the underlying valve pathology is and which valve is to be replaced.

**Acute failure of percutaneous coronary angioplasty**

Since the advent of intracoronary stents, the need for emergency CABG following complications of percutaneous transluminal coronary angioplasty (PTCA) is low at <1 per cent. The mortality rate in this group is significantly higher than for elective CABG.

**Preparation for surgery**

**Clinical assessment**

Before CABG, the severity and stability of the patient’s IHD, the presence of significant valvular disease and the status of left ventricular function should be properly evaluated.

Any comorbid risk factors for IHD should be documented and, in particular, the state of coexisting diseases assessed. Attention is paid to the presence of carotid artery disease, peripheral vascular disease, respiratory status, preoperative diabetic control and presence of associated diabetic complications, significant renal dysfunction or coagulopathy. All medications taken by the patient are noted. Ideally, some should be stopped before surgery, in particular any anti-platelet agents, including aspirin and anti-coagulants, as well as oral hypoglycaemics. Others drugs, such as diuretics and angiotensin-converting enzyme (ACE) inhibitors, are stopped on the discretion of the surgeon. However, apart from the exceptions noted, as a general rule all cardiac and anti-hypertensive medications should be taken preoperatively.

**Risk assessment**

Myocardial revascularization is appropriate when the expected benefits, in terms of survival or health outcomes exceed the expected negative consequences of the procedure. Therefore, risk assessment is an important aspect of contemporary clinical practice, being of value to clinicians and patients. Over the long term, it allows quality control and the assessment of health economics. Numerous different models have been developed for risk stratification in cardiac surgery including the EuroSCORE and STS (Society of Thoracic Surgeons).

The EuroSCORE validated to predict surgical mortality was recently shown to be an independent predictor of major adverse cardiac events (MACE). Therefore, it can be used to determine the risk of revascularization irrespective of, and even before, the selection of treatment strategy. However, it is important to acknowledge that no risk score can accurately predict events in an individual patient. Moreover, limitations exist with all databases used to build risk models, and differences in definitions and variable content can affect the performance of risk scores when they are applied across different populations. Ultimately, risk stratification should be used as a guide, while clinical judgement and multidisciplinary discussion (heart team) remain essential.

**Selection of conduit**

**Venous grafts**

The long saphenous vein is the most common vein used as a conduit as it is straightforward to harvest, provides good length and is easy to handle. The ten-year patency rate for long saphenous vein grafts is reported to be 50–60 per cent, with 10–15 per cent occluding in one year. However, recent studies suggest that the early use of lipid-lowering agents and anti-platelet agents, such as low-dose aspirin, can improve vein graft long term patency. In assessing the patient preoperatively, the legs should be checked for varicose veins. Alternative vein conduits include the short saphenous vein or upper limb veins, such as the cephalic vein.

**Arterial grafts**

The left internal mammary artery (LIMA) or internal thoracic artery has become the conduit of choice for the LAD. Since the mid-1980s, long patency rates of >98 per cent have been reported, with improved long-term survival and fewer reoperations. As
LIMA–LAD anastomosis avoids the late complication of vein graft atherosclerosis, particular interest has focused on the use of bilateral internal mammary artery (BIMA) grafts. However, there is still debate regarding the appropriateness in certain subgroups of patients, such as the obese diabetic in whom sternal wound complications appear higher.

The use of the radial artery as a second or alternative arterial bypass graft has enjoyed a revival. This has been driven to some extent by the developing concept of total arterial revascularisation and the belief that this will help improve long-term results of coronary surgery. Recent randomised controlled studies in the United States and UK have demonstrated excellent patency rates at one and five years. In assessing a patient in whom a radial artery harvest is planned, an Allen’s test is performed (Summary box 54.7). Alternative arterial bypass grafts include the gastroepiploic artery and the inferior epigastric artery.

Summary box 54.7

**Allen’s test**

- The patient makes a tight fist while the surgeon compresses both distal and ulnar arteries digitally; this squeezes blood from the hand
- The hand is then relaxed and compression of the ulnar artery is released; the speed of returning colour to the hand is assessed
- If colour returns in 5–7 seconds, patency and collateral flow from the ulnar artery is confirmed

The operation

Intraoperative monitoring includes monitoring of continuous central venous pressure and blood pressure (via a central line in the internal jugular or subclavian vein and radial artery line, respectively), urine output via a urinary catheter, temperature using a probe positioned at the nasal septum, and the ECG.

The operation commences with harvesting of the conduits (long saphenous vein from the leg (Figure 54.4) or/and radial artery), while the chest is opened via a median sternotomy and the LIMA is dissected from the chest wall (Figure 54.5). The patient is typically placed on CPB after heparinising, the aorta is cross-clamped and the heart arrested with cardioplegia. The grafts are anastomosed to coronary arteries distal to the stenosis (Figure 54.6).

The aortic cross-clamp is removed and the heart is reperfused with oxygenated blood. A side-biting clamp is applied to the ascending aorta and the proximal anastomoses are completed. Occasionally, the surgeon may opt to carry out the whole operation while the cross-clamp is applied to reduce the risks associated with aortic manipulation. The patient is warmed and weaned from CPB. The heparin is reversed and the patient is returned to the intensive care unit (ICU).

Edgar van Nuyss Allen, 1900–1961, Professor of Medicine, The Mayo Clinic, Rochester, MN, USA.
Postoperative recovery

The majority of patients are extubated a few hours after returning from surgery and remain in the ICU for 24 hours or so. In some centres, ‘fast tracking’ appropriate patients allows for an earlier transfer to a recovery area or high-dependency unit (HDU). Discharge is routinely 4–8 days after surgery.

Postoperative complications

Bleeding

Significant bleeding occurs in approximately 2–3 per cent of patients. Rarely, acute cardiac tamponade or profound hypotension may occur in the early postoperative period and requires emergency resternotomy.

Arrhythmias

The most common postoperative arrhythmia is sinus tachycardia, closely followed by atrial fibrillation (AF). It occurs in around 30 per cent of patients undergoing CABG and often spontaneously reverts to sinus rhythm. Treatment includes correction of potassium (>4.5 mmol/L), the use of amiodarone or digoxin and, if necessary, cardioversion. Bradycardia is seldom seen, but temporary pacing via epicardial pacing wires inserted intraoperatively may be required in the postoperative period.

Poor cardiac output state

Myocardial function typically declines in the first few hours following cardiac surgery, presumably in response to an ischaemia/reperfusion-type injury. Often, inotropic agents are required at this time to support the heart and circulation. Occasionally, the patient develops a persistent low cardiac output state. The clinical manifestations of such a situation include poor peripheral perfusion, with poor urine output, a developing metabolic acidosis and low blood pressure.

There are several mechanisms that account for this complication in the early postoperative period, including depressed myocardial contractility, reduced preload, increased afterload, and a disturbance in heart rate or rhythm.

Treatment is aimed at the underlying cause, but generally includes oxygenation, optimising preload, reducing afterload, managing any rhythm disturbances and improving contractility. If the low cardiac output state persists, the heart may require pharmacological or mechanical support.

Pharmacological support

Inotropic drugs act in a variety of ways to alter the systemic vascular resistance, increase the heart rate and increase the force of myocardial contractility. Commonly used inotropes include isoprenaline, dopamine, dobutamine, adrenaline (epinephrine) and noradrenaline (norepine); they are often used in conjunction with vasodilating agents that decrease the afterload.

Mechanical support

If low cardiac output persists despite inotropic support, the heart may require mechanical support while it recovers its function. Mechanical support can be achieved by using an intra-aortic balloon pump (IABP) counterpulsation, or a ventricular assist device (VAD).

IABP is a device that is inserted, either percutaneously or under direct vision, into the common femoral artery. It is threaded into the aorta until its tip lies just distal to the arch vessels (Figure 54.7). The balloon is triggered by the ECG, deflating during ventricular systole (thus reducing afterload) and inflating in diastole (displacing blood that perfuses the coronary arteries retrogradely). When the heart has recovered sufficiently, the balloon is removed.

VAD is a mechanical circulatory supporting device used to replace the function of a failing heart partially or completely. It can be used as a short-term measure typically for patients recovering from heart attacks or heart surgery, or as a long-term support for patients suffering from congestive heart failure. VAD pumps can be pulsatile which mimic the natural pulsing action of the heart, or continuous flow pumps. Blood is exposed in these devices to a non-biologic surface which can activate proinflammatory and coagulation cascades leading to strokes and bleeding. Another important complication associated with VAD is infection which can be caused Gram-positive bacteria, Gram-negative bacteria, and fungi.

Neurological dysfunction

Stroke leading to a focal neurological deficit occurs in approximately 2 per cent of patients following CABG. Embolisation, probably originating from the aortic arch or heart chambers, is the most common mechanism for territorial infarcts, with hypoperfusion leading to watershed infarcts. Diffuse neurological injury may occur leading to more subtle cognitive abnormalities in memory, concentration and attention.

Wound infection

Significant deep wound infection resulting in sternal dehiscence and mediastinitis occurs in around 0.5–2 per cent of patients.
This can be associated with significant morbidity with a prolonged hospital stay and further surgical interventions for debridement and/or rewiring of the sternum. It still has a significant mortality rate of as high as 40 per cent. Wound infections are more common in diabetics and the obese.

**Mortality**

In the UK, the overall mortality rate for patients undergoing CABG is 2–3 per cent. Multiple factors have been demonstrated to affect mortality after CABG, including age, gender, left ventricular function, use of LIMA and complete revascularisation.

**Surgical outcome**

**Relief of symptoms**

If revascularisation is complete, CABG alleviates or improves anginal symptoms in more than 90 per cent of patients at one year; this falls to 80 per cent at five years and 60 per cent at ten years. This symptomatic deterioration usually reflects progression of atherosclerotic disease in vein grafts and native coronary arteries.

**Survival**

Early surgical versus medical studies have reported survival rates to be 95 per cent at one year, 90 per cent at five years, 75 per cent at ten years and 60 per cent at 15 years. Through changes in surgical practice, such as an increased use of arterial conduits and the widespread use of dual antiplatelet therapy, B-blockers, and lipid-lowering agents, post-CABG survival may well improve in the future (Summary box 54.8).

**Off-pump coronary artery surgery**

CABG without the use of CPB is a well-established and increasingly popular method that may be combined with a minimally invasive approach or carried out through a conventional sternotomy. It offers the advantages that it avoids the physiological stress associated with CPB and, to some extent, the aortic manipulation that can lead to neurological injury through atherosclerotic embolisation. Since the introduction of cardiac stabilising devices, such as the Octopus® (Figure 54.8), off-pump coronary artery bypass (OPCAB) grafting has become widespread. One of the concerns, however, associated with off-pump surgery is related to the quality of anastomosis as its carried out on a beating heart and bloody field which can limit the surgeon’s vision. The advantages of off-pump surgery over on-pump has recently been questioned especially with the development of the mini-bypass machines which offer a closed circuit and minimal unphysiological surface area, though reducing proinflammatory activation, but at the same time allow the surgeon to operate on a still heart in a bloodless field.

**Minimal access surgery**

Minimally invasive direct coronary artery bypass (MIDCAB) grafting is performed through a strategically placed minimal access incision and so avoids all invasive aspects of conventional CABG. Through an anterior submammary incision, the LIMA can be dissected down with the aid of a thoracoscope and grafted to the LAD. More lateral MIDCAB incisions allow access to other coronary vessels including branches of the circumflex artery. Patient selection remains, at least at present, a restriction to the ever-increasing minimally invasive methods being developed. Although not yet critically evaluated, one particular approach is to combine MIDCAB (typically LIMA to LAD) with PCI to other less accessible coronary arteries (‘hybrid’ coronary revascularisation).

**VALVULAR HEART DISEASE**

**Introduction**

Early surgical management of valvular heart disease concentrated on valvular repair. The heroic early procedures for valve stenosis were closed and therefore ‘blind’ commissurotomies. They were replaced by open procedures with full visualisation allowing precise repair and replacement. The first prosthetic valve replacement was performed by Harken in 1960 replacing the aortic valve, followed by a mitral valve replacement by Starr a
year later. Continued improvements in perioperative care, myocardial protection and, in particular, the development of prosthetic heart valves have improved long-term haemodynamic effects, and provided symptom relief and prolonged survival. The majority of valvular operations involve surgery on the aortic or mitral valve; tricuspid and pulmonary valve surgery is rarely undertaken.

**Surgical anatomy**

Heart valves function to maintain pressure gradients between cardiac chambers and so ensure unidirectional flow of blood without reflux through the heart. The aortic valve is tricuspid with semilunar leaflets attached to the aortic wall at the annulus with the aortic sinuses being above the base of each leaflet, two of which form the origin or ostium of the coronary arteries. The intrinsic shape of the aortic semilunar valve allows blood to leave the ventricle during systole and prevents its regurgitation during diastole. If disease leads to disruption of the leaflets or the annulus, valve function will be affected.

The mitral valve is bileaflet; the anterior leaflet is larger in area. The leaflets, like those of the aortic valve, are attached to an annulus. The leaflets join at two commissures and are supported by a subvalvular apparatus consisting of chordae tendinae and papillary muscles. The papillary muscles contract in ventricular systole, pulling the cusps towards the atrioventricular orifice and holding blood within the ventricle. The proper functioning of the mitral valve depends on the integrity of the annulus, leaflets, chordae and papillary muscles. If surgical correction is required, emphasis is on the preservation of these structures when possible (Figure 54.9).

**Surgical options for heart valve disease**

The decision of whether to repair or replace the diseased valve depends on the underlying pathology, the severity of disease, and quality and/or involvement of the surrounding supporting structures. Generally, repair is increasingly favoured when possible in mitral valve disease, particularly in mitral regurgitation in which it has been shown to have good long-term outcomes. Repair is the operation of choice in tricuspid valve disease, but aortic valve surgery generally involves replacing the diseased valve (Table 54.1).

Important factors in selecting the type of procedure and prosthesis include the age of the patient and the need for anticoagulation. Because of uncertainties about its lifespan, there is debate about when a bioprosthetic valve should be used, with most accepting its use in those over 65 years. The need for anticoagulation may have an impact on choice of valve, particularly in women of child-bearing age, the elderly, the presence of congenital or acquired bleeding diathesis and when there is the need for further major surgery.

Types of prosthetic valves

Mechanical valves
Mechanical valves can be used in any age group to replace any valve (Figure 54.10). They are extremely durable, but the components of the valve are thrombogenic and therefore the patient requires systemic anticoagulation, usually with warfarin. This subjects the patients to a lifetime of blood tests, medication and the constant threat of haemorrhagic (intracerebral, epistaxis, gastrointestinal bleed) or thrombotic (cerebral infarction) complications.

Biological valves
Biological valves include homograft (or allograft) valves, removed from cadavers; autografts, a patient’s own valve; and, most commonly, heterografts (or xenografts) prepared from animal tissues. All share the basic design of three semilunar leaflets with central flow, so decreasing pressure gradients and minimising turbulence (Figure 54.11). Heterograft ‘tissue’ valves are the most commonly used valves and can be stented with a limited durability of 10–15 years, whereas stentless (or frameless) valves are expected to have less late calcific degeneration, but are more technically difficult to insert.

Prosthetic valve dysfunction and complications

Structural valve failure
Bioprosthetic valves are vulnerable to degenerative changes. Structural failure rates for biological valves, although rare in those over 70 years of age, can reach 60 per cent after 15 years. However, newer biological valve have a reoperative rate of less than 10 per cent at 20 years. Structural failure of a mechanical valve is generally uncommon.

Paravalvular leak
Early-onset paravalvular leaks usually result from technical difficulties at insertion. Late-onset leaks can occur and may be related to an episode of endocarditis or, in the presence of bioprostheses, leaflet degeneration. The leak can cause haemolytic anaemia or haemodynamic compromise and the valve may need replacement.

Thrombosis and thromboembolism
Thrombus formation on a prosthetic valve remains the most common complication of mechanical and biological valves (Figure 54.12). The risk of thromboembolism is greater with a valve in the mitral position (mechanical or biological) than with one in the aortic position. Improved haemodynamic function lowers the probability of thromboembolism. The incidence of thromboembolism in current mechanical valves is 0.5–3 per cent per patient-year.

Prosthetic valve endocarditis
The incidence of prosthetic valve endocarditis (PVE) is 2–4 per cent. The risk is lifelong and at its greatest in the first 15 weeks after surgery. The incidence of PVE is higher with mechanical and bioprosthetic valves and lowest with homograft and autograft valves. The diagnosis is suspected following symptoms of septicemia, appearance of a new murmur or a septic embolus. It is confirmed with echocardiography, which may show vegetations and even abscess formation. A high index of suspicion is required and early multiple blood cultures are needed to confirm the diagnosis, identify the infective organism and choose appropriate antibiotic therapy. The most common organisms that can lead to PVE are the Staphylococcus species, particularly Staphylococcus epidermidis in early PVE and Staphylococcus aureus (at least 50 per cent of cases); the Streptococcus species, usually Streptococcus viridans, but also Streptococcus pneumoniae, and less commonly, Gram-negative bacilli, as well as fungal organisms.

The treatment of choice is early aggressive intravenous antibiotic therapy. Serial echocardiography to assess extent of infection into surrounding myocardial tissue, as well as functional assessment of the infected valve, may help in optimising decisions on timing of surgical intervention. The prognosis of PVE remains poor with an overall mortality rate of over 50 per cent.

Postoperative management

Antibiotic prophylaxis
Valve surgery, like all cardiac procedures, requires perioperative and immediate postoperative antibiotic prophylaxis. If prosthetic
infective endocarditis is to be avoided, further prophylaxis with appropriate antibiotics is required during dental and minor surgical procedures in all patients with prosthetic heart valves.

**Anti-thrombotic therapy**

All patients with mechanical valves require warfarin, usually started on the second postoperative day. The use of anticoagulation or anti-platelet therapy with biological valves is variable and depends on the patient’s underlying rhythm postoperatively.

**Mitral valve disease**

Approximately one-third of all valve surgery performed in the UK is for mitral valve disease, with increasing emphasis on valve repair as the importance of preserving the mitral valve apparatus has become apparent.

**Mitral regurgitation**

Any pathological process affecting the mitral valve apparatus may lead to mitral regurgitation. As such, there are many causes of regurgitation and they can be broadly classified into five headings (Summary box 54.9).

### Summary box 54.9

**Causes of mitral regurgitation and likely pathology**

**Degenerative**
- Mitral valve prolapse
- Floppy valve: degeneration of the leaflets with/without chordal rupture
- Senile calcification: calcified annulus
- Connective tissue disorders (e.g. Marfan syndrome, Ehlers-Danlos syndrome): disruption of mitral valve apparatus

**Ischaemic**
- Papillary muscle rupture: following myocardial infarction
- Dynamic mitral regurgitation: as a result of transient ischaemia
- Poor left ventricular function: most common ‘functional’ cause secondary to myocardial ischaemia

**Rheumatic**
- Previous acute rheumatic fever: stiffened leaflets unable to coapt

**Infective**
- Endocarditis: leaflet destruction

Adapted from Hall R. Mitral valve disease. Medicine 1997; 25. 27.

**Pathophysiology**

There is an important distinction between acute and chronic mitral regurgitation. The former is usually as a result of ischaemic papillary muscle rupture or following infective endocarditis, whereas the latter is a result of myxomatous degeneration of the leaflets leading to a floppy valve.

In acute mitral regurgitation, the left ventricle ejects blood back into a small poorly compliant left atrium, imposing a sudden volume load on the left atrium during ventricular systole. This leads to an abrupt rise in left atrial pressure followed by a rise in pulmonary venous pressure and pulmonary oedema.

In chronic mitral regurgitation, the process is sufficiently slow to allow compensatory left ventricular dilatation and hypertrophy, and dilatation of the left atrium without any significant increase in pressure, so protecting the pulmonary circulation. As the disease advances and left atrial dilatation can no longer cope, left atrial pressure begins to rise, leading to a rise in pulmonary venous pressure and progressive pulmonary congestion, and eventual congestive cardiac failure.

**Clinical features**

In acute mitral regurgitation, the patient is usually unwell, presenting with clinical and radiological evidence of acute pulmonary oedema and a loud apical pansystolic murmur. Patients with mild chronic mitral regurgitation are usually asymptomatic. With progressive pulmonary congestion and left ventricular failure, the patient develops fatigue, dyspnoea on exertion and orthopnoea. The development of atrial fibrillation with left atrial dilatation is common. The enlarged left ventricle leads to a heaving apical impulse and a pansystolic murmur.

**Investigations**

- **ECG** may show only left atrial hypertrophy (bifid P waves), left ventricular hypertrophy and atrial fibrillation.
- **Chest radiography**. There may be cardiomegaly with prominent pulmonary vasculature.
- **Echocardiography** is often combined with colour flow Doppler imaging, which shows the severity of the regurgitant jet of mitral regurgitation.
- **Coronary angiography**. To investigate the coronary arteries.

**Indications for surgery**

Indications for surgery include severe symptoms as assessed by the New York Heart Association (NYHA) functional classification system, a progressive increase in left ventricular volume leading to ventricular dysfunction, uncontrolled endocarditis and severe acute mitral regurgitation (Figure 54.13). Timing of
surgery is crucial, as surgery performed too late in the natural history of the condition does not benefit the patient because of the damage already done.

**Mitral stenosis**

The most common cause of mitral stenosis remains rheumatic fever (Summary box 54.10), despite the fact that the incidence of overt rheumatic fever in the developed world has decreased. During the healing phase of acute rheumatic fever, the valve leaflets become adherent to each other at their free border so that the commissures become obliterated and the valve orifice narrows. Symptoms from mitral stenosis usually develop more than ten years after the acute attack.

**Pathophysiology**

Mitral stenosis slows ventricular filling during diastole and the pressure in the left atrium rises to maintain cardiac output. This leads to atrial hypertrophy and dilatation. Pulmonary congestion results from the rise in left atrial pressure but, with time, the lungs are protected against pulmonary oedema by constriction of the pulmonary vessels. However, this adaptive response, along with the passive ‘back pressure’ generated by the rise in left atrial pressure, leads to pulmonary hypertension. This leads to an increased demand on the right ventricle with eventual right heart failure and tricuspid regurgitation. The development of atrial fibrillation is common and can lead to a significant reduction in cardiac output. Atrial fibrillation predisposes to thrombi forming in the left atrium, which may embolise.

**Clinical features**

Patients may remain asymptomatic for years and then present with symptoms when the heart is stressed by an event such as pregnancy, fever or a chest infection, or with the onset of atrial fibrillation. The common symptoms are fatigue and dyspnoea on exertion, which result from the combination of reduced forward flow and increased back pressure. The resulting pulmonary congestion adds to the breathlessness and may produce a cough or haemoptysis. If mitral stenosis is advanced, there may also be a right ventricular heave due to right ventricular hypertrophy in response to pulmonary hypertension. Auscultation reveals an opening snap soon after the second heart sound, as the diseased valve is opened forcibly by the high pressure in the left atrium. The reverse happens when the valve closes and there is a loud ‘tapping’ first heart sound. In addition, a rumbling mid-diastolic murmur can be heard. The duration of the murmur is related to the severity of the mitral stenosis, increasing in length as the mitral stenosis becomes more severe.

**Investigations**

- **ECG** may show left atrial enlargement (P-mitrale) or AF. Right axis deviation and other ECG signs of right ventricular hypertrophy (tall QRS complexes in the right ventricular leads V1–3) may also be present.
- **Chest radiography.** There is a small aortic outline and a prominent pulmonary artery. The left atrium is enlarged (sometimes to an enormous degree) along with upper lobe diversion as a result of the raised pulmonary venous pressure. The right ventricle also appears enlarged (Figure 54.14).
- **Echocardiography,** in combination with colour flow Doppler imaging, allows assessment of the flow across the valve and, therefore, the degree of stenosis. Transoesophageal
echocardiography (TOE) may be better at assessing valve morphology in detail and excluding the presence of an atrial clot.
- **Coronary angiography.** To investigate the coronary arteries.

**Indications for surgery**

Medical management includes the use of anticoagulation in patients with AF or left atrial enlargement. Prophylactic antibiotics for endocarditis should be administered before invasive procedures. Tachyarrhythmias, including fast AF, which may lead to decompensation and cardiac failure, should be avoided. Digoxin is the mainstay of treatment, but other rate-controlling agents are increasingly used. Diuretics may provide some benefit. Surgery is indicated for severe symptoms (NYHA class III or IV), severe mitral stenosis (mitral valve area ≤1.5 cm²), or signs of left ventricular dysfunction. These include an ejection fraction of less than 60 per cent and a left ventricular end systolic dimension (LVESD) of more than 45 mm, or systemic emboli. Prognosis is determined by the severity of the stenosis, the size of the atrium, the onset of AF, rising pulmonary artery pressure and the unpredictable risk of embolism from a large, fibrillating atrium (Figure 54.15). Surgical options include mitral valve repair or mitral valve replacement. Old surgical procedures, such as commissurotomy or valvotomy, are rarely currently performed.

**Mitral valve operations**

Depending on the type of procedure and approach to the mitral valve, a median sternotomy or, occasionally, a right thoracotomy is completed. The mitral valve can be approached directly through the left atrium in the interatrial groove, through the left atrium and then the interatrial septum, or through the left atrial appendage.

**Mitral valve repair**

The restoration of normal valve function and preservation of the mitral apparatus is preferable to replacement. The functional classification system developed by Carpentier serves as a guideline in valve reconstruction. It allows classification of any mitral insufficiency into one of three groups according to the amplitude of the leaflet motion and provides a useful framework for the mechanisms of failure of the mitral valve. As a rule, several valvular lesions or abnormalities are involved in a functional abnormality, with specific techniques developed to correct each lesion.

At surgery, the anatomy of the valvular apparatus and subvalvular structures has to be carefully inspected. In particular, the extent of annular dilatation, leaflet prolapse and chordal dysfunction are assessed. The mitral valve reconstruction is completed using various techniques, including insertion of a prosthetic ring annuloplasty (Figure 54.16), quadrangular resection of the leaflet, use of a sliding plasty, chordal shortening and chordal transposition. There are many different techniques which is an indication that so far, no one technique will address all the issues that can occur during mitral regurgitation. Valve repair, however, offers better preservation of ventricular function and avoids the need for prolonged anticoagulation as well as avoiding valve-related complications, such as PVE or structural dysfunction. Recent advances in surgical techniques and the development of various types of rings lead to increased use of mitral valve repair with excellent results making it the gold standard operation. The operative mortality is 1–3 per cent. Complication-free survival at five years ranges from 80 to 95 per cent.

**Mitral valve replacement**

When valve repair is not feasible mitral valve replacement is necessary. This usually involves a median sternotomy and access to the left atrium on CPB. The diseased valve is exposed, excised and a suitably sized mechanical or bioprosthetic valve is implanted. The atriotomy is closed following de-airing of the left heart. Intraoperative TOE can be used to assess adequate valve function.

The operative mortality rate for elective mitral valve replacement is approximately 5–6 per cent. This depends largely on the state of the myocardium and the general condition (including age) of the patient. Common serious in-hospital complications include stroke (<4 per cent) and renal failure (3 per cent), although any complication of heart surgery is possible. The longer-term prognosis for patients following mitral valve replacement is generally good in comparison with the natural history of mitral valve disease.

---

**Figure 54.15** Features and pathophysiology of mitral stenosis. The aorta and left ventricle are relatively small because of chronically reduced cardiac output. The atrium is enlarged and may fibrillate, become stagnant and contain a thrombus. The ventricle fills with a turbulent jet that may be detected as a diastolic murmur or a thrill at the apex.

*Alain Frédéric Carpentier, born 1933, cardiothoracic surgeon, Hôpital European Georges Pompidou, Paris, France, referred to as ‘the father of modern mitral valve repair’.*
Percutaneous mitral valve repair (MitraClip)
The MitraClip® is a device used to reduce mitral valve regurgitation. The method involves suturing of the leaflets of the mitral valve together so that regurgitation into the left atrium is prevented. The valve continues to open through the sides of the suture and therefore blood continues to flow into the left ventricle, although this method is less invasive, associated with rapid recovery, and reduced in-hospital stay. However, it is technically demanding and long-term durability of the results of the device is unknown.

Recent data suggest that Mitraclip may be suitable for a small subset of high-risk or chronic heart failure patients, but not for the vast majority, who are better served by surgery, which leaves them with substantially less mitral regurgitation.

Aortic valve disease
Approximately two-thirds of all valve surgery performed in the UK is for aortic valve disease, which remains common despite a reduction in the incidence of rheumatic fever in the developed world.

Aortic stenosis
Aortic stenosis (AS), as opposed to aortic sclerosis, occurs when a pressure gradient can be demonstrated across the valve. Therefore, the difference is not absolute, as sclerosis can progress to stenosis. The common cause of aortic stenosis in adults is an acquired, degenerative, calcific process that results in immobile aortic valve cusps. Progressive fibrosis and calcification of a congenitally abnormal valve can mimic this degenerative process. The usual congenital abnormality is commissural fusion, leading to a bicuspid aortic valve, which occurs in approximately 1 per cent of the population (Figure 54.17).

Pathophysiology
A pressure gradient develops between the left ventricle and the aorta, with the left ventricle adapting to this systolic pressure overload by an increase in left ventricular wall thickness or hypertrophy. This adaptive response is an attempt to normalise left ventricular wall stress in the face of increased left ventricular systolic pressure, and may maintain a normal cardiac output, prevent left ventricular dilatation and avoid significant symptoms for a number of years. Eventually, myocardial function is affected and, together with insufficient left ventricular hypertrophy to normalise wall stress (load mismatch), ventricular contractility is reduced.

When aortic stenosis is severe and cardiac output is normal, a >50 mmHg gradient between peak systolic left ventricular and aortic pressure exists. As aortic stenosis worsens, cardiac output cannot increase with exertion and eventually becomes insufficient at rest. The reduction in ventricular contractility leads to an irreversible decline in left ventricular function, with dilatation and a rise in left ventricular end-diastolic pressure, to the point of overt left heart failure.

Clinical features
Patients are often asymptomatic until decompensation occurs, typically presenting with dyspnoea and angina, which is due to increased oxygen needs of the hypertrophied left ventricle, reduced coronary filling and inadequate cardiac output during exertion. Patients often describe a feeling of light-headedness or ‘near’ syncope on effort. Cardiac arrhythmias can also occur.

Auscultation of the heart demonstrates a murmur that is typically harsh, ejection in nature and best heard over the aortic area with radiation to the carotids. With critical aortic stenosis and a fall in cardiac output, the murmur may become quieter. The apex beat may be displaced in late disease along with signs of cardiac congestion (Figure 54.18).

Investigations
- ECG. There is left ventricular hypertrophy with tall R waves in the lateral leads and sometimes a ‘strain pattern’ (S–T depression with inverted T waves in the lateral leads).
- Chest radiography. May be normal. Cardiomegaly and pulmonary congestion can be seen in the presence of left ventricular failure. Post-stenotic dilatation of the aorta is occasionally seen (Figure 54.19).

Figure 54.17 (a) Formaldehyde-treated aortic valve (normal tricuspid configuration). (b) Aortic stenosis, different pathologies.
Echocardiography confirms the diagnosis and, together with colour flow Doppler imaging, allows assessment of the aortic valve gradient, calculation of valve area, and evaluation of left ventricular dimensions and wall thickness.

Coronary angiography. To investigate the coronary arteries.

Indications for surgery
Medical management focuses on the avoidance of systemic hypotension and arterial vasodilatation, which may reduce myocardial perfusion pressure and therefore provoke ischaemia.

The natural history of symptomatic patients with aortic stenosis is dismal, with a ten-year mortality rate of 80–90 per cent. The patient is at risk of sudden death related to the severity of the stenosis. An estimated or actual peak systolic gradient of >6.7 kPa (50 mmHg) with impaired ventricular function on dynamic testing is sufficient indication for aortic valve replacement.

Indications for surgery in asymptomatic patients with severe aortic stenosis are controversial. Most would consider surgery in patients with left ventricular dysfunction, concomitant coronary artery disease, in patients over 60–65 years, severe left ventricular hypertrophy, arrhythmias and silent ischaemia.

Aortic regurgitation
The causes of aortic regurgitation can be classified according to the speed of development of the regurgitant jet (acute or chronic) or according to the anatomical location of pathology (valve leaflet or aortic wall). The causes of acute aortic regurgitation include infective endocarditis, aortic dissection and trauma. The common causes of chronic aortic regurgitation include degeneration leading to aortic root and/or annular dilatation, congenital bicuspid valve and previous rheumatic fever or endocarditis (Summary box 54.11).

Summary box 54.11
Causes of aortic regurgitation according to predominant anatomical location of pathology

Valve leaflet disease
- Congenital, e.g. bicuspid valve leading to degenerative changes, with ventricular septal defect
- Rheumatic heart disease
- Infective endocarditis

Aortic wall pathology
- Inflammatory, e.g. connective tissue disorders, such as ankylosing spondylitis, systemic lupus erythematosus, rheumatoid arthritis
- Systemic disease, e.g. tertiary syphilis
- Degenerative, e.g. Marfan syndrome, aortic root dissection, senile aortopathy, leading to aortic root/annular dilatation

Pathophysiology
Acute aortic regurgitation imposes a volume load on the left ventricle because of backflow. It causes a sharp rise in left ventricular end-diastolic pressure, premature closure of the mitral valve and inadequate forward left ventricular filling. The result is sudden haemodynamic deterioration and acute respiratory compromise.

In chronic aortic regurgitation, volume load and left ventricular end-diastolic pressure increase gradually, leading to compensatory left ventricular dilatation and eccentric hypertrophy to maintain adequate cardiac output. Systolic and diastolic function is abnormal, and sudden deterioration can occur.

Clinical features
Long-standing aortic regurgitation is asymptomatic until the left ventricle begins to fail, when exertional dyspnoea may be the only symptom. Angina can also develop. A wide pulse pressure due to a reduction in diastolic pressure and collapsing pulse (waterhammer pulse) are commonly seen. Other manifestations of the wide pulse pressure include visible capillary pulsation of the nail bed (Quincke’s sign), pulsatile head bobbing (de Musset’s sign), visible arterial pulsation in the neck (Corrigan’s sign), a ‘pistol shot’ sound on auscultating over the femoral artery (Traube’s sign) and uvular pulsation (Müller’s sign). The apex is displaced laterally, often visible and hyperdynamic or

Ludwig Traube. 1818–1876, physician, The Charité, Berlin, Germany. He worked alongside Rudolf Virchow (1821–1902) and was cofounder of the science of experimental pathology in Germany.
'thrusting' in nature because of the left ventricular hypertrophy. Auscultation reveals a high-pitched early diastolic murmur best heard at the left sternal edge (Figure 54.20).

**Investigations**

- **ECG.** There is left ventricular hypertrophy and sometimes a ‘strain pattern’.
- **Chest radiography.** Cardiomegaly can be seen if the left ventricle is dilating; sometimes, the aortic shadow may also indicate dilatation.
- **Echocardiography.** This allows assessment of the underlying cause and severity of aortic regurgitation and enables the diameter of the aortic root, as well as left ventricular dimensions, to be determined. Colour flow Doppler imaging quantifies the size of the regurgitant jet.
- **Coronary angiography.** To investigate the coronary arteries.

**Indications for surgery**

Medical therapy with vasodilator drugs for the relief of dyspnoea or angina is designed to improve forward stroke volume and reduce regurgitant volume. However, symptomatic relief does not alter the need for valve surgery.

The indications for surgery are the onset of symptoms of NYHA class III or IV. Minor degrees of aortic regurgitation are well tolerated, but if the left ventricle deteriorates and dilates it may be too late for surgery. An end-diastolic pressure of $>70\,\text{mmHg}$, an end-systolic pressure of $>50\,\text{mmHg}$, an end systolic dimension of $>50\,\text{mm}$ and an end-diastolic dimension of $>70\,\text{mm}$ indicate severe pathology warranting surgical intervention, even in patients with mild symptoms (NYHA class II). Asymptomatic patients with left ventricular dysfunction during exercise should be followed up with regular echocardiography. Aortic valve replacement is recommended if there is progressive left ventricular dilatation or a fall in systolic function occurs (Summary box 54.12).

**Aortic valve surgery**

Unlike mitral valve surgery, there are few occasions when the aortic valve can be repaired and usually the valve requires replacement. However, in neonates and children, aortic valve repair or valvotomy is well established. Percutaneous aortic balloon valvotomy has a role in children, but appears to offer no benefits in adult aortic valve disease.

**Summary box 54.12**

**Causes of aortic valve disease**

- **Stenosis**
  - Congenital
  - Rheumatic heart disease
  - Acquired calcification and fibrosis of valve or chordae tendineae with age

- **Regurgitation**
  - Rheumatic heart disease
  - Infective endocarditis
  - Congenital
  - Inflammatory:
    - Systemic lupus erythematosus
    - Rheumatic ankylosing spondylitis
  - Dilatation of aortic root:
    - Marfan syndrome
    - Dissection
  - Systemic disease:
    - Syphilis
    - Ulcerative colitis

**Aortic valve replacement**

This is performed through a median sternotomy on CPB. The aorta is cross-clamped and opened proximally to reveal the diseased valve. Cardioplegic solution is infused into the coronary arteries to arrest the heart in diastole. The valve is then excised leaving the annulus in situ, but removing as much calcific debris as possible. The annulus is sized and the mechanical or biological valve is then sutured into position at the level of the native annulus and the aortotomy is closed.

The operative mortality rate for elective aortic valve surgery is $<5\,$per cent, but is higher in emergency surgery, in surgery for endocarditis and in older patients. Major complications include stroke (2 per cent), perioperative myocardial infarction (2 per cent) and heart block requiring a permanent pacemaker (<1 per cent). The major determinant of late survival after aortic valve surgery is preoperative left ventricular function. The five-year survival rate is approximately 75–85 per cent, with the majority of late deaths related to myocardial factors.

**Transcatheter aortic-valve implantation**

Although aortic valve replacement (AVR) is still the gold standard treatment, a significant number of patients affected by severe AS requiring AVR do not undergo surgery because they are considered too old or too frail for such an invasive procedure, or because they are affected by concomitant comorbidities that noticeably increase the operative risk. In such patients, transcatheter aortic valve implantation is an attractive alternative to standard AVR. Other indications include heavily calcified ascending aorta (‘porcelain’ aorta) and the presence of a severe congenital thoracic distortion.

There are different approaches for valve implantation; the most commonly used are transapical (antegrade) and transluminal (retrograde).

- **Transapical approach.** The main advantage of performing transapical procedures is that the feasibility does not rely on the absence of a concomitant peripheral vascular disease.
or previous aortic surgery. This approach reduces the risk of calcium dislodgement due to the passage of a stiff transluminal device into a diseased aortic arch. In transapical transcatheter aortic-valve implantation (TAVI), the cardiac apex is prepared through a small left anterolateral mini-thoracotomy using a purse-string or a crossing suture reinforced by pledgets and, after the procedure, a chest tube is routinely inserted into the left pleura.

- Transluminal approach. This can be carried out via the femoral or subclavian approach. This is a useful technique for patients with previous cardiac surgery; however, the presence of peripheral vascular disease, small vessel diameters, tortuous vessels, aortic disease or previous aortic surgery contraindicates this approach.

Whichever approach is used, a balloon catheter is advanced into the left ventricle over a guidewire and positioned at the opening of the aortic valve. The existing aortic valve is dilated in order to make room for the prosthetic valve. Rapid right ventricular pacing is used to interrupt cardiac output through the existing aortic valve and to reduce movement during implantation. The new valve, mounted on a metal stent, is manipulated into position and is either self-expanding or deployed using balloon inflation. Deployment leads to obliteration of the existing aortic valve.

Complications associated with TAVI include mortality (3–18 per cent at 30 days), mild-to-moderate aortic regurgitation (30–50 per cent), stroke (3–9 per cent), perioperative open conversion (9–12 per cent), vascular complications (10–15 per cent) and atroventricular block (4–8 per cent). A recent myocardial infarction (less than three months), severe pulmonary dysfunction, and the presence of an apical thrombus are contraindications for transapical TAVI, whereas a left ventricular ejection fraction (LVEF) below or equal to 20 per cent contraindicates all TAVI procedures.

CONGENITAL HEART DISEASE

Introduction

Congenital heart diseases are abnormalities of cardiac structure that are present from birth. Such abnormalities in the development of the heart typically arise in the third to eighth week of gestation. The first operation for congenital heart disease was the ligation of a patent ductus arteriosus (PDA) by Gross in 1938. With the development of neonatal CPB, improved methods of myocardial protection and microsurgical techniques, an increasing number of corrective and palliative operations is possible.

Development of the heart and fetal circulation and circulatory changes at birth

By 12 weeks of fetal life, the primitive vascular tube is fully developed. The fetal circulation differs from that of the adult in that the right and left ventricles pump blood in parallel rather than in series. Such an arrangement allows the heart and head to receive more highly oxygenated blood. In the fetus, this is possible because of the presence of three structural shunts: the ductus venosus, the foramen ovale and the ductus arteriosus (Figure 54.21).

Soon after birth, pulmonary vascular resistance falls because of the action of breathing and the resulting pulmonary vasodilatation. In addition, within 30 minutes of delivery, the ductus arteriosus constricts in response to an increase in blood oxygen levels. The result is a reversal of the pulmonary–systemic pressure gradient and termination of blood flow from the pulmonary artery into the aorta.

After birth, the act of cutting and tying the umbilical cord stops venous blood flow from the placenta. This lowers the pressure in the inferior vena cava and, with the fall in pulmonary vascular resistance, right atrial pressure falls. The result is closure of the foramen ovale. The abolition of venous return from the placenta also causes the ductus venosus to close.

The closure of the fetal circulatory shunts in the few hours following birth is functional, with complete structural closure typically taking several months. In 20 per cent of adults, the structural closure of the foramen ovale remains incomplete, but is of no cardiovascular significance.

Abnormalities of cardiac structure may arise from the persistence of normal fetal channels (PDA, patent foramen ovale), failure of septation (atrial septal defect, ventricular septal defect, tetralogy of Fallot), stenosis (intracardiac–supravalvular, valvular, infravalvular or extracardiac–coarctation of the aorta), atresia or abnormal connections (transposition of the great arteries, total anomalous venous drainage). Fetal echocardiography is now sufficiently sensitive to detect intracardiac lesions in the second trimester.

Incidence

Congenital heart disease is the most common congenital abnormality in the UK; the incidence of significant cardiac abnormalities is eight cases per 1000 live births. Many
spontaneous abortions or stillbirths have cardiac malformations or chromosomal abnormalities associated with structural heart defects. In neonates and children with congenital heart disease, 15 per cent will have more than one cardiac abnormality and 15 per cent will have another extracardiac abnormality.

Aetiology

There is often no obvious aetiology; most abnormalities appear to be multifactorial with both genetic and environmental influences. There are well-recognised associations (Summary box 54.13).

Summary box 54.13

Recognised associations with congenital heart disease
- Maternal (environmental) factors
  - Infection: rubella
  - Disease: systemic lupus erythematosus, diabetes mellitus
  - Drugs/medications: alcohol abuse, warfarin, phenytoin
- Genetic factors
  - Single gene defects: Marfan, Noonan and Holt–Oram syndromes
  - Chromosomal defects: trisomy 21 (Down syndrome), trisomy 18 (Edwards syndrome), trisomy 13 (Patau syndrome), Turner syndrome
  - Deletions: DiGeorge and Williams syndromes

Diagnosis

Occasionally, an antenatal diagnosis is possible, with severe congenital heart disease detected in utero at 16–18 weeks. If an infant is suspected of having a congenital heart disease, a diagnostic evaluation begins with an accurate history from the parents and specific questions about maternal health and drug intake during pregnancy. A detailed family history is important because some defects are familial. Clinical examination may reveal a murmur, evidence of heart failure, failure to thrive and cyanosis. In addition, congenital heart disease can present with hypertension, an arrhythmia, evidence of polycythaemia or a thromboembolic event. Investigation is much the same as for the adult patient and, with fetal echocardiography available, cardiac catheterisation is now avoided whenever possible.

Classification

Congenital heart disease can be broadly classified according to the presence or absence of cyanosis, although the distinction is not always clear-cut. The presence of central cyanosis, blueness of the trunk and mucous membranes, results from levels of deoxygenated haemoglobin of >3–5 g/dL in the arterial circulation.

Cyanotic congenital heart diseases make up one-third of cases and are usually less complex. Such defects result in an increase in the work imposed on the heart because of either:
- A left-to-right shunt with increased pulmonary blood flow, which causes an increase in volume work of the heart. Examples include PDA, atrial septal defect (ASD) and ventricular septal defect (VSD).
- Obstruction of the blood flow across a heart valve on the left side of the heart, such as aortic stenosis, or in the aorta itself, as occurs with coarctation of the aorta, leading to an increase in pressure and work of the heart.

Typically, acyanotic congenital heart disease presents as heart failure in infancy because of pulmonary congestion caused by increased pulmonary blood flow or increased pulmonary venous blood pressure resulting from an obstructive lesion. The common acyanotic cardiac defects can also present as a murmur in infancy or later.

A cyanotic congenital heart disease represents the other two-thirds of cases and are usually less complex. Such defects result in an increase in the work imposed on the heart because of either:
- Parallel systemic and pulmonary blood flow rather than in series. If there is no mixing, this is incompatible with life, so typically neonates have a patent foramen ovale that allows some mixing of the two circulations at this level. The most common example of this is transposition of the great vessels (TGV).
- Defects in the connections of the heart in which there is mixing of the systemic and pulmonary flows. An example of such a complex lesion is total anomalous pulmonary venous drainage.

Ae...
Transposition of the great vessels

The condition, first described by Morgagni, is the second most common cyanotic congenital heart disease and is the most common cause of cyanosis from a congenital cardiac defect discovered in the newborn period. TGV results from abnormal development and typically occurs when the aorta arises from the right ventricle and the pulmonary artery from the left ventricle (Figure 54.23). The resulting transposition causes the pulmonary and systemic circulations to run in parallel rather than in series, so that oxygenated pulmonary venous blood returns back to the lungs and desaturated systemic venous blood is pumped around the body. The situation is incompatible with life and mixing of the blood must occur through associated shunts such as a patent foramen ovale or associated VSD. The most obvious presentation is severe central cyanosis occurring in the first 48 hours of life. However, if there is a large ASD or VSD, there may be minimal cyanosis initially. Typically, progress is poor and, as pulmonary vascular resistance declines in the neonatal period, high pulmonary flow develops, with cardiac enlargement and left ventricular failure.

The chest radiograph shows pulmonary plethora, with the heart having an ‘egg on its side’ appearance, with a small pedicle (aorta in front of pulmonary artery). Cardiac catheterisation and echocardiography confirm the diagnosis and delineate the anatomy. Initial palliation is by percutaneous (Rashkind) balloon atrial septostomy or, alternatively, intravenous prostaglandin to keep the ductus open. Definitive repair is usually by the arterial switch procedure, mostly carried out as a two-stage procedure, whereby the pulmonary artery is first banded to ‘tone up’ the left ventricle. However, the arterial switch procedure without prior pulmonary artery banding is increasingly being carried out in the newborn with TGV and an intact ventricular septum. The long-term results are impressive and it has replaced the atrial switch or baffle (Mustard or Senning) operations.

Total anomalous pulmonary venous drainage

Total anomalous pulmonary venous drainage (TAPVD) accounts for only 1–2 per cent of congenital heart disease. In this condition, the pulmonary venous drainage has become disconnected from the left atrium and drains into the systemic venous circulation at some other point (inferior vena cava, superior vena cava, coronary sinus or right atrium). Typically, TAPVD presents after the first week of life with cyanosis that is mild to moderate depending on pulmonary flow. Infants with high pulmonary flow develop cardiac failure, recurrent chest infections, failure to thrive and feeding difficulties. If high pulmonary flow is associated with a large ASD, cyanosis is often minimal and the lesion is tolerated well. If there is additional venous obstruction, cyanosis presents at birth with dyspnoea and pulmonary oedema. Echocardiography and cardiac (pulmonary) angiography are necessary to confirm the diagnosis and establish the location of the anomalous drainage.

The surgical principle is to re-establish the pulmonary venous drainage into the left atrium. The exact operative technique depends on the anatomy and type of TAPVD. The long-term results for survivors of the operation are generally good. Late death following repair is uncommon but, when it occurs, it is often caused by intimal fibroplasia of the pulmonary veins away from the anastomosis.

Eisenmenger’s syndrome

Eisenmenger’s syndrome is becoming less common as corrective surgery is undertaken increasingly early and fewer patients develop a fixed increase in their pulmonary vascular resistance. It occurs following the reversal of a left-to-right shunt across a previous left-to-right shunt, such as with an ASD, VSD or a patent ductus arteriosus. These congenital anomalies cause an increase in flow and higher right-sided pressures, which lead to compensatory right ventricular hypertrophy and a subsequent rise in pulmonary artery pressure. Increasing pulmonary hypertension leads to equalisation of pressures either side of the shunt but, at some point, the right-sided pressures will exceed those on the left side, resulting in shunt reversal and desaturated blood entering the left side of the circulation. Cyanosis and dyspnoea are the most common clinical features. Closure of the shunt is contraindicated if pulmonary hypertension is irreversible.
because the right-to-left shunt now serves to decompress the pulmonary circulation.

**A cyanotic congenital heart disease**

**Patent ductus arteriosus**

The ductus arteriosus, a normal fetal communication, facilitates the transfer of oxygenated blood from the pulmonary artery to the aorta, shunting blood away from the lungs. Normally, functional closure of the ductus occurs within a few hours of birth; it is abnormal if it persists beyond the neonatal period. The ductus closes in response to an increase in peripheral oxygen saturation and a drop in the resistance of the pulmonary circulation as the lungs expand; this causes the ductal tissue to contract through a prostaglandin inhibition mechanism. A cycloxygengase inhibitor (e.g. indomethacin) may be used therapeutically to close the ductus in the first few weeks of life. In premature babies, the ductus is more likely to remain patent for longer or permanently. In the isolated case of PDA, there is a left-to-right shunt of blood, resulting in a high pulmonary blood flow. Small shunts usually cause few symptoms and signs apart from the continuous machinery murmur in the left second intercostal space. Larger ducts cause cardiac failure and can uncommonly lead to shunt reversal with cyanosis and clubbing. The diagnosis is best confirmed by echocardiography with colour flow Doppler imaging. Cardiac catheterisation is performed only if additional lesions are suspected.

After six months of age, spontaneous closure of a PDA is rare. Most should be closed by preschool age, regardless of the absence of symptoms, if the risks of infective endocarditis, developing left ventricular failure or, rarely, Eisenmenger’s syndrome are to be avoided. In the adult, surgical treatment is indicated if there is a persistently left-to-right shunt, even in the presence of pulmonary hypertension. In the premature infant, if medical treatment to close the ductus is unsuccessful, the lesion may be treated by interventional cardiology using an umbrella or coil duct occlusion device inserted percutaneously. If the lesion is very large or the patient very small, surgical closure via a left thoracotomy is preferred. This can be accomplished by either ligation or division of the PDA. The operative mortality rate is low and outcome generally very good.

**Coarctation of the aorta**

This accounts for 6–7 per cent of congenital heart disease and is defined as a haemodynamically significant narrowing of the aorta, usually in the descending aorta just distal to the left subclavian artery, around the area of the ductus arteriosus (Figure 54.24). The coarctation typically puts a pressure load on the left ventricle, which can ultimately fail. The upper body is well perfused but the lower body, including the kidneys, is poorly perfused, leading to fluid overload, excess renin secretion and acidosis. Coarctation usually affects boys and if it occurs in girls is suggestive of Turner’s syndrome.

In the neonatal period, coarctation, often referred to as ‘infantile’ or preductal coarctation, presents with symptoms of heart failure. The child may appear well in the first few days of life because the coarctation is bypassed by the ductus arteriosus and oxygenated blood reaches the entire systemic circulation. As the ductus closes, the child becomes progressively more unwell. In adult-type coarctation, which is often juxtaductal or slightly postductal, obstruction is gradual with complications developing in adolescence or early adulthood. Hypertension is a common presenting problem in older children, often upper body hypertension only with development of enormous collateral vessels that may cause rib-notching and flow murmurs over the scapula. Other symptoms include prominent pulsation in the neck, tired legs or intermittent claudication on exercise. Clinical examination of the pulses may demonstrate a radio-femoral delay and a murmur that is continuous and heard best over the thoracic spine or below the left clavicle.

The chest radiograph classically demonstrates rib-notching from the age of six to eight years because of dilated posterior intercostal vessels. The heart is usually of normal size in the older child and shows a classical ‘three sign’ replacing the typical aortic knuckle. The upper part of the three sign is the dilated left subclavian, the middle part is the narrowing at the coarctation site, and the lower part is the post-stenotic dilatation of the descending aorta. Echocardiography is diagnostic, with cardiac catheterisation performed if other anomalies are present. Infant coarctation typically presents with cardiac failure, often requiring vigorous medical treatment, including the administration of prostaglandin to reopen the ductus and general resuscitation, before corrective surgery. Definitive treatment is usually surgical repair via a left thoracotomy. Coarctation presenting in the child or later typically requires surgical repair, as most patients die before the age of 40 years because of the associated complications. Percutaneous balloon dilatation is an alternative procedure in older children and adults and, in particular, for recoarctation. Without correction, the majority of deaths are caused by heart failure, infective endocarditis, rupture of the aorta or haemorrhagic stroke. The preoperative hypertension may not resolve despite surgical repair.

---

**Figure 54.24** Coarctation of the aorta. Coarctation causes severe obstruction of blood flow in the descending thoracic aorta. The descending aorta and its branches are perfused by collateral channels from the axillary and internal thoracic arteries through the intercostal arteries (arrows).

---

**Victor Eisenmenger, 1864–1932, Austrian physician who first described this condition in 1897, but the term ‘Eisenmenger’s syndrome’ was first introduced in 1958 by Paul Hamilton Wood (1907–1962).**

**Henry Hubert Turner, 1892–1970, Professor of Medicine, The University of Oklahoma, Oklahoma City, OK, USA.**
**Atrial septal defects**

An ASD is a defect in the septum between the left and right atria leading to a left-to-right shunt, the significance of which is determined by the size of the defect and the relative compliance of the ventricles. The development of the atrial septum is complex and abnormalities of development lead to three commonly recognised ASDs (Figure 54.25).

The most common type is an ostium secundum ASD. The anomaly is caused by a defect in the floor of the fossa ovalis, resulting in failure of the septum secundum to develop completely and cover the foramen ovale. Secundum defects are usually asymptomatic in childhood, with symptoms developing insidiously, typically presenting in middle age with congestive cardiac failure secondary to pulmonary hypertension or with atrial arrhythmias.

In ostium primum ASD, the anomaly is a form of partial atrioventricular canal defect or endocardial cushion defect. The abnormalities are confined to the atrial septum and are caused by the endocardial cushions failing to develop and so close the ostium primum part of the interatrial septum. The defect is associated with abnormalities of the mitral valve, leading to mitral regurgitation. There is a relatively high incidence of this abnormality in trisomy 21 (Down syndrome). Typically, the primum defect presents earlier than ostium secundum in childhood, with dyspnoea, recurrent chest infections and, if pulmonary hypertension develops, cyanosis.

A sinus venosus ASD is a rare defect and is the result of failure of partition of the pulmonary and systemic venous circulations. These defects are most commonly located high in the atrial septum at the junction of the superior vena cava and the right atrium. They are frequently associated with anomalous pulmonary venous drainage with right superior pulmonary veins draining into the superior vena cava or right atrium directly (Summary box 54.14).

Closure is performed during the first decade of life, even in the absence of symptoms, to avoid late-onset right ventricular failure, endocarditis and paradoxical emboli. In adults, closure is still appropriate for symptomatic improvement and avoidance of complications. The traditional method of closure involves open-heart surgery with CPB and closure of the defect either directly with sutures, as with most secundum defects, or, if the defect is large, using a pericardial or synthetic patch. Closure of small to moderate ASDs using percutaneous catheter-delivered devices in the cardiology catheter laboratory is increasingly common. Primum atrioventricular defect repairs may require additional mitral valve repair. The operative mortality rate for isolated atrioventricular defect repairs is <1 per cent, with an excellent prognosis. Surgical correction of complete atrioventricular canal defects, with closure of the ASD and ventricular septal components and mitral valve repair, is possible with a higher surgical mortality rate.

**Ventricular septal defects**

A VSD is a defect in the interventricular septum that allows a left-to-right shunting of blood. VSDs account for 20–30 per cent of congenital heart disease and affect approximately 2 in 1000 live births. They may occur in isolation or as part of a more complex set of cardiac abnormalities (e.g. tetralogy of Fallot, complete atrioventricular canal defect). Four major anatomical types of VSD are described, based on the anatomical subsections of the interventricular septum (Summary box 54.15 and Figure 54.26).

The VSD permits a left-to-right shunt at the ventricular level, with subsequent right ventricular volume overload and increased pulmonary blood flow. This may lead to progressive pulmonary oedema and congestive cardiac failure. Persistently elevated pulmonary blood flow and pulmonary vascular resistance also lead to irreversible pulmonary hypertension. They may eventually result in reversal of flow across the defect and Eisenmenger’s syndrome. The clinical presentation reflects the magnitude of the left-to-right shunt, which in turn depends on the size of the VSD and the pulmonary and systemic vascular resistances. Small defects may close or cause little systemic disturbance (maladie de Roger); infants are asymptomatic with

---

**Summary box 54.14**

**ASDs**

- **Common defects**
  - Ostium secundum: fossa ovalis defect (approximately 70 per cent of ASDs)
  - Ostium primum: atrioventricular septal defect (approximately 20 per cent of ASDs)
  - Sinus venosus defect: often associated with anomalous pulmonary venous drainage (approximately 10 per cent of ASDs)

- **Patent foramen ovale:** common in isolation, usually no left-to-right shunt (not strictly an ASD)

- **Rarer defects**
  - Inferior vena cava defects: a low sinus venous defect and may allow shunting of blood into the left atrium
  - Coronary sinus septal defect: also known as unroofed coronary sinus with the left superior vena cava draining to the left atrium as part of a more complex lesion
pleurisy as the infected ‘emboli’ in a VSD with a typical left-to-right shunt flows into the pulmonary circulation.

**THE THORACIC AORTA**

The most common pathology affecting the thoracic aorta is aneurysm formation or dissection.

**Thoracic aortic aneurysms**

A true aneurysm is a localised dilatation of a blood vessel involving all layers of the vessel, whereas a false aneurysm has compressed supporting tissue as its wall and is usually the result of a defect in the vessel intima (from trauma, dissection or previous surgery). Aneurysms are described as fusiform when the whole circumference is affected or saccular when only part of the circumference is involved.

Aortic aneurysms can develop anywhere along its length, but thoracic aortic aneurysms, including those that extend into the upper abdomen (thoracoabdominal aneurysms), account for 25 per cent, typically occurring in men in the fifth to seventh decade or younger in those with connective tissue disorders.

**Aetiology**

The most common aetiology is atherosclerosis, but connective tissue disorders account for many aneurysms in the aortic root and ascending aorta now that tertiary syphilis is rare. Marfan syndrome is associated with cystic medial degeneration involving the vessel wall and causes widening of the proximal aorta and aortic root, leading to aortic valve insufficiency. Other disorders associated with aneurysm formation and dissection include Ehlers–Danlos syndrome and osteogenesis imperfecta.

Trauma, typically following blunt chest injury, can lead to aneurysm formation, usually involving the descending aorta. However, these are usually false aneurysms containing haematoma from injury to the aortic vessel wall.

**Clinical features**

Many aneurysms are asymptomatic and are discovered incidentally on routine chest x-rays. Others present as a space-occupying lesion in the thorax with pain caused by pressure on adjacent structures (vertebra), hoaseness (left recurrent laryngeal nerve), dysphagia (oesophagus) and respiratory symptoms (left main bronchus). Aortic root aneurysms may lead to dilatation of the aortic root annulus and aortic regurgitation.

Rupture can lead to cardiac tamponade or haemorrhage into the left pleural space, leading to dyspnoea and, if the tracheobronchial airway or oesophagus is involved, haemoptysis or haematemesis, respectively.

**Investigations**

The diagnosis is confirmed by CT or MRI. Arteriography is not necessary for diagnosis but is often required to demonstrate the relation of the arch vessels to the aneurysm.

**Indications for surgery**

Without treatment, the aneurysm is likely to expand and ultimately rupture. Important factors to consider when planning treatment are age, comorbidity and coexisting coronary disease.

---

**Summary box 54.15**

**Types of VSD**

- **Perimembranous defect**
  - Also called conoventricular VSD; the most common defect (70–80 per cent), usually located within the membranous septum and may extend to the tricuspid valve annulus or base of the aortic valve
- **Muscular defect**
  - Also called trabecular VSD; occurs in 10 per cent of cases and is located within the membranous septum and often multiple
- **Atrioventricular defect**
  - Also called atrioventricular canal-type defect; occurs in 5 per cent of cases and is located in the atrioventricular canal beneath the tricuspid valve
- **Subarterial defect**
  - Also called infundibular or subarterial VSD; occurs in 5–10 per cent of cases and lies within the conal septum immediately subaortic

---

![Ventricular septum viewed from the right, showing the characteristic sites of ventricular septal defects.](image-url)
In ascending aneurysms, the presence of progressive aortic valve insufficiency is an important indication for surgery. Other indications in this group, including Marfan-related aneurysms, are a diameter of 5–6 cm and the presence of symptoms. In descending aneurysms, indications for surgery include symptoms, acute enlargement and a diameter of approximately 6 cm.

**Surgical options**
The approach adopted for surgical treatment depends on the location of the aneurysm, but typically involves a median sternotomy, CPB and cooling the patient to 18°C before cross-clamping the aorta above the aneurysm (Figure 54.27). If the aortic root is involved, the aorta, together with its annulus and valve, is resected and a composite graft is sutured to the aortic root. The circulation is arrested and, after removal of the aortic cross-clamp, the distal anastomosis is completed. The coronary ostia require reimplantation into the graft (Bentall's operation). If the ascending aorta is involved, it is resected and replaced with a tube graft. For aortic arch aneurysms, surgery on this section of the aorta is a formidable undertaking because the cerebral and subclavian vessels have to be anastomosed to the graft, either separately or en bloc. Typically, it involves a period of circulatory arrest and some form of cerebral protection. Excision of a descending aortic aneurysm is with graft replacement under CPB with exposure via a left thoracotomy or with a heparin-bonded shunt. Increasingly, thoracic aneurysms at the aortic arch or more distal are repaired using a percutaneous approach via the femoral artery with insertion of an endovascular stent.

**Surgical outcome**
The operative mortality rate is variable depending on the location and type of repair required but electively is between 5 and 15 per cent. An emergency repair has a considerably higher operative mortality rate. Long-term survival depends on underlying pathology but, for ascending aneurysm repairs, the five-year survival rate is approximately 65 per cent. The major complications of descending aneurysm repairs include paraplegia, renal failure and ventricular dysfunction.

**Aortic dissection**
This occurs when there is a defect or flap in the intima of the aorta, resulting in blood tracking into the aortic tissues splitting the medial layer and creating a false lumen. It most commonly occurs in the ascending aorta or less often just distal to the left subclavian artery. It is also more common in men, typically those aged 50–70 years, and in Afro-Caribbeans.

**Aetiology**
It usually occurs as a spontaneous or sporadic event, although very often a history of hypertension is noted. Other important associations include Marfan syndrome and pregnancy (Summary box 54.16).

**Clinical features**
The presentation is often a tearing intrascapular pain not unlike the pain of myocardial ischaemia, and it may be difficult to distinguish between the two. The extent of arterial dissection may produce widespread symptoms and signs.

The dissection can extend distally down the aorta to involve:
- the renal arteries (renal pain and renal failure);
- the mesenteric arteries (abdominal pain and bowel ischaemia);
- the spinal arteries (paraplegia);
- the iliac arteries (leg pain, pallor, loss or reduced pulses and limb ischaemia).

The dissection may track proximally to involve:
- the head and neck vessels (symptoms and signs of a stroke or transient ischaemic attack);
- the coronary vessels (myocardial infarction);
- the aortic root (aortic regurgitation).

The aneurysm may rupture back into the lumen or externally into the pericardium (cardiac tamponade) or mediastinum (left haemothorax).

**Classification**
There are two classifications, both of which are limited in their application but widely used. The DeBakey classification is based on the pattern of dissection, whereas the Stanford classification is based on whether the ascending aorta is involved (Figure 54.28).

**Investigations**
The diagnosis is suspected when chest radiography demonstrates a widened mediastinum, often associated with fluid in the left costophrenic angle. Diagnosis is confirmed by whatever method is most readily at hand and includes echocardiography, ideally TOE, CT of the thorax or MRI (Figure 54.29). Traditionally,

---

*Figure 54.27 A large thoracic aortic aneurysm.*

Hugh Henry Bentall, formerly Professor of Cardiac Surgery, The Royal Postgraduate Medical School, Hammersmith Hospital, London, UK.
aortography was the 'gold standard' technique and it still provides excellent information before surgery but, increasingly, advanced three-dimensional CT angiography and MRI are used when available.

**Management**

In the emergency situation, before further imaging, blood pressure (which is usually high at presentation) should be brought under control to prevent extension of the dissection.

**Surgical options**

**Type A (or type I and II) dissections**

Those involving the ascending aorta usually require surgical intervention. The chest is opened through a median sternotomy and CPB is started with core cooling down to 18°C. The aorta is cross-clamped as high as possible and opened. Cardioplegia solution is infused into the coronary ostia to arrest the heart in diastole. If the intimal tear is present and localised, the ascending aorta is excised with the tear and replaced with a synthetic graft. The distal anastomosis is performed with circulatory arrest. Recently, there have been attempts to carry out endovascular stenting of type A dissection with variable degrees of success.

**Type B (or type III) dissections**

Initially, these are best managed medically with antihypertensive drugs. Surgery is indicated if the pain increases (signalling impending rupture), the aneurysm is expanding on serial chest radiographs or complications, such as organ, limb or neurological symptoms, develop. The operation may be performed with a heparin-bonded shunt or under CPB. There is a real risk of paraplegia from this operation, which should be mentioned specifically to the patient before operation. Use of percutaneously placed endovascular stents is likely to increase in the future, although currently its role in the acute setting remains to be established. There has been a shift in the surgical management of type B dissection towards endovascular stenting which can be a part of a hybrid operation including surgical replacement of parts of the aorta, such as the arch.

**Outcomes**

If dissection is untreated, the mortality rate is 50 per cent within 48 hours and 75 per cent within 1–2 weeks. Almost all patients with type A dissections will die if not operated on, whereas patients with type B dissections have a better prognosis. The surgical mortality rate is variable but is around 15 per cent for proximal aortic dissection. The overall survival rate for patients leaving hospital, regardless of the type of dissection, is around 80 per cent at five years and 40 per cent at ten years.

**PERICARDIAL DISEASE**

There is a fibrous envelope covering the heart and separating it from the mediastinal structures. This fibrous structure includes a parietal layer and allows the heart to move with each beat. It is not essential for life because it can be left wide open after cardiac surgery without any ill-effects; however, there are a number of conditions affecting the pericardium that may present to the surgeon.

**Pericardial effusion**

There is a continuous production and resorption of pericardial fluid. If a disease process disturbs this balance, a pericardial effusion may develop. If the pressure exceeds the pressure in the atria, compression will occur, venous return will fall and the circulation will be compromised. This state of affairs is called ‘tamponade’. A gradual build up of fluid (e.g. malignant infiltration) may be well tolerated for a long period before tamponade occurs, and the pericardial cavity may contain 2 litres of fluid. Acute tamponade (from penetrating trauma, during coronary angiography or postoperatively) may occur in minutes with small volumes of blood. The clinical features are low blood pressure with a raised jugular venous pressure and paradoxical pulse. Kussmaul’s sign is a characteristic pattern that is seen when the jugular venous pressure rises with inspiration as a result of the impaired venous return to the heart.

Emergency treatment of pericardial tamponade is aspiration of the pericardial space. A wide-bore needle is inserted under local anaesthesia to the left of the xiphisternum, between the angle of the xiphisternum and the ribcage (Figure 54.30). The needle is advanced towards the tip of the scapula into the pericardial space. An ECG electrode attached to the needle will indicate when the heart has been touched. This will relieve
the situation temporarily until the cause of the tamponade is established. Penetrating wounds of the heart usually require exploration through a median sternotomy. Emergency room thoracotomy is rarely required. Chronic tamponade is usually a result of malignant infiltration of the pericardium (usually secondary carcinoma from breast or bronchus) or, very occasionally, uremia or connective tissue disease. Treatment sometimes requires a pericardial window between the pericardial space and the pleural or peritoneal space.

**Pericarditis**

Infection and inflammation may also affect the pericardium. Acute pericarditis usually occurs following a viral illness. Treatment is with non-steroidal anti-inflammatory drugs and bed rest (in case there is an underlying myocarditis). Acute purulent pericarditis is uncommon, but requires urgent drainage and intravenous antibiotics with attention to the underlying cause.

Chronic pericarditis is an uncommon condition in which the pericardium becomes thickened and non-compliant. The heart cannot move freely and the stroke volume is reduced by the constrictive process. The central venous pressure is raised and the liver becomes congested. Peripheral oedema and ascites are also a feature. Treatment is aimed at relieving the constriction.

**Management of Cardiac Arrest after Cardiac Surgery**

**Introduction**

The incidence of cardiac arrest after cardiac surgery is around 0.7–2.9 per cent with 17–79 per cent survival rates. Ventricular fibrillation (VF), tamponade and major bleeding account for most arrests. Multiple variables may dictate differences in the management of cardiac arrest after cardiac surgery when compared to other situations. Therefore, EACTS published guidelines for resuscitation of cardiac arrest post-cardiac surgery which are summarised below.

**Cardiac arrest with ‘non-shockable’ rhythm**

Cardiac surgical patients who have a non-VF/VT (ventricular tachycardia) arrest may have tamponade, tension pneumothorax, or severe hypovolaemia. Prompt treatment is associated with an excellent outcome. Resternotomy should be performed promptly if connecting the pacemaker and administering atropine fail to resolve the arrest especially if prolonged period of cardiopulmonary resuscitation (CPR) is needed which will be better performed by internal massage.

**Emergency resternotomy for ventricular fibrillation or pulseless ventricular tachycardia**

A precordial thump may be performed if within 10 s of the onset of VF or pulseless VT, however, this should not delay cardioversion by defibrillation. In VF or pulseless VT, emergency resternotomy should be performed after three failed attempts at defibrillation.

**Emergency resternotomy**

After the identification of cardiac arrest, basic life support according to the ALS (advanced life support) guidelines should be initiated while preparing for emergency resternotomy. Emergency resternotomy may be required in 0.8–2.7 per cent of all patients undergoing cardiac surgery. Emergency resternotomy is a multi-practitioner procedure, which should be rapidly performed with full aseptic technique.

**Preparation for emergency resternotomy**

- Don a gown and gloves in a sterile fashion.
- Apply the thoracic drape ensuring that the whole bed is covered. (If an all-in-one sterile drape is used, then there is no need to prepare the skin with antiseptic.)
- Use the scalpel to cut the sternotomy incision, including all sutures deeply down to the sternal wires.
- Cut all the sternal wires with the wire cutters. The sternal edges will separate a little which may relieve tamponade.
- Use suction to clear excessive blood or clot.
- Place the retractor between the sternal edges and open the sternum.
- If cardiac output is restored, wait for expert assistance. If there is no cardiac output, carefully identify the position of any grafts and then perform internal cardiac massage and internal defibrillation if required.

**Internal cardiac massage**

This is a potentially dangerous procedure. Risks include avulsion of a bypass graft, with the left internal mammary artery being at particular risk, and right ventricular rupture especially if it is thin or distended. Therefore, it is important to carefully remove any clot and identify structures at risk, such as grafts, before placing hands around the heart.

There are several methods of internal massage, however, the two-hand technique is the safest.

**Two-hand technique**

The heart should be inspected to locate the internal mammary and any other grafts if present followed by removing any blood clots. The right hand is passed over the apex of the heart and then advanced round the apex to the back of the heart, palm up and hand flat. The left hand is then placed flat onto the anterior surface of the heart and the two hands squeezed together at a rate of 100 per minute. Flat palms and straight fingers are important to avoid an unequal distribution of pressure onto the heart, thereby minimising the chance of trauma. If there is a mitral valve

---

replacement or repair, care should be taken not to lift the apex by the right hand, as this can cause a posterior ventricular rupture.

**FURTHER READING**

INTRODUCTION

Anatomical development of the lungs

The lungs are derived from an outpouching of the primitive foregut during the fourth week of intrauterine life. This bud becomes a two-lobed structure, the ends of which ultimately become the lungs. The lobar arrangement is defined early and is fairly constant but anomalies of fissures and segments leading to anatomical variation in the adult are common.

The primitive lungs drain into the cardinal veins, which ultimately become the pulmonary veins draining into the left atrium. Variability in venous drainage is very common and is usually of little functional significance. At the most severe end of the spectrum is total anomalous drainage, which presents in early infancy because oxygenated blood is all directed back to the right heart.

Anatomy of the lungs

The left lung is divided by the oblique fissure, which lies nearer vertical than horizontal, so the upper and lower lobes could also be called anterior and posterior. On the right, the equivalent of the left upper lobe is further divided to give the middle lobe. Each lobe is composed of segments, with anatomically defined and named bronchial, pulmonary arterial and venous connections (Figure 55.1).

The right main bronchus (RMB) is shorter, wider and nearly vertical compared with the left main bronchus (LMB). As a consequence, inhaled foreign bodies are more likely to enter the right main bronchus than the left (Figure 55.2). The trachea and bronchi have a systemic arterial blood supply delivered by the bronchial arteries, which arise directly from the nearby thoracic aorta.

Lymphatic drainage tends to follow the bronchi. Lymph nodes are both named and identified by numbered 'stations', which are of importance in staging of lung cancer (Figure 55.3).

Mechanics of breathing

The intercostal muscles contract, causing the ribs to move upwards and outwards, thereby increasing the transverse and anteroposterior dimensions of the chest wall. The diaphragm contracts simultaneously and flattens, increasing the vertical dimension of the chest cavity. As the volume increases, the intrathoracic pressure falls and air flows in until the alveolar pressure is the same as the atmospheric pressure. The only force used in normal expiration is the elastic recoil of the lung.

Coughing to clear sputum is an essential part of recovery from surgery. In a vigorous cough, probably the only muscle in the body that is relaxed is the diaphragm; as the abdomen and chest wall muscles contract, the limbs are braced and the sphincters are tightened. When the intrathoracic and abdominal pressure is built up, the glottis is opened and the diaphragm is forced up...
velocity achieved during an expiration delivered with maximal force from the total lung capacity. It is a reliable and reproducible test but has the disadvantage of being effort dependent, and it may therefore be affected by abdominal or thoracic wound pain. PEFR measurements are often used in managing asthma, but there are many other causes of low PEFR, such as a problem with large airway patency.

**Forced expiratory volume in 1 second**

The forced expiratory volume in 1 s (FEV₁) is the amount of air forcibly expired in 1 s. It is low in obstructive lung disease and may be normal in patients with poor gas exchange.

**Forced vital capacity**

The forced vital capacity (FVC) is the volume of air forcibly displaced following maximal inspiration to maximal expiration. The FEV₁ and the FVC can be measured using a Vitalograph and a ratio (FEV₁/FVC) can be calculated (Figure 55.4). A low ratio indicates obstruction and the test should be repeated after bronchodilators. A normal ratio (FVC and FEV₁ reduced to the same extent) indicates a restrictive pathology.

There are two physiological categories of lung disease: obstructive and restrictive (Table 55.1). In obstructive conditions, such as asthma or emphysema, the flow of air in and out of the lungs is impaired. In restrictive disease, such as lung fibrosis, the lungs have lost size or elasticity, becoming 'stiff' so that they do not fill or expand properly.

**Diffusion capacity**

The diffusion capacity (DLCO) is a measurement of the lung’s ability to transfer gases and is often referred to as the ‘transfer factor’. It cannot be performed at the bedside, requires the patient’s current haemoglobin level and is a test of the integrity of the lung’s alveolar-capillary surface area for gas exchange. In lung diseases that damage the alveolar walls, such as emphysema, or thicken the alveolar membrane, such as lung fibrosis, it may be reduced.

**Oxygen saturation**

Oxygen saturation (SpO₂) refers to the degree of oxygen molecules (O₂) carried in the blood attached to haemoglobin (Hb) molecules. It is a measure of how much oxygen the blood is carrying as a percentage of the maximum it could carry. The common method of monitoring the oxygenation of a patient’s haemoglobin is through a pulse oximeter.

---

*Basil Martin Wright, 1912–2001, member of the Scientific Staff of the Medical Research Council Research Centre, Northwick Park Hospital, Harrow, Middlesex, UK.*
Blood gases

SpO₂ measured non-invasively with a pulse oximeter measures only oxygenation, not ventilation and provides no information regarding a patient's carbon dioxide or bicarbonate levels, blood pH, base deficit. This requires arterial blood sampling or ‘blood gases’ (Table 55.2).

The pleura

The key to many aspects of practical chest surgery is an understanding of the pleura and of the mechanics of breathing. Management of the essentially healthy pleural space is logical and simple and needs minimal technology. On the other hand, when pleural disease is advanced, for example when there is gross pleural sepsis surrounding a leaking and trapped lung, management is difficult and the patient may require prolonged care with repeated interventions.

The physiology of pleural fluid

The turnover of fluid in the human pleural space is about 1–2 litres in 24 hours, with only 5–10 mL of fluid present at any one time as a film, about 20 µm thick, between the visceral and parietal pleura.

The mechanisms and equations given are simplifications, but serve to explain the clinical conditions encountered. The fluid is produced from the capillaries of the parietal pleura as a
transudate, according to the Starling capillary loop pressures. However, there is a further negative force in the pleura. The elastic content of the lung causes it to recoil and collapse if not held open by the negative pressure in the pleura. This elastic recoil exerts about 4 mmHg negative pressure and favors accumulation of fluid. The secreting forces add up to about 11 mmHg in health. Pleural fluid is mainly reabsorbed (about 90 per cent) by the visceral pleura, whose capillaries are part of the pulmonary circulation. The principal force in absorption of pleural fluid is oncotic pressure (approximately 25 mmHg) less the difference in mean capillary hydrostatic pressure of the pulmonary capillary (8 mmHg). Thus, the overall absorbing pressure is $25 - 8 = 17$ mmHg, producing a net drying effect ($17 - 11$) of about 6 mmHg (Figure 55.5).

**Gas in the pleural space**

There is normally no free gas in the pleural space because the same physiological mechanism that absorbs air from a pneumothorax prevents any gas accumulating.

The partial pressures (water as saturated vapour pressure) of the gases in venous/end-capillary blood are:

| $P_{O_2}$ | 40 mmHg | 5.3 kPa |
| $P_{CO_2}$ | 46 mmHg | 6.1 kPa |
| $P_{N_2}$ | 573 mmHg | 76.4 kPa |
| $P_{H_2O}$ | 47 mmHg | 6.3 kPa |

These partial pressures add up to less than atmospheric pressure (760 mmHg). Free gas is therefore absorbed into the blood and lost to the atmosphere through the lungs, with the gases moving in relation to their solubility (carbon dioxide quickest and nitrogen slowest) and relative concentrations in the pleural space and the blood. This does not favour nitrogen, which constitutes about 80 per cent of atmospheric air. Breathing oxygen accelerates nitrogen removal by reducing the content of nitrogen in the blood and increasing the gradient for its absorption. Nitrous oxide anaesthesia is dangerous in the presence of a pneumothorax; nitrous oxide is very soluble and, although not normally present in the pleural space, it will be rapidly transported into the space if the patient is given nitrous oxide to breathe.

**Pleural Disease**

**Pneumothorax**

Pneumothorax is the presence of air outside the lung, within the pleural space. It must be distinguished from bullae or air cysts within the lung. Bullae can be the cause of an air leak from the lung and can therefore coexist with pneumothorax.

**Spontaneous pneumothorax** occurs when the visceral pleura ruptures without an external traumatic or iatrogenic cause. They are divided into primary spontaneous pneumothorax (PSP) and secondary spontaneous pneumothorax (SSP). Pneumothoraces can also cause occur following trauma or be caused by iatrogenic injury, such as insertion of a central line. Tension pneumothorax is when (independent of aetiology) there is a build up of positive pressure within the hemithorax, to the extent that the lung is completely collapsed, the diaphragm is flattened and the mediastinum is distorted and, eventually, the venous return to the heart is compromised. Any pleural breach is inherently valve-like because air will find its way out through the alveoli but cannot be drawn back in because the lung tissue collapses around the hole in the pleura. Patients being mechanically ventilated following trauma are at particular risk.

**Surgical emphysema** is the presence of air in the tissues. It requires a breach of an air-containing viscus in communication with soft tissues, and the generation of positive pressure to push the air along tissue planes. The most serious cause is a ruptured oesophagus. Mediastinal surgical emphysema can also occur with asthma or barotrauma from positive pressure ventilation. A poorly managed chest drain with intermittent build up of pressure allows air to track into the chest wall through the point where the drain breaches the parietal pleura.

**Primary spontaneous pneumothorax**

This is a common disease characteristically seen in young people from their mid-teens to late twenties. About 75 per cent of cases are in young men, who tend to be tall, and the condition runs in families. It is due to leaks from small blebs, vesicles or bullae, which may become pedunculated, typically at the apex of the upper lobe or on the upper border of the lower or middle lobes.

**Secondary spontaneous pneumothorax**

This occurs when the visceral pleura leaks as part of an underlying lung disease; any disease that involves the pleura may cause pneumothorax, including tuberculosis, any degenerative or cavitating lung disease and necrosing tumours. As such it tends to occur in older patients, often with a history of underlying lung disease, such as emphysema. The pneumothorax may be less well tolerated.

---

Ernest Henry Starling. 1866–1927, Professor of Physiology, University College, London, UK.
Usually, pneumothorax presents with sharp pleuritic pain and breathlessness. The pleura is exquisitely sensitive and the movement of the lung on and off the parietal pleura causes severe discomfort. As a result, it is mild cases that are more painful, whereas complete collapse is usually painless but causes more breathlessness. Bleeding and tension pneumothorax can occur. They are usually self-limiting; careful observation is wiser than too-ready resort to a chest drain. If the patient is not in respiratory distress or hypoxic, there is no urgency. Tension pneumothorax should be immediately relieved by inserting a cannula into the hemithorax in as safe a position as possible (Figure 55.6).

The risk of recurrent pneumothorax is increased after the first episode. The best estimates of recurrence rates are:

- of patients who experience a first event, only about one-third experience recurrence;
- of those who have a second episode, about one-half go on to experience a third episode;
- those who have had three episodes will probably go on to have repeated recurrences.

Current recommendations from the British Thoracic Society are that in cases of persistent air leak following drain insertion or failure of the lung to re-expand, an early (3–5 days) thoracic surgical opinion should be sought. Other indications for thoracic surgical referral are given (Summary box 55.1).

Current recommendations focus on the use of small bore (10–14 Fr) chest drains, usually of a Seldinger-type inserted ideally under ultrasound guidance. However, knowledge of the role of the ‘surgical’ chest drain and how to safely insert it is still required.

**Inserting and managing a chest drain**

An intercostal tube connected to an underwater seal is central to the management of chest disease; however, the management of the pleura and of chest drains can be troublesome, even in experienced hands.

---

**Summary box 55.1**

**Indications for surgical intervention for pneumothorax**

- Second ipsilateral pneumothorax
- First contralateral pneumothorax
- Bilateral spontaneous pneumothorax
- Spontaneous haemothorax
- Professions at risk (e.g. pilots, divers)
- Pregnancy

---

**Figure 55.6** British Thoracic Society (BTS) guidelines on management of spontaneous pneumothorax [2010] (adapted from www.bts.org.uk).
The safest site for insertion of a drain (Figure 55.7) is in the triangle that lies:
- anterior to the mid-axillary line;
- above the level of the nipple;
- below and lateral to the pectoralis major muscle.

This will ideally find the fifth space. The technique includes the following:
- Meticulous attention to sterility throughout.
- Adequate local anaesthesia to include the pleura.
- Sharp dissection only to cut the skin.
- Blunt dissection with artery forceps down through the muscle layers; these should only be the serratus anterior and the intercostals.
- An oblique tract, so that the skin incision and the hole in the parietal pleura do not overlie each other and the drain is in a short tunnel, which reduces the chance of entraining air.
- A drain for pneumothorax and haemothorax should aim towards the apex of the lung. A drain for pleural effusion or empyema should be nearer to the base. The drain should pass over the upper edge of the rib to avoid the neurovascular bundle that lies beneath the rib.
- The retaining stitch should be secure, but not obliterate the drain.
- A vertical mattress suture is inserted for later wound closure. This is vital for pneumothorax management, but should be omitted if the drain is for empyema (provided there is adherence of the pleura) because that tract should lie open.
- Connect the drain to an underwater seal device which functions as a one-way valve.
- After completion, check that the drain has achieved its objective by taking a chest x-ray.

It is preferable not to apply suction to the drain or to clamp it. The danger is that the clamp may be applied for transport and forgotten. Dangers of disconnection and siphoning are small or best averted in other ways apart from clamping. A bubbling drain should (almost) never be clamped. Remove the drain when it no longer has a function (Summary box 55.2).

### Summary box 55.2

**Suction on a pleural tube**
- Beware! Inserting the drain, and not the suction, is the life-saving manoeuvre
- If the lung is reluctant to expand, the suction deviates the mediastinum
- If the lung is fragile, it may worsen an air leak

### Definitive management of pneumothorax

**Pleurectomy and pleurodesis**

Surgery for pneumothorax can be performed by video-assisted thoracoscopic surgery (VATS) or as an open procedure (thoracotomy).

The object of the exercise is three-fold:
- to deal with any leaks from the lung;
- to search for and obliterate any blebs and bullae (Bullectomy);
- to make the visceral pleura adherent to the parietal pleura so that any subsequent leaks are contained and the lung cannot completely collapse.

Pleural adhesion is achieved in one of three ways:
- **Pleurectomy**: systematically strip the parietal pleura from the chest wall.
- **Pleural abrasion**: a scouter is used to scrape off the slick surface of the parietal pleura.
- **Chemical pleurodesis**: usually talc is used and is insufflated into the chest cavity.

**Pleural effusion**

Pleural effusion can be readily understood with reference to the physiological mechanisms governing the flux of pleural fluid given above. Pleural effusions are divided into exudates and
transudates, depending on protein content (more (exudates) or less (transudates) than 30 g/L), and characterised further according to glucose content, pH and lactate dehydrogenase content. The following are the most common ways in which the pleural fluid balance is disturbed:

- **Elevated pulmonary capillary pressure.** If left atrial pressure rises, the pulmonary capillary pressure must rise with it, whether as a result of impaired cardiac performance or an overloaded circulation.
- **Reduced intravascular oncotic pressure.** If the plasma proteins fall because of renal or hepatic disease or malnutrition, the absorption mechanism fails.
- **Accumulation of pleural protein** due to obstruction of the mediastinal lymphatics secondary to lymphoma or cancers that invade the lymphatic system.
- **Excessive permeability of the capillaries to fluid and protein** as in inflammatory diseases, particularly the collagen vascular diseases. Of particular importance to the surgeon is the effusion associated with pleural infection (empyema) and malignant effusions.

### Malignant pleural effusion

Pleural effusion is a common complication of cancer. This may be due to:

- lung cancer;
- pleural involvement with primary or secondary malignancy;
- mediastinal lymphatic involvement.

- **Lung cancer.** There may be direct involvement of the parietal and/or visceral pleura, collapse of the lung parenchyma and spread to the mediastinal lymphatics, or a combination of these, causing pleural fluid accumulation. It is usually regarded as a feature that puts lung cancer beyond surgical cure.

- **Pleural malignancy.** The only primary malignancy of the pleura seen with any regularity is malignant mesothelioma. This is a consequence of asbestos exposure with few exceptions. The peak of asbestos imports into the UK was from 1960 to 1975 and the incidence of mesothelioma is rising and is expected to peak around 2015. Mesothelioma commonly presents with breathlessness because of pleural effusions, pain and systemic features of malignancy. Diffuse seeding of the parietal and visceral pleura is a common pattern of dissemination of cancers, particularly adenocarcinoma of any origin.

- **Mediastinal lymphatic involvement.** In many instances, particularly in breast cancer, there is no evident disease in the pleura. The disease is in the mediastinal lymphatics, which are obstructed, and this upsets the balance of physiological forces that control pleural fluid.

### Surgery for patients with malignant pleural effusion

The surgeon has two roles:

- to make the diagnosis;
- to achieve effective palliation by draining the fluid and pleurodesis.

### Diagnosis

Pleural biopsy can be obtained by a range of techniques with VATS being the most common. An unequivocally positive biopsy is useful but a negative biopsy may be a sampling error (Summary box 55.3).

#### Summary box 55.3

### Pleural infection and empyema

Empyema is the end stage of pleural infection from any cause. It most commonly results from infection of the underlying lung by pneumonia or lung abscess, but can occur as a complication of any thoracic operation. It is seen if a traumatic hemothorax becomes infected or in the course of management of pneumothorax or pleural effusions. It may be associated with pus under the diaphragm (Table 55.3). The pathological diagnosis requires the presence of thick pus with a thick cortex of fibrin and coagulum over the lung.

When empyema presents de novo it usually follows pneumonia and three phases are described:

1. In the exudative phase, there is protein-rich (>30 g/L) effusion. If this becomes infected with the organisms from the lung (typically *Streptococcus milleri* and *Haemophilus influenzae* in children), the scene is set for empyema. At this stage, antibiotics may be all that is required. Aspiration or drainage to dryness in addition is preferred.

2. Over the next days, the fluid thickens to what is known as the fibrinopurulent phase. Drainage at this stage is prudent as antibiotics may be all that is required. Aspiration or drainage to dryness in addition is preferred.

3. The organising phase causes the lung to be trapped by a thick peel or ‘cortex’ for which surgical management may be required.

---

Leon David Abrams, formerly cardiothoracic surgeon, The United Birmingham Hospitals, Birmingham, UK.
Surgical management of pleural effusions and infections

Thoracoscopy or video-assisted thoracoscopic surgery

The direct-vision thoracoscope has been used for many years, but its use was limited mainly to performing biopsies. The instrument had a limited view and was uncomfortable to use for any length of time. All this has changed since the advent of video-assisted thoracoscopy (Figure 55.8) where the surgeon’s hands are freed because the camera is attached to the thoracoscope, which can be operated by an assistant with the image displayed on a television screen. The surgeon is able to manipulate instruments with both hands to perform a variety of procedures. The number of ports required depends on the type and complexity of the surgery. The patient is usually positioned with the diseased side uppermost, having had a double lumen endotracheobronchial tube placed by the anaesthetist to allow for single-lung ventilation.

Pneumonectomy, lobectomy and empyema drainage are all possible. However, lung biopsy and the treatment of recurrent pneumothorax are the most frequent indications. The principal advantage is that a large incision is avoided resulting in less postoperative pain and a more rapid recovery.

VATS drainage, pleural biopsy and talc pleurodesis

VATS drainage, pleural biopsy and talc pleurodesis is an increasingly performed procedure for managing patients with an undiagnosed or malignant pleural effusion. It can be performed using a single or two ports and allows for direct visualisation of the pleural cavity for complete drainage, multiple pleural biopsies and excellent talc insufflation to achieve pleurodesis.

VATS debridement of empyema

Pleural infection, particularly early in its evolution, requires drainage but once the fluid component becomes fibrinopurulent and loculated it requires surgical debridement which can often be achieved through a VATS approach. The lung is isolated through the use of a double lumen tube, the patient is positioned disease side up, and the pleural cavity is entered. The fluid and debris are vigorously debrided, freeing the lung and allowing for re-expansion. At the end of the case, carefully positioned chest drains are placed to allow for dependent drainage. The drain/s must exit the skin anterior to the mid-axillary line otherwise the patient will have to lie on the drain(s), causing pain and possibly obstructing the tube. The drain should lie obliquely in its course through the skin and chest wall and into the pleura, or it will kink.

Following the procedure, the patient requires good analgesic control, typically patient controlled analgesia (PCA) and physiotherapy to help fully re-expand the lung prior to final removal of chest drains.

Decortication

If the lung fails to re-expand after drainage of the empyema, the more radical operation of decortication may be required (Figure 55.9). The fibrous cortex or peel from the entrapped underlying lung is removed so that the lung can expand to obliterate the pleural space. This is performed through a posterolateral thoracotomy and requires careful dissection to remove the parietal and visceral cortex, taking care not to damage the visceral pleura.

PRESENTATION OF LUNG DISEASE

Haemoptysis

Diseases causing repeated haemoptysis include carcinoma, bronchiectasis, carcinoid tumours and some infections. Severe mitral stenosis is now a rare cause. Patients with repeated haemoptysis should be investigated, at the very least by chest radiography and bronchoscopy. Haemoptysis following trauma may be from a lung contusion or injury to a major airway. Treatment depends on the underlying cause.

Common associated chest symptoms include cough with...
or without sputum, pain, breathlessness, hoarseness and more general symptoms of systemic upset, including fatigue and loss of weight. Occasionally, chest disease may cause palpitation due to atrial fibrillation. Any of these symptoms in association with haemoptysis requires urgent investigation.

**Investigation**

**Bronchoscopy**

Flexible bronchoscopy may be performed with the patient awake and the oropharynx anaesthetised with topical lignocaine (Figure 55.10). The bronchoscope is passed into the nose or mouth and through the vocal folds under direct vision. As the scope is flexible, its tip can be directed into the segmental bronchi with ease. Tissue and sputum samples may be obtained for diagnostic purposes. There is a greater range of movement with this instrument, but the biopsies are relatively small and suction limited.

Rigid bronchoscopy requires general anaesthesia in most instances. It is ideal for therapeutic manoeuvres, such as removal of foreign bodies, aspiration of blood and thick secretions, and intraluminal surgery (laser resection or stent placement). The surgeon and the anaesthetist share control of the airway. Continuous electrocardiography (ECG) and pulse oximetry monitoring are now essential. The technique involves the operator standing behind the patient and lifting the maxilla by the upper teeth, using the middle finger and forefinger of the left hand. The bronchoscope rests on the left thumb as it is introduced over the tongue in the midline. Care must be taken not to trap the lips or tongue between the teeth and the bronroscope, and the fulcrum should be the left thumb and not the teeth. The bronchoscope is passed under direct vision into the oropharynx, behind the epiglottis, until the vocal folds are seen. Turning the instrument through 90° will help to negotiate the vocal folds; only then should the neck be extended.

The tracheal rings and the carina should be easily seen. Advancing the bronchoscope into the right and left main bronchus reveals the orifices of the more peripheral bronchi. Operability of an endobronchial tumour may be assessed in terms of its location (e.g. the proximity of a lesion to the carina). Complications are rare, but include bleeding, pneumothorax, laryngospasm and arrhythmia (Summary box 55.4).

Other techniques of biopsy of intrathoracic lesions are often necessary to confirm diagnosis, stage disease and plan treatment. The options range from percutaneous needle biopsy under radiological control, endobronchial ultrasound, to open-lung biopsy. However, high-quality, contrast-enhanced, multi-slice helical CT scanning will reduce the requirement for invasive assessment (Table 55.4).

**Airway obstruction**

Tracheal obstruction may present acutely as a life-threatening emergency or insidiously with little in the way of symptoms until critical narrowing and stridor occur. The more common causes of airway narrowing are outlined in Table 55.5.

**Table 55.5 Causes of airway narrowing.**

</tbody>
</table>
Treatment depends on the underlying cause. Tracheostomy may be required to overcome the obstruction, but there are few indications to do this as an emergency. Tracheal replacement with artificial substitutes has so far been unsuccessful, but resection of up to 6 cm of trachea is now possible. Sleeve resections of the major bronchi are also possible.

**Inhaled foreign bodies**

This is a fairly common occurrence in small children and is often marked by a choking incident that then apparently passes. Surprisingly large objects can be inhaled and become lodged in the wider calibre and more vertically placed right main bronchus. There are three possible presentations:

1. asymptomatic;
2. wheezing (from airway narrowing) with a persistent cough and signs of obstructive emphysema;
3. pyrexia with a productive cough from pulmonary suppuration.

A chest x-ray is vital; even if the object is not radio-opaque, there may be other changes. An experienced anaesthetist is required. The procedure may be very difficult if there is a severe inflammatory reaction.

**MALIGNANT LUNG TUMOURS**

**Primary lung cancer**

Lung cancer is one of the most common cancers throughout the world. In the UK, there are 40,000 cases a year, making it the most common cause of cancer death. From the time of diagnosis, 80 per cent of patients are dead within one year and only 5 per cent survive for five years.

Surgical resection has a limited role in curative treatment because at the time of presentation many cases are locally advanced or widely disseminated and are beyond surgical cure. The proportion of lung cancers in which resection is attempted varies from fewer than 10 per cent in the UK to about 25 per cent in the United States. However, the thoracic surgeon working in a cancer team has a role in diagnosis, staging and palliation apart from resection in appropriate cases. The disease is so common that surgeons of all disciplines will encounter cases of lung cancer presenting with various manifestations.

Cigarette smoking is undoubtedly the major risk factor for developing bronchial carcinoma and accounts for 85–95 per cent of all cases. To a lesser extent, atmospheric pollution and certain occupations (radioactive ore and chromium mining) contribute. The risk is related to the lifetime burden of cigarette smoking, which is commonly quoted as ‘pack-years’ (a ‘pack’ being 20 cigarettes): the number of packs smoked per day multiplied by the number of years of exposure. In the UK, the mortality rate from lung cancer for individuals smoking more than 40 cigarettes per day is over 210 deaths per 100,000 population per year. This compares with a mortality rate of less than four deaths per 100,000 population per year in non-smokers.

**Pathological types**

For practical purposes, lung cancers are divided into small cell and non-small cell lung cancer (NSCLC), which are seen in a ratio of about 1:4:

- The pattern of disease, the prognosis and the results of treatment for small cell (also known as oat cell) carcinoma differ from all other types sufficiently for these to be managed differently from the onset on the basis of the histological classification.
- Subdivisions of NSCLC according to histological characteristics are much less important, but pathological staging is critical to treatment and outcome.

**Histological classification of lung cancer**

- **Small cell lung cancers** were known as oat cell cancers because of the packed nature of small dense cells. These represent about 20 per cent of all lung cancer. They tend to metastasise early to lymph nodes and by blood-borne spread. The median survival is measured in months. The tumours are very responsive to chemotherapy such that median survival may be doubled (but is still short), but they are rarely, if ever, cured. Surgery is rarely offered unless in very limited stage disease.

- **Adenocarcinoma** is now the most common of the NSCLC types, having overtaken squamous cancer. The increasing incidence is partly due to an increasing incidence in women and may be the result, in part, of a move towards lower-tar cigarettes that are inhaled more deeply to get the same effect.

- **Squamous carcinoma** typically appears as a cavitating tumour.

- **Large cell undifferentiated** is a discrete histological type of NSCLC and is included within neuroendocrine tumours.

- **Bronchioalveolar carcinoma** has a distinct pattern of growth following the pre-existing pulmonary architecture and is thus much less dense; it appears as a patchy diffuse shadow (‘ground glass’) on the radiograph, rather than a solid mass and has a histological appearance to match. After resection, it can appear in another lobe or the other side.

Accurate diagnosis and staging of the tumour are vital if surgery is to be considered.

**Clinical features**

Clinical features of lung carcinoma depend on:

- the site of the lesion;
- the invasion of neighbouring structures;
- the extent of metastases.

Common symptoms include a persistent cough, weight loss, dyspnoea and non-specific chest pain.

- Haemoptysis occurs in fewer than 50 per cent of patients presenting for the first time.
- Cough, or a changed cough, is a common presentation but non-specific in this population.
- Severe localised pain suggests chest wall invasion with the infiltration of an intercostal nerve. Invasion of the apical area may involve the brachial plexus, leading to Pancoast’s syndrome.
- Dyspnoea may come from loss of functioning lung tissue, lymphatic invasion or the development of a large pleural effusion.
- Pleural fluid is an ominous feature and the presence of blood in a pleural effusion suggests that the pleura has been directly invaded.
- Clubbing (Figure 55.11) and hypertrophic pulmonary osteoarthropathy accompany some lung cancers and may resolve with excision of the primary lesion.
- Invasion of the mediastinum may result in hoarseness (because of recurrent laryngeal nerve involvement), dysphagia...
(because of the involvement of, or extrinsic pressure on, the oesophagus) and superior vena caval obstruction.

- Small cell carcinoma is associated with the development of myopathies including the Eaton–Lambert syndrome, which is similar to myasthenia gravis (Summary box 55.5).

- Clubbing
- Hoarseness
- Myopathies

**Treatment of lung cancer**

Careful investigation is required to determine which tumours are operable and will benefit from a major thoracic resection. The internationally agreed tumour–node–metastasis (TNM) staging system gives prognostic information on the natural history of the disease. Tumours graded up to T3, N1, M0 can be encompassed within an anatomical surgical resection and have a much improved prognosis when treated surgically, so the tumour must be staged accurately before resection (Table 55.6). A number of non-tumour factors, including the general fitness of the patient and the results of lung function tests, help to determine the appropriate treatment. In patients with incurable disease, treatment is palliative to maximise quality of life and disease-free survival.

**Survival**

Carcinoma of the bronchus generally has a low survival rate after diagnosis (Table 55.7). Important factors in determining

prognosis are the histological type of the tumour, the spread (stage) and the general condition of the patient. Early detection and surgical resection offer the best hope for cure.

**Diagnosis and staging**
Increasing emphasis in recent years has been the early detection of lung cancer, with guidance on symptoms and signs of potential lung cancer that require urgent chest x-ray and referral to lung cancer team (Table 55.8).

**Non-invasive investigations**

**Chest x-ray**
A chest x-ray will detect most lung cancers but some, particularly early curable tumours, are hidden by other structures. Secondary effects such as pleural effusion, distal collapse and raised hemidiaphragm may be evident (Figure 55.12).

**Computed tomography**
This is the first investigation in suspected lung cancer. The surgeon needs to know if the primary is resectable (T stage) and which if any lymph nodes are involved (N stage). Lymph nodes of

more than 2 cm in diameter are likely to be involved in the disease (70 per cent) (Figure 55.13) and those less than 10 mm in the shorter axis are unlikely to be involved. If the presence of cancer in the nodes is critical to management, further evidence from positron emission tomography with radiolabelled fluorodeoxyglucose (FDG-PET) or biopsy (see below) is essential. Remote metastases to the liver, adrenals or elsewhere may be detected.

**Positron emission tomography**
The patient is given radiolabelled FDG, which is taken up by all metabolising cells but more avidly by cancer cells. The FDG enters the Kreb’s cycle but cannot complete it and accumulates in proportion to the glucose avidity of the cells. High accumulation is associated with lung cancers and secondaries. Infection or other inflammation, and lymphadenopathy secondary to it, are also FDG avid (Figure 55.14).

**Sputum cytology**
Sputum cytology may reveal malignant cells, but the false-negative rate is high.

**Invasive investigations**
Once lung cancer is suspected, diagnosis and further staging are sought. The choice of investigation depends on the position of the primary tumour in the lung (peripheral or central) and the clinical stage of the cancer (presence of enlarged lymph nodes or metastasis).

**Bronchoscopy**
A flexible bronchoscopy is usually performed under sedation particularly in more centrally placed lung cancers. It allows assessment of the segmental airway, cytological testing through brushing and washing of the concerned segmental bronchi and transbronchial needle aspiration (TBNA).

**Endobronchial ultrasound**
Endobronchial ultrasound (EBUS) allows bronchoscopic assessment of suspicious mediasternal lymph nodes with an ultrasound probe incorporated into the tip of the bronchoscope to aid TBNA (Figure 55.15). Endoscopic ultrasound (EUS) is a similar technique that by passing down the oesophagus allows fine needle aspiration (FNA) of less approachable mediastinal lymph nodes.

**Computed tomography-guided biopsy**
Percutaneous CT-guided FNA may give a good yield of cells for cytological examination. Alternatively, a core of tissue can be obtained for formal histology. These techniques are best for larger and more peripheral lesions. Pneumothorax is common (30 per cent), but rarely requires intercostal tube drainage. The contraindications include poor respiratory reserve when even a small pneumothorax would be hazardous.

**Surgical diagnosis and staging**
Mediastinoscopy, mediastinotomy, VATS or thoracotomy lymph node/lung biopsy are aimed at establishing a tissue...
Malignant lung tumours

863
diagnosis and assessing the degree of spread (staging), which determines resectability. Histological proof of the status of mediastinal nodes may be important to avoid unnecessary thoracotomy for incurable cancers and, conversely, to not deny surgery to patients whose lymph nodes are enlarged but benign.

Mediastinoscopy

This procedure is performed under general anaesthesia with the patient supine and his or her neck extended (Figure 55.16). A transverse incision is made 2 cm above the sternal notch and deepened until the strap muscles are reached. These are retracted laterally and the thyroid isthmus is retracted superiorly to reveal the pretracheal fascia. Careful blunt dissection in this plane allows access to the paratracheal and subcarinal nodes. A mediastinoscope is introduced for direct visualisation and biopsy. Great caution should be used in the presence of superior vena cavae obstruction. Complications include pneumothorax and haemorrhage.

Mediastinotomy

An incision is made through the second intercostal space to gain access to some of the mediastinal lymph nodes on the affected side. On the left, this includes lymph nodes in the para-aortic or sub-aortic fossa. Damage to the internal mammary artery and the phrenic nerve must be avoided. Mediastinal extension of tumour can also be assessed, for example left upper lobe tumours which invade the mediastinum around the aortic arch.

These techniques may also be used in the diagnosis of other mediastinal conditions, including:

- lymphoma;
- anterior mediastinal tumours;
- thymoma;
- sarcoid, tuberculosis or any other cause of lymphadenopathy.

VATS mediastinal lymph node and lung biopsy

For inaccessible mediastinal lymph nodes, or when diagnosis of the lung tumour has not been possible through radiological or bronchoscopic techniques, VATS performed through two or three ports allows diagnosis of the tumour, staging of the mediastinum and gives the opportunity to assess the likely operability of the lung cancer.

Surgical approach to lung cancer resection

Thoracotomy

Although the most frequent reason for thoracotomy is lung cancer, all surgeons dealing with trauma should be able to perform a thoracotomy, if required. The standard route into the thoracic cavity is through a posterolateral thoracotomy. The incision is used for access to the:

- lung and major bronchi;
- pleura;
- thoracic aorta;
- oesophagus;
- posterior mediastinum.

A double-lumen endotracheal tube is used to allow ventilation of one lung while the other is collapsed, to facilitate surgery and to protect the non-operated lung and retain control of ventilation (Figure 55.17).

Sir Hans Adolf Krebs, 1900–1981, Professor of Biochemistry, The University of Oxford, Oxford, UK. Was elected as a Fellow of the Royal Society of London in 1947, he is known best for identification of the urea cycle and the citric acid cycle. The latter known as the Kreb’s cycle, earned him a share of the Nobel Prize in Physiology or Medicine in 1953.
The patient is turned to the lateral position with the affected side up (Figure 55.18). The lower leg is flexed at the hip and the knee, with a pillow between the legs. Table supports are used to maintain the position and additional strapping is used at the hips for stability. The patient’s hips are placed below the break point of the operating table to allow opening of the intercostal spaces as the table is angulated. The upper arm may be supported by a bracket in a position of 90° flexion. The lower arm is flexed and positioned by the head. It is important for both the surgeon and the anaesthetist to be completely satisfied with the position of the patient and the tube and lines at this stage.

- The incision passes 1–2 cm below the tip of the scapula, and extends posteriorly and superiorly between the medial border of the scapula and the spine.
- The incision is deepened through the subcutaneous tissues to the latissimus dorsi. This muscle is divided with coagulating diathermy, taking care over haemostasis.
- A plane of dissection is developed by hand deep to the scapula and serratus anterior. The ribs can be counted down from the highest palpable rib (which is usually the second) and the sixth rib periosteum is scored with the diathermy near its upper border. A periosteal elevator is used to lift the periosteum off the superior border of the rib or alternatively the intercostal muscle is cut with diathermy just above the rib (Figure 55.19).
- This reveals the pleura, which may be entered by blunt dissection. A rib spreader is inserted between the ribs and opened gently to prevent fracture.
- Exposure may be facilitated by dividing the rib at the costal angle or by dividing the costotransverse ligament. Resection of a rib is not usually required.
- The anaesthetist is now able to deflate the affected lung to allow a better view of the intrathoracic structures.

In an emergency thoracotomy for penetrating wounds of the heart, a more anterior approach is used and no specialised supporting equipment is required (Figure 55.20). The incision is taken down to the fourth or fifth rib with a scalpel, and using scissors the pleural cavity opened. This gives rapid access to the left pleural cavity in cases of massive left haemothorax and the pericardium if cardiac tamponade is suspected. A left anterior thoracotomy can be quickly converted to a clamshell or bilateral thoracotomy if necessary.

---

**Figure 55.18** Correct positioning for thoracotomy.

**Figure 55.19** Incision and layers encountered during anterolateral thoracotomy. A The latissimus dorsi is divided in line with the skin incision. B If the serratus anterior is divided, it should be close to its attachment to ribs 6, 7 and 8. It can be left intact and mobilised along its inferior border. C The intercostal muscles are stripped off the upper border of the rib.

**Figure 55.20** Emergency left anterior thoracotomy for access to the heart. Requires no special supports or devices.
Surgical management of lung cancer

The principle of surgery is to remove all cancer (the primary and the regional lymph nodes), but to conserve as much lung as possible. The selection of patients in terms of the stage of the lung cancer and fitness to undergo such surgery is paramount. Surgery with curative intent is offered to patients with early stage lung cancer (T1–3, N0–1) (Table 55.9). Assessment of a patient’s fitness to undergo lung cancer resection involves considering premorbid conditions which can be aided using risk scores such as Thorascore, cardiovascular function and lung function (Table 55.10). Lung function particularly will aid the surgeon in selecting the type of procedure offered and likely breathlessness or dyspnoea following lung resection.

Table 55.10 National Institute for Health and Clinical Excellence (NICE) recommendations for assessing fitness for treatment with curative intent (including surgery).

- Cardiovascular function
  - Assess risk factors and cardiac functional capacity
  - Seek cardiology review if active cardiac condition, three or more risk factors or poor cardiac functional capacity
  - Consider revascularisation before surgery in stable angina
  - Continue anti-thrombotic therapy as soon as possible
  - Discus perioperative platelet treatment if patient has a coronary stent

- Lung function
  - Perform spirometry, measure T1CO if disproportionate breathlessness or other lung pathology, perform segment count and assess exercise tolerance, and consider shuttle walk testing (cut-off 400 m) and cardiopulmonary exercise testing (cut-off 1.5 mL/kg/minute) if moderate to high risk of postoperative dyspnoea
  - Offer surgery if normal FEV1 or FEV1/T1CO below 30% and patient accepts the risks of dyspnoea
  - Offer radiotherapy with curative intent if lung function poor but patient is otherwise suitable for radiotherapy with curative intent and volume of irradiated lung is small

**Choice of lung resection**

**Segmentectomy and wedge resection**

Segmentectomy and wedge resections are performed in patients with small tumours and with borderline fitness through thoracotomy or VATS. Each lobe of the lung has segments which allows anatomical dissection and ligation of the segmental pulmonary artery, vein and bronchus (segmentectomy) (Figure 55.2) or non-anatomical excision can be performed (wedge resection) combined with removal of regional lymph nodes.

**Lobectomy**

Lobectomy remains the treatment of choice in patients with early stage lung cancer. The surgery can be performed via thoracotomy or VATS. Following dissection of the fissure and hilar structures, the branches of the pulmonary artery and veins to the lobe are isolated and ligated. The bronchus is usually stapled but can be sewn.

At the completion of the operation, the remaining lung is reinflated. Some air leak is common and usually settles within a few days. One or two intercostal drains are inserted. The patient does not routinely need intensive care and postoperative ventilation is best avoided. The 30-day mortality rate is 2–3 per cent, with morbidity such as chest infection or cardiac arrhythmia of around 10 per cent. The average length of stay is around 5–7 days.

**Pneumonectomy**

Pneumonectomy is removal of a whole lung and has a higher mortality rate (5–8 per cent). The surgeon must be satisfied that the patient is fit to tolerate this procedure from the preoperative work up. This procedure is reserved for either centrally placed tumours involving the main bronchus or those that straddle the fissure. At thoracotomy, an inspection of the lung and direct palpation of the mass will determine resectability and lymph node spread. Fixation of the tumour to the aorta, heart or oesophagus implies irresectability. Involvement of the mediastinal lymph node chain is associated with a poor prognosis. With modern preoperative imaging, resection is abandoned in only about 3 per cent of cases.

Pneumonectomy is anatomically more straightforward than lobectomy and involves dissecting and ligating the main pulmonary artery, the superior and inferior pulmonary veins and the main bronchus which is divided so that no blind stump remains (Figure 55.21). The technique of stump closure is important if a bronchopleural fistula is to be avoided. The tissues are carefully handled and the stump is usually stapled and sometimes covered using pleural, pericardium or a vascular pedicle such as an intercostal muscle. Drainage of the space is a matter of debate. Most use an underwater-seal drain and either leave it unclamped or unclamp it for 1 minute every hour until the drainage ceases; others prefer not to drain. The critical point is that no suction should be applied as there is now a sealed space with the mobile mediastinum on one side of it. The air in the pneumonectomy space is gradually absorbed and the fluid level within the space rises (Figure 55.22).

**Complications of lung resection**

- **Bleeding.** Bleeding should be avoidable by the use of a careful surgical technique, but may be severe in the presence of dense adhesions.
- **Respiratory infection.** Many of these patients are ex-smokers and so basal collapse and hypoxaemia are common postoperatively.
- **Persistent air leak.** Chest drains are placed at the time of surgery to deal with the air leak. Rarely, the air leak persists and the remaining lung does not expand. Repeat thoracotomy may then be necessary to seal the leak.
- **Bronchopleural fistula.** Bronchopleural fistula is a serious complication. Following pneumonectomy, the space left behind is initially filled with air. This is slowly reabsorbed and the space fills with tissue fluid. The fluid level rises until the air is finally reabsorbed. Dehiscence of the bronchial stump leads to the development of a bronchopleural fistula and the fluid in the space (which is almost inevitably infected) is expectorated in large quantities. This complication has a high morbidity and mortality rate.

---

**Figure 55.21** Mediastinal structures after removal of right lung.
The patient is nursed sitting up and turned so that the affected space is dependent, to prevent infected fluid from entering the remaining lung while arrangements are made to site a pleural drain. This should be connected to an underwater seal, but not suction. Bronchopleural fistulas are unlikely to resolve spontaneously and management is highly specialised.

**Postoperative care**

Patients have limited respiratory reserve following lung resection, so infection and fluid overload are to be avoided. Once air leaks have settled, the drains are removed. Mobilisation, breathing exercises and regular physiotherapy are begun as soon as the patient’s condition permits.

**Postoperative pain**

It is important to deal with post-thoracotomy pain effectively so that a normal breathing pattern and gas exchange are achieved in the early postoperative period. Three strategies are routinely used in combination:

- patient-controlled analgesia (PCA) with intravenous boluses of opiates;
- paravertebral/extrapleural or epidural catheter-delivered local anaesthetic;
- background oral analgesia with paracetamol.

Long-term post-thoracotomy pain can be reduced by careful attention to detail during the operation. Sources of avoidable chronic pain include rib fracture and the entrapment of intercostal nerves during wound closure.

### BENIGN LUNG TUMOURS

Benign tumours of the lung are uncommon and account for fewer than 15 per cent of solitary lesions seen on chest x-rays. A peripheral tumour usually causes no symptoms until it is large; a central tumour may present with haemoptysis and signs of bronchial obstruction while small. A tumour is likely to be benign if it has not increased in size on chest x-rays for more than two years or it has some degree of calcification; however, a tissue diagnosis is usually pursued.

Most benign nodules are granulomas (tuberculosis or histoplasmosis). The most common benign tumour is a hamartoma, a developmental abnormality containing mesothelial and endothelial elements. Diagnosis (and definitive treatment) is achieved by excision of the lesion. Any of the mesodermal elements of the lung may form a mesodermal tumour (chondroma, lipoma, leiomyoma). Deposits of amyloid may give similar radiographic appearances of a nodule (pseudotumour).

**Bronchopulmonary carcinoid tumours**

These carcinoid tumours are derived from the neuroendocrine cells of bronchial glands. Most (80 per cent) are found in the major bronchi and are characteristically slow growing and highly vascular. They are currently classified within a spectrum of neuroendocrine tumours. Most behave in a benign way; however, approximately 15 per cent metastasise. The patient often presents with a history of recurrent pneumonia or haemoptysis, but carcinoid syndrome is rare unless there is extensive pulmonary or hepatic metastases. Surgical excision is preferred as prognosis following complete resection is excellent (>90 per cent ten-year survival). Segmental or wedge resection may be sufficient for
a small peripheral tumour, while lobectomy or pneumonectomy may be necessary for central tumours. Where possible, a lung-sparing bronchoplastic or sleeve resection should be considered. This allows resection of proximal endobronchial lesions in an effort to preserve more distal, uninvolved lung parenchyma.

**The Mediastinum**

The mediastinum refers to the central area in the chest between the thoracic inlet and the diaphragm, between the right and left pleural surfaces and which extends from the inner aspect of the sternum to the vertebral column. It contains the heart, great vessels, trachea and the oesophagus, and is arbitrarily subdivided into compartments (superior, inferior, anterior, middle and posterior). Much of the regional lymph node chains draining the chest and its organs are also found in the mediastinum. Various surgical procedures to approach structures and particularly lymph nodes in the mediastinum have been described earlier under Surgical diagnosis and staging, and are performed usually as diagnostic procedures. The surgical approach when mediastinal tumours require resection depends on the anatomical location of the tumour (Figure 55.23) and includes median sternotomy for anterior mediastinal pathology, thoracotomy or VATS for posterior mediastinal pathology and transcervical (neck incisions) for superior mediastinal pathology. The middle mediastinum can usually be approached through thoracotomy or VATS.

**Primary Tumours of the Mediastinum**

Thymoma, neurogenic tumours, germ cell tumours and lymphoma are the usual primary tumours of the mediastinum.

- **Thymoma.** This is the most common mediastinal tumour, accounting for 25 per cent of the total and is derived from the thymus gland (Figure 55.24). Thymomas vary in behaviour from benign to aggressively invasive as reflected in the Masaoka classification system used to stage thymomas (Table 55.11). They are often related to myasthenia gravis (MG), a neuromuscular condition which can have a high associated incidence of thymomas, and interestingly may respond to excision of the thymus gland even when the gland has no associated thymoma present. The only reliable indicator of malignancy is capsular invasion. Diagnosis and treatment are best achieved by complete thymectomy, which is usually performed as a median sternotomy. However, if the thymoma is small or when the patient has MG and the thymus is being excised as a treatment, a transcervical approach with or without an additional VATS procedure can be performed.

After Masaoka A et al., Cancer 1981; 48:2485.

- **Germ Cell Tumour.** The anterior mediastinum is the most common site of extragonadal germ cell tumours. They account for 13 per cent of all mediastinal masses and cysts and contain elements from all three cell types (mesoderm, endoderm and ectoderm). They tend to present in young adults and 75 per cent are benign and cystic, although they may cause compression of neighbouring structures; hence, dermoid cysts are best excised. Malignancy is suspected if elevated levels of serum alpha-fetoprotein, human chorionic gonadotrophin and carcinoembryonic antigen are detected. After initial treatment with chemotherapy, a patient with tumour marker normalisation and a persistent mass on CT may be considered...
Medical conditions for which surgery may be required

for surgical resection. If tumour markers fail to normalise, further chemotherapy is usually offered.

- **Lymphoma.** Lymphoma is a common cause of a mediastinal mass lesion, particularly the anterior mediastinum, and can lead to superior vena cava obstruction or other symptoms of local compression. The main treatment is chemotherapy, and surgery is rarely required apart from obtaining tissue for diagnosis.

- **Mesenchymal tumours.** Lipomas are common in the anterior mediastinum. Other mesenchymal tumours are very rare.

- **Thyroid.** Ectopic thyroid tissue (and parathyroid) may be found in the anterior mediastinum, but usually the mass is an extension of a thyroid lesion (retrosternal goitre). Excision of retrosternal thyroids may be required if there is local airway compression and stridor and can be performed via a transcervical incision, but occasionally median sternotomy may be required.

- **Neurogenic tumours.** These may derive from the sympathetic nervous system or the peripheral nerves and are more prevalent in the posterior mediastinum. They may be painful but are more often discovered accidentally on routine chest radiography and can be quite large (Figure 55.25). They include neuroblastoma in childhood, and schwannomas and neurofibromas in adults, which are usually benign. Phaeochromocytoma arises from the sympathetic chain and produces the characteristic endocrine syndrome. Excision of neurogenic tumours is generally recommended particularly if the patient is developing symptoms. This can be performed through a thoracotomy, though for smaller tumours a VATS approach can be used (Figure 55.26).

- **Enlarged mediastinal lymph nodes** are commonly involved by metastatic tumour mimicking a primary mediastinal lesion. Symptoms are generally secondary to compression or invasion of a structure within the mediastinum. Surgery, such as mediastinoscopy, is reserved for diagnosis only.

Other conditions of the mediastinum

Many of the primary tumours, such as neurogenic tumours and germ cell tumours, can present as cysts or have a cystic quality. In addition, the mediastinum can contain other cysts often with an embryological aetiology. Thymic cysts, pericardial cysts, bronchogenic and foregut cysts can all present asymptomatically or with local compression (Figure 55.27). Surgical excision is recommended if diagnosis is unclear or the patient has symptoms.

**MEDICAL CONDITIONS FOR WHICH SURGERY MAY BE REQUIRED**

**Bronchiectasis**

Bronchiectasis is chronic irreversible dilatation of the medium-sized bronchi, which may occur following a suppurative pneumonia or bronchial obstruction. It is the pathological end-stage of a range of conditions. If generalised, it is almost never considered for surgical resection. Cases caused by whooping cough and measles are decreasing in frequency in developed countries.

**Treatment**

Removal of the bronchiectatic part of the lung for symptoms of bleeding, recurrent infection or copious symptoms can be very effective when the disease is localised.
Lung abscess
The causes of lung abscess are shown in Table 55.12. The chest radiograph shows a cavity with a fluid level or, in mycetoma, a fungal ball. Most acute abscesses resolve with appropriate antibiotic therapy and postural drainage. Surgery is avoided. Small radiologically sited drains are sometimes used in the intensive care unit.

Tuberculosis
Surgery is rarely indicated for tuberculosis in developed countries but, when it is, it must be combined with adequate antitubercular chemotherapy or the benefit of surgery will be lost (Summary box 55.6).

Summary box 55.6

Tuberculosis: indications for surgery
- Suspicious lesion on chest radiograph in which neoplasia cannot be excluded
- Chronic tuberculous abscess, resistant to chemotherapy
- Aspergilloma within a tuberculous cavity
- Life-threatening haemoptysis

Diagnosis
Surgical procedures may be necessary to establish the diagnosis if suspected clinically, but sputum or pus cultures are persistently negative.

Complications, such as an aspergilloma in a chronic cavity causing life-threatening haemoptysis, may require lobectomy.

Pulmonary sequestration
This describes a section of non-functional lung separated from the normal bronchial connection with other abnormalities of development, which often include a direct systemic arterial supply from the aorta. Venous return is to the pulmonary veins in the majority of cases. The segment becomes cystic and infected, resulting in the common appearance of a solid lung mass that may be homogenous or heterogenous, occasionally with cystic changes on CT scan. Interlobar sequestration occurs within the lung substance. It may present with recurrent chest infections and/or haemoptysis. Patients with extralobar sequestration are usually asymptomatic as air spaces are not present, and therefore usually present as an incidental finding.

Lung cysts
Developmental lung cysts have a tendency to become infected. Acquired lung cysts may contain air or fluid and may be single or multiple. Pulmonary hydatid disease is a cause in endemic areas. Air cysts (bullae) may be spontaneous, but may be secondary to emphysematous degeneration (Figure 55.28).

LUNG TRANSPLANTATION
Lung transplantation is an established therapy for those with end-stage parenchymal or pulmonary vascular disease, which is limited by the number of donor lungs available.

CHEST TRAUMA
The approach to trauma must be methodical and exact, because the signs, particularly in the presence of other injury, may easily be missed. The general principles of resuscitation and ATLS (advanced trauma and life support) must be followed.

Thoracic trauma is responsible for over 70 per cent of all deaths following road traffic accidents. Blunt trauma to the chest in isolation is fatal in 10 per cent of cases, rising to 30 per cent if other injuries are present. The indications for emergency room thoracotomy in blunt chest trauma include massive haemothorax,
suspected cardiac tamponade and witnessed cardiac arrest in the resuscitation area. Success rates are low. Penetrating thoracic wounds vary according to the prevalence of civil violence, with a mortality rate of 3 per cent for simple stabbing to 15 per cent for gunshot wounds. The indications for emergency room thoracotomy are similar to blunt chest trauma. The standard approach is a left anterior thoracotomy, unless the penetrating injury is in the right chest, however it may be necessary to extend the incision to bilateral thoracotomies or a clam-shell incision.

Early deaths after thoracic trauma are caused by hypoxaemia, hypovolaemia and tamponade. The first steps in treating such patients should be to diagnose and treat these problems as early as possible because they may be readily corrected. Young patients have a large physiological reserve, and serious injury may be overlooked until this reserve is used up, by which time the situation is critical and may be irreversible. The best approach is to remain highly suspicious if life-threatening conditions are to be anticipated and treated. Early consultation with a regional thoracic centre is advised in cases of doubt. In an emergency, it is essential that experienced help is summoned.

Management of chest trauma is covered in detail in Chapter 28.

**THE DIAPHRAGM**

The diaphragm is the fibromuscular structure separating the thorax from the abdomen (Figure 55.29).

**Diaphragmatic disorders**

Disorders of the diaphragm can be broadly classified as disorders of innervation, leading to paralysis of the diaphragm, with elevation and reduction of thoracic volume leading to breathlessness; or disorders of anatomy, which are further categorised into congenital diaphragmatic hernias or acquired hernias usually secondary to trauma. There are two well recognised congenital sites where abdominal viscera can herniate into the chest (Figure 55.30):

- **The foramen of Morgagni.** A hernia in the anterior part of the diaphragm with a defect between the sternal and costal attachments. The most commonly involved viscus is the transverse colon.
- **The foramen of Bochdalek.** Through the dome of the diaphragm posteriorly.

Traumatic rupture of the diaphragm may occur with blunt trauma. Unless there is severe bleeding or strangulation of the viscera it is best managed at an interval. In a severely injured patient being ventilated, it can wait until other injuries are dealt with and weaning from the ventilator is being considered.

When the diaphragm is breached as in anatomical disorders, repair with either primary closure or with a mesh is usually possible via a thoracotomy. Diaphragmatic paralysis, particularly idiopathic unilateral paralysis can be plicated returning the diaphragm to a lower position and improving thoracic volume.

**THE CHEST WALL**

**Tumours of the chest wall**

These can be tumours of any component of the chest wall, i.e. bone, cartilage and soft tissue. They are treated similarly to those that occur in other sites and require specialist surgical input only if major resection and chest wall reconstruction are contemplated.

**Other diseases of the chest wall**

Congenital abnormalities are often incidental findings on chest x-ray (bifid rib), but there are some important exceptions.
Cervical rib and thoracic outlet syndrome

This rib is usually represented by a fibrous band originating from the seventh cervical vertebra and inserting onto the first thoracic rib. It may be asymptomatic, but because the subclavian artery and brachial plexus course over it, a variety of symptoms may occur. The lower trunk of the plexus (mainly T1) is compressed, leading to wasting of the interossei and altered sensation in the T1 distribution. Compression of the subclavian artery may result in a post-stenotic dilatation with thrombus and embolus formation. The diagnosis, assessment and surgery are fraught with uncertainties and are best left to those with a well-developed interest in this problem.

Pectus excavatum

The sternum is depressed, with a dish-shaped deformity of the anterior portions of the ribs on one or both sides. It is never a cause of respiratory problems. It can be repaired to improve its cosmetic appearance either as an open procedure (the Ravitch procedure) which involves resecting the affected costal cartilages and mobilising the sternum, or as a minimally invasive technique, the Nuss procedure. A metal bar is paced behind the sternum to hold this central panel in its new position and has to be removed after a period of time (Figure 55.31a,b).

Pectus carinatum (pigeon chest)

In this condition, the sternum is elevated above the level of the ribs and treatment is offered for cosmetic reasons. The sternum is mobilised and allowed to fall back into place.

It often comes to light during the growth spurt at adolescence when, of course, the teenager is particularly sensitive about appearance. Most patients are asymptomatic and the only

Figure 55.30 Chest x-ray of congenital diaphragmatic hernia. (a) Colon occupying a Morgagni hernia (courtesy of Dr Oliver Smith, Birmingham, UK). (b) Foramen of Bochdalek hernia on the left side in an infant. The left pleural cavity is occupied by intestine, the mediastinum is displaced to the right and the right lung is aerated very little.

Figure 55.31 (a) Insertion of preformed bar placed thoracoscopically beneath the pectus excavatum. (b) Chest x-ray following insertion of a metal bar bracing the sternum forward (the Nuss procedure).
Further reading

cojustification for treatment is on cosmetic grounds. Some surgeons make a very good case for this, but the risk of morbidity and of a less than perfect result must be clearly spelt out to the patients and their parents. Surgery involves mobilising the sternum with the costal cartilages so that the sternum can be flattened to a more anatomical position. Surgery is best left until the late teens, when further growth of the chest wall is unlikely.

Arterial disorders

LEARNING OBJECTIVES

To understand:
- The nature and associated features of occlusive arterial disease
- The investigation and treatment options for occlusive arterial disease
- The principles of management of the severely ischaemic limb
- The nature and presentation of aneurysmal disease, particularly of the abdominal aorta
- The investigation and treatment options for aneurysmal disease
- The arteritides and vasospastic disorders

INTRODUCTION

Arterial disorders represent the most common cause of morbidity and death in Western societies. Much of this is due to the effects of atheroma on the arteries supplying the heart muscle (coronary thrombosis and myocardial infarction) and brain (stroke), although atheroma is also common at other sites. This chapter addresses diseases that are typically the province of the vascular surgeon, namely those affecting the arteries of the body, excluding those of the heart and those within the cranium.

ARTERIAL STENOSIS AND OCCLUSION

Cause and effect

Arterial stenosis or occlusion is commonly caused by atheroma, but can occur acutely as a result of emboli or trauma. Stenosis or occlusion produces symptoms and signs that are related to the organ supplied by the artery: e.g. lower limb (claudication, rest pain and gangrene); brain (transient ischaemic attacks and stroke); myocardium (angina and myocardial infarction); kidney (hypertension and renal failure) (Figure 56.1); intestine (abdominal pain and infarction). The severity of the symptoms is related to the size of the vessel occluded and whether the stenosis or occlusion occurs suddenly (acute) in a previously normal artery or gradually (chronic) with progressive narrowing of the artery over time. In chronic arterial narrowing, a collateral circulation may develop and provide an alternative route for blood flow which reduces symptoms until a critical stenosis or occlusion has developed (Figure 56.2).

Features of chronic arterial stenosis or occlusion in the leg

Intermittent claudication

Intermittent claudication is a cramp-like pain felt in the muscles that is:
- brought on by walking;
- not present on taking the first step (unlike osteoarthritis);
- relieved by standing still (unlike nerve compression from a lumbar intervertebral disc prolapse or osteoarthritis of the spine or spinal stenosis).

The distance that a patient is able to walk without stopping varies only slightly from day to day. It is altered by walking up hill, the speed of walking, carrying heavy weights and changes in general health, such as anaemia or heart failure.

The pain of claudication is usually felt in the calf because the superficial femoral artery is the most commonly affected (70 per cent of cases). Aortoiliac disease (30 per cent of cases) may cause...
thigh or buttock claudication. Buttock claudication in association with sexual impotence resulting from arterial insufficiency is eponymously called Leriche’s syndrome. It is very rare.

Rest pain
Rest pain occurs with the limb at rest and is felt in the foot; it is exacerbated by lying down or elevation of the foot. Characteristically, the pain is worse at night and it may be lessened by hanging the foot out of bed or by sleeping in a chair. The pressure of bed clothes on the foot usually makes the pain worse.

Ulceration and gangrene
Ulceration occurs with severe arterial insufficiency and may present as a painful erosion between the toes or as shallow, non-healing ulcers on the dorsum of the feet, on the shins and especially around the malleoli. The blackened mummified tissues of frank gangrene are unmistakable (Figure 56.3), and superadded infection often makes the gangrene wet.

Colour, temperature, sensation and movement
An acutely ischaemic foot is often cold, white, paralysed and insensate. However, a chronically ischaemic limb tends to equilibrate with the temperature of its surroundings and may feel quite warm under the bedclothes. Chronic ischaemia does not produce paralysis and sensation is usually intact. Elevation of the limb produces pallor which changes to a red/purple colour when the limb is allowed to hang down (dependent rubor or the sunset foot sign). The capillary refill time may be elicited by pressing the skin of the heel or toe causing blanching and then releasing to allow colour to return (normally this takes 2–3 seconds, but may be prolonged to 10 seconds in severe ischaemia (Figure 56.4)).

Arterial pulses
It is standard practice to examine the femoral, popliteal, posterior tibial and dorsalis pedis arteries, together with the abdomen for an aneurysm which may coexist with occlusive disease. Diminution of a pulse can often be appreciated by comparing it with its opposite number. Popliteal pulses are difficult to feel and, if prominent, may suggest popliteal aneurysm. Pulsation distal to an arterial occlusion is usually absent although the presence of a highly developed collateral circulation may allow distal pulses to be normal – this is most likely to occur with an iliac stenosis. In this case, exercise (walking until claudication develops) usually causes the pulse to disappear as vasodilation occurs below the obstruction causing the pulse pressure to reduce. An arterial bruit, heard on auscultation over the pulse, indicates turbulent flow and suggests a stenosis. It is an unreliable clinical sign as tight stenoses often do not have bruits. A continuous ‘machinery’ murmur over an artery usually indicates an arteriovenous fistula (Summary box 56.1).

Summary box 56.1
Features of chronic lower limb arterial stenosis or occlusion
- Intermittent claudication
- Rest pain
- Dependent rubor or sunset foot
- Ulceration
- Gangrene
- Arterial pulsation diminished or absent
- Arterial bruit
- Slow capillary refilling

Relationship of clinical findings to site of disease
In most cases, the site of arterial obstruction can be determined from the symptoms and signs (Table 56.1). Severe ischaemia (rest pain, ulceration, gangrene) is usually caused by multilevel disease, e.g. iliac and femoropopliteal disease.

Risk factors and natural history
The common modifiable risk factors for occlusive arterial disease are smoking, hypertension, diabetes mellitus and hyperlipidaemia. The natural history of claudication is often to improve if the patient stops smoking and exercises. This encourages development of collaterals and the risk of limb loss is very low. For patients with rest pain or worse, intervention is usually required to prevent major amputation.
Investigation of arterial occlusive disease

Most patients with symptoms of arterial disease do not need invasive treatment, such as angioplasty or surgical reconstruction, and the decision whether or not to intervene can often be made without recourse to special investigations.

General investigation

Patients with arterial disease tend to be elderly and atherosclerosis is a generalised disease; if active intervention is contemplated, full assessment is essential. Many patients have age-related diseases, such as cardiac ischaemia, chronic obstructive pulmonary disease and malignancy. Blood tests to exclude anaemia, diabetes, renal disease and lipid abnormalities should include a full blood count, blood glucose, lipid profile and serum urea and electrolytes. High blood viscosity (polycythaemia and thrombocytolaemia) may be caused by smoking, but may also be associated with cancer; renal impairment (raised serum creatinine and low glomerular filtration rate (GFR)) may be caused by drugs and may be exacerbated by intravenous contrast agents used during angiography.

An electrocardiogram (ECG) may show coronary ischaemia, left ventricular hypertrophy or rhythm abnormalities, although a normal ECG does not rule out these conditions. More information may be gained by a cardiac echo or exercise testing. Arterial blood gases and pulmonary function test may be appropriate in patients with severe lung disease.

Doppler ultrasound blood flow detection

A hand-held Doppler ultrasound probe is very useful in the assessment of occlusive arterial disease (Figures 56.5 and 56.6). A continuous-wave ultrasound signal is transmitted from the probe at an artery and the reflected beam is picked up by a receiver within the probe itself. The change in frequency in the reflected beam compared with that of the transmitted beam is due to the Doppler effect. If the reflected beam is Doppler-shifted to a higher frequency than the transmitted beam, this indicates that the blood cells are moving away from the probe and towards the receiver; if the reflected beam is Doppler-shifted to a lower frequency than the transmitted beam, this indicates that the blood cells are moving towards the probe and away from the receiver. The Doppler effect can be used to determine the direction of blood flow, but not the velocity of blood flow.

(a) Figure 56.4 Colour changes with elevation (a) and dependency (b).

The best results from surgery are obtained by operation on the larger vessels, which allows a high volume of blood flow through bypass grafts. For instance, aortoiliac bypass is longer lasting than femorotibial bypass.

The problem of assessing blood flow and vascular patency has been addressed by using a sphygmomanometer to assess blood pressure in small vessels. This is possible even when the arterial pulse cannot be palpated. Both the pressure and signal quality are important; a normal artery has a triphasic signal that can be detected by a trained observer. However, although the presence of a Doppler signal indicates moving blood, it does not necessarily indicate that the blood flow is sufficient to maintain limb viability and prevent limb loss.
The ankle–brachial pressure index (ABPI) is the ratio of systolic pressure at the ankle to that in the arm. The highest pressure in the dorsalis pedis, posterior tibial or peroneal artery serves as the numerator, with the highest brachial systolic pressure being the denominator. Resting ABPI is normally about 1.0; values below 0.9 indicate some degree of arterial obstruction (claudication), less than 0.5 suggests rest pain and less than 0.3 indicates imminent necrosis. However, the values are merely a guide and normal values may be present with intermittent claudication. Retesting after exercise can be useful; a normal ABPI may subsequently fall in patients with ischaemia. Artificially high readings can be caused by calcified, incompressible arteries which are often found in diabetics.

**Duplex scanning**

This major non-invasive technique uses B-mode ultrasound to provide an image of vessels (Figures 56.7 and 56.8). The image is created because of the varying ability of different tissues to reflect the ultrasound beam. A second ultrasound beam is then used to insonate the imaged vessel and the Doppler shift...
obtained is analysed by a computer. Most scanners now have colour coding which allows detailed visualisation of blood flow, turbulence, etc. Different colours indicate changes in direction and velocity of flow with areas of high flow usually indicating a stenosis. In experienced hands, Duplex scanning is as accurate as angiography and has the advantages of cost-effectiveness and safety. However, the aortoiliac segment can be difficult to visualise particularly in obese patients. A computed tomography (CT) angiogram can provide better imaging of this segment in these cases (see below).

**Angiography**

Angiography is invasive and only appropriate if intervention is being contemplated. It involves injection of a radio-opaque dye into the arterial tree by a percutaneous catheter method (Seldinger technique) usually involving the femoral artery (Figures 56.9 and 56.10). Hazards include bleeding, haematoma, false aneurysm formation, thrombosis, arterial dissection, distal embolisation, renal dysfunction and allergic reaction. Digital subtraction angiography (DSA) is now the standard technique whereby the images obtained are digitised by computer and the extraneous background (bone, soft tissues, etc.) is removed to provide clearer images. CT angiography and magnetic resonance (MR) angiography (Figure 56.11) are new techniques gaining in popularity although the image quality is not as good as DSA. They can be useful where duplex scanning is not possible (intrathoracic arteries) or produces poor images (aortoiliac segment). MR has the added advantage of avoiding the need for ionising radiation.

**Non-surgical management of arterial stenosis or occlusion**

**General**

For many patients with claudication, stopping smoking and regular exercise (walking) will lead to improvement of symptoms over the first six months as collaterals develop. Walking regularly within the limits of the disability is ideal; there is nothing to be gained from walking in pain. Supervised exercise programmes, dietary advice, and weight loss in obese patients, will help. If this advice is followed, the risk of progression to critical leg ischaemia and amputation is very small. Unfortunately, claudication is often a marker of silent coronary and cerebral arterial disease and 50 per cent of claudicants will

---

*Sven Ivar Seldinger, 1921–1998, radiologist, Karolinska Institute, Stockholm, Sweden, introduced percutaneous arterial catheterisation in 1953.*
die within ten years from myocardial infarction or stroke. Patients with rest pain or tissue necrosis require urgent revascularisation to prevent limb loss.

**Drugs**

Medication may be required for diseases associated with arterial disorders, such as hypertension and diabetes; some antihypertensives (particularly β-blockers) may exacerbate claudication. Raised blood lipids require active drug treatment, but even when the lipid profile is normal, a statin should be prescribed as they may stabilise atherosclerotic plaques and protect against cardiac death. An antiplatelet agent is also necessary, usually 75 mg/day of aspirin, with 75 mg/day of clopidogrel as an alternative for those who are aspirin intolerant. Other agents, such as vasodilators, are unlikely to prove beneficial. Drugs are now available to help with smoking cessation.

**Transluminal angioplasty and stenting**

Arterial occlusive disease may be treated by inserting a balloon catheter into an artery and inflating it within a narrowed or blocked area (Figures 56.12 and 56.13). This technique is suitable for patients with claudication, rest pain or tissue necrosis, and is usually done in the radiology department (Figures 56.14 and 56.15). The basic method involves percutaneous femoral artery puncture under local anaesthetic followed by insertion of a guidewire which is negotiated through the stenosis or occlusion under fluoroscopic control. A balloon catheter is then inserted over the guidewire and positioned within the lesion. The balloon is then inflated at high pressure for approximately 1 minute and deflated. Satisfactory dilation of the lesion is confirmed by performing an angiogram. Percutaneous transluminal angioplasty (PTA) has proved very successful in dilating the iliac and femoropopliteal segments; the results below the knee are less successful. Long occlusions may be treated by the technique of subintimal angioplasty where the guidewire crosses the lesion in the subintimal space (in the arterial wall) and a new lumen is created by inflation of the balloon. Complications occur in about 5 per cent of cases and include failure, haematoma, bleeding, thrombosis and distal embolisation.

If the vessels fail to stay adequately dilated (often caused by elastic recoil of the artery), it may be possible to hold the lumen open using a metal stent (Figures 56.16 and 56.17). This may be
Arterial stenosis and occlusion

Arterial stenosis and occlusion

Operations for arterial stenosis or occlusion

Site of disease and type of operation

Surgical operations are usually reserved for patients with severe symptoms where angioplasty has failed or is not possible. Aortoiliac occlusion responds well to aortofemoral bypass.

introduced on a balloon catheter and expanded by balloon inflation; or alternatively a self-expanding stent may be used which is contained inside a plastic sheath and deployed by withdrawal of the sheath.

Figure 56.14 Narrowed superficial femoral artery before and after transluminal angioplasty (courtesy of J Mclvor, FRCS, London, UK). The advantage of this technique is that it can be carried out under local anaesthesia using the Seldinger technique of percutaneous arterial puncture, and is therefore especially useful in the treatment of patients who are medically unfit for major surgery.

Figure 56.15 Before (a) and after (b) balloon dilatation of a severely stenosed left renal artery in a 20-year-old woman with uncontrollable hypertension. The blood pressure fell to normal after the procedure. The stenosis was probably due to fibromuscular hyperplasia, but no tissue was available for histological diagnosis.
Justin H Miller, vascular surgeon, Royal Adelaide Hospital, Adelaide, SA, Australia.

(Figure 56.18a) using a Dacron graft (Figure 56.19a); although the operation carries a mortality rate of about 5 per cent. In unfit patients, an axillofemoral bypass is an alternative although patency rates are less. If only one iliac system is occluded, an iliofemoral or femorofemoral crossover graft may be performed.

Superficial femoral artery disease can be treated by femoropopliteal bypass (Figure 56.18b); long-term graft patency is determined by the quality of inflow and outflow, graft length (whether the distal anastomosis is above or below the knee) and the conduit used for the bypass. Autogenous saphenous vein gives the best results and can be used reversed or in situ after valve disruption. If the long saphenous vein is not available from either leg, short saphenous or arm veins may be used. If no vein is available, a prosthetic polytetrafluoroethylene (PTFE) graft may be employed (Figure 56.19b), although patency rates are less; many surgeons construct the lower anastomosis using a small collar of vein (Miller cuff) between the PTFE and the recipient artery, which may improve patency. Isolated common femoral artery or profunda disease can be treated with endarterectomy and patch (vein or prosthetic) or a short bypass in the groin.

Sometimes, in patients with critical leg ischaemia, the occlusion extends beyond the popliteal artery into the tibial vessels. Limb salvage can be attempted with a femorodistal bypass with success even more dependent on the state of the run-off vessel and the quality of the vein conduit (minimum diameter 3 mm). The risk of early graft failure with limb loss is high and these long bypasses are only appropriate for limb salvage.

**Technical details**

For aortofemoral bypass, the aorta is approached through a midline or transverse abdominal incision. The common femoral arteries and their branches are exposed through vertical groin incisions. The small bowel is retracted to the right and the posterior peritoneum opened. Retroperitoneal tunnels are made from the aorta to the groins. Heparin (5000 U) is given intravenously and the vessels clamped. A vertical incision is made in the anterior aspect of the aorta to which an obliquely cut, bifurcated
Dacron graft is sutured end-to-side. The graft limbs are then fed down to the groins where they are anastomosed end-to-side to the common femoral arteries or, if there is evidence of profunda stenosis, to an arteriotomy running from the common femoral vessel down into the profunda. The posterior peritoneum is closed over the Dacron to prevent adhesion of the graft to bowel, and the abdomen and groin wounds are closed.

For femoropopliteal bypass, the popliteal artery above or below the knee is exposed through a medial incision. The common femoral artery is exposed at groin level. The long saphenous vein may be used in two different ways. First, it may be excised, its tributaries tied, and the vein used in a reversed fashion so the valves do not obstruct the flow of blood. Alternatively, it may be left in place (in situ) and the valves disrupted with a valvulotome. The graft is sutured to the femoral artery proximally and to the popliteal artery distally. Femorodistal bypass involves fashioning the distal anastomosis to a tibial vessel. If no suitable vein is available, prosthetic material (usually PTFE) may be used, with or without a small vein collar (Miller cuff) at its distal end (Figure 56.20a,b).

A femorofemoral crossover graft involves tunnelling a prosthetic graft subcutaneously above the pubis between the groins. An axillofemoral graft is tunnelled subcutaneously between the axillary artery proximally, to reach one or both of the femoral arteries; the patency rates of an axillofemoral bypass is better than an axillo(uni)femoral bypass.

Results of operation

Long-term results of aortoiliac reconstructive surgery are good, usually marred only by progressive infrainguinal disease. Femoropopliteal surgery is less successful. Immediate postoperative success for vein bypass exceeds 90 per cent, but the five-year patency is around 60 per cent. PTFE bypass yields poorer results than vein bypass, with five-year success rates of less than 50 per cent. Although the results of femorodistal bypass are even less satisfactory, such surgery can ensure limb salvage in patients who are generally debilitated and whose expected lifespan is limited; long-term patency is less important.

Other sites of atheromatous occlusive disease

The principles of arterial surgery outlined above can be applied at other arterial sites. Carotid stenosis (at the carotid bifurca-
tion in the neck) may cause transient ischaemic attacks (TIA). These short-lived mini-strokes are often recurrent and cause unilateral motor or sensory loss in the arm, leg or face, transient blindness (amaurosis fugax) or speech impairment. They are caused by distal embolisation of platelet thrombi that form on the atheromatous plaque into the cerebral circulation. They are a warning of impending major stroke. Patients should be assessed with a duplex scan. If a tight stenosis (>70 per cent) is detected, carotid endarterectomy should be offered (Figure 56.21). Current guidelines for carotid endarterectomy are listed in Summary box 56.2. This involves clamping the vessels, an arteriotomy in the common carotid artery continued up into the internal carotid artery through the diseased segment, removal of the occlusive disease (endarterectomy) and closure of the arteriotomy, often with a patch. Many surgeons also use a temporary shunt to maintain cerebral blood flow while the carotid system is clamped.

Subclavian artery stenosis may cause claudication in the arm or digital ischaemia from distal embolisation. It may be treated by angioplasty or surgical bypass. Sometimes subclavian artery lesions are associated with neck pathology, such as a cervical rib which should be removed during arterial repair (see Chapter 57, Figure 57.37). Subclavian steal syndrome may occur if the first part of the subclavian artery is occluded. Arm exercise causes syncope because of reversed flow in the vertebral artery leading to cerebral ischaemia. It can be treated by angioplasty or surgery and is rare.

Mesenteric artery occlusive disease may cause pain after eating (intestinal angina) and weight loss. In general, two of the three enteric vessels (coeliac axis, superior mesenteric artery, inferior mesenteric artery) must be occluded to produce symptoms and other intestinal disorders must be excluded before treatment with PTA, endarterectomy or bypass. Renal artery stenosis may cause hypertension and eventual renal failure. Although it is possible to improve renal blood flow with PTA or surgery, the mainstay of treatment is drugs to control hypertension, diabetes, etc.

GANGRENE
Gangrene refers to death of macroscopic portions of tissue which turn black because of the breakdown of haemoglobin and the formation of iron sulphide. It usually affects the most distal part of a limb because of arterial obstruction (from thrombosis, embolus or arteritis). Dry gangrene occurs when the tissues are desiccated by gradual slowing of the bloodstream; it is typically a warning of impending major stroke. Patients should be assessed with a duplex scan. If a tight stenosis (>70 per cent) is detected, carotid endarterectomy should be offered (Figure 56.21). Current guidelines for carotid endarterectomy are listed in Summary box 56.2. This involves clamping the vessels, an arteriotomy in the common carotid artery continued up into the internal carotid artery through the diseased segment, removal of the occlusive disease (endarterectomy) and closure of the arteriotomy, often with a patch. Many surgeons also use a temporary shunt to maintain cerebral blood flow while the carotid system is clamped.

Subclavian artery stenosis may cause claudication in the arm or digital ischaemia from distal embolisation. It may be treated by angioplasty or surgical bypass. Sometimes subclavian artery lesions are associated with neck pathology, such as a cervical rib which should be removed during arterial repair (see Chapter 57, Figure 57.37). Subclavian steal syndrome may occur if the first part of the subclavian artery is occluded. Arm exercise causes syncope because of reversed flow in the vertebral artery leading to cerebral ischaemia. It can be treated by angioplasty or surgery and is rare.

Mesenteric artery occlusive disease may cause pain after eating (intestinal angina) and weight loss. In general, two of the three enteric vessels (coeliac axis, superior mesenteric artery, inferior mesenteric artery) must be occluded to produce symptoms and other intestinal disorders must be excluded before treatment with PTA, endarterectomy or bypass. Renal artery stenosis may cause hypertension and eventual renal failure. Although it is possible to improve renal blood flow with PTA or surgery, the mainstay of treatment is drugs to control hypertension, diabetes, etc.

**Summary box 56.2**

**Indications for carotid endarterectomy in symptomatic patients**

- 70% or greater carotid stenosis and:
  - Ipsilateral amaurosis fugax or monocular blindness
  - Contralateral facial paralysis or paraesthesia
  - Arm/leg paralysis or paraesthesia
  - Hemianopia
  - Dysphasia (if dominant hemisphere)
  - Sensory or visual inattention/neglect

![Figure 56.20](a) Completion angiogram of femoropopliteal bypass graft (with Miller cuff). (b) Completion angiogram of femorodistal bypass graft in situ.)
the result of atheromatous occlusion of arteries. Wet gangrene occurs when superadded infection and putrefaction are present. Crepitus may be palpated as a result of infection by gas-forming organisms commonly in diabetic foot problems.

Separation of gangrene
A zone of demarcation between the truly viable and the dead or dying tissue will eventually appear. Separation is achieved by the development of a layer of granulation tissue, which forms between the dead and the living parts. In dry gangrene, if the blood supply of the proximal tissues is adequate, the final line of demarcation appears in a matter of days and separation occurs neatly and with the minimum of infection. If bone is involved, complete separation takes longer than when soft tissues alone are affected, and the stump tends to be conical as the bone has a better blood supply than its coverings. In moist gangrene, the infection and suppuration extends into the neighbouring living tissue, causing the final line of demarcation to be more proximal than in dry gangrene.

If the arterial supply to the proximal living tissue is poor, the line of final demarcation is very slow to form or does not develop at all. Unless the arterial supply can be improved, the gangrene will spread to adjacent tissues or will suddenly appear as 'skip' areas further up the limb. These skip lesions may occur on the other side of the foot, on the heel, on the dorsum of the foot or even in the calf. Infection may also cause gangrene to spread proximally into areas of extensive inflammation. To attempt local amputation in the presence of poor circulation will fail and gangrene will reappear in the wound or skin edges.

Treatment of gangrene
How much of a limb or digit can be salvaged depends on the blood supply proximal to the gangrene. Poor circulation can sometimes be improved by radiological or surgical intervention and this may allow a more conservative debridement or distal amputation. However, major limb amputation may be required in the presence of life-threatening sepsis, when the blood supply cannot be improved or in patients whose limb is useless because of contractures, stroke, etc.

Specific varieties of gangrene
Diabetic gangrene
Diabetic gangrene is usually caused by a combination of three factors – ischaemia secondary to atheroma, peripheral neuropathy which leads to trophic skin changes and immunosuppression caused by excess of sugar in the tissues which predisposes to infection (Figure 56.22). The neuropathy is usually sensory which favours the neglect of minor injuries and infections. Motor involvement is frequently accompanied by loss of reflexes and deformities (neuropathic joints). Thick callosities develop on the sole of the foot which together with poor chiropody may allow the entry of infection that can spread rapidly and proximally in subfascial planes. Treatment depends on the degree of arterial involvement which should be investigated and treated rapidly with angioplasty or surgery. The gangrene is treated by drainage of pus, debridement of dead tissue with local amputation of necrotic digits and antibiotics.

Bedsores
A bedsore is gangrene caused by local pressure (Figure 56.23). Bedsores are predisposed to by five factors: pressure, injury, anaemia, malnutrition and moisture. They can appear and extend rapidly in immobile patients and in those with debili-
Prophylactic measures must be taken, including the avoidance of pressure over bony prominences by the use of foam blocks or similar, regular turning, and nursing on specially designed beds that reduce the pressure to the skin. A water bed or a ripple bed is sometimes desirable. Injury from wrinkled sheets and maceration of the skin by sweat, urine, faeces or pus must be prevented by skilled nursing and the use of appropriate dressings.

A bedsore can be expected if erythema appears that does not change colour on pressure. Once pressure sores develop, they are difficult to heal. They should be kept clean and debrided if necessary. Advice from a plastic surgeon should be sought for major lesions; vacuum dressings and rotation flaps can be effective.

Frostbite
Frostbite is caused by exposure to cold. It is seen both in climbers at high altitudes and in the elderly or the vagrant during cold weather (Figure 56.24). Cold injury damages the wall of the blood vessel which causes swelling and leakage of fluid together with severe pain. When the pain disappears, a waxy appearance remains; blistering and then gangrene follow. Treatment is gradual rewarming, analgesics and delayed conservative amputation after demarcation of devitalised tissue.

ACUTE ARTERIAL OCCLUSION
Sudden occlusion of an artery is usually caused by an embolus. It may also happen when thrombosis occurs on an atherosclerotic plaque, although the outcome is usually less dramatic because collaterals are likely to have developed in chronic arterial stenosis.

Embolic occlusion
An embolus is a body that is foreign to the bloodstream and which may become lodged in a vessel and cause obstruction. It is often a thrombus that has become detached from the heart or a more proximal vessel. Sources include the left atrium in atrial fibrillation, a left ventricular mural thrombus following myocardial infarction; vegetations on heart valves in infective endocarditis, thrombi in aneurysms and on atherosclerotic plaques. Emboli may lodge in any organ and cause ischaemic symptoms.

- Arm and leg. Pain, pallor, paralysis, palselessness and paraesthesia (Figure 56.25). Acute arterial occlusion due to an embolus differs from occlusion due to thrombosis on pre-existing atheroma; in the latter case, a collateral circulation has often built up over time (Figures 56.26 and 56.27). It is essential to differentiate between the two as they require different management.

Figure 56.23 Bedsores typically appear over areas exposed to pressure, such as the sacrum and (as in this case) the heel.

Figure 56.24 (a) Frostbite of the foot. Note the clear demarcation. (b) Frostbite of the middle finger in the same patient. The index finger was lost two years before, also from frostbite.
Acute arterial occlusion

- Mesenteric vessels. Possible gangrene of the corresponding loop of intestine.

**Acute limb ischaemia**

**Clinical features**

Embolic arterial occlusion is an emergency that requires immediate treatment. Ischaemia beyond 6 hours is usually irreversible and results in limb loss. The leg is often affected, with pain, pallor, paralysis, loss of pulsation and paraesthesia (or anaesthesia) (Figure 56.25). The limb is cold and the toes cannot be moved, which contrasts with venous occlusion when muscle function is not affected. The diagnosis can be made clinically in a patient who has no history of claudication and has a source of emboli, who suddenly develops severe pain or numbness of the limb, which becomes cold and mottled. Movement becomes progressively more difficult and sensation is lost. Pulses are absent distally, but the femoral pulse may be palpable, even thrusting, as distal occlusion results in forceful expansion of the artery with each pressure wave despite the lack of flow. A similar picture will occur in the arm with a brachial embolus.

**Treatment**

Because of the ensuing stasis, a thrombus can extend distally and proximally to the embolus. The immediate administration of 5000 U of heparin intravenously can reduce this extension and maintain patency of the surrounding (particularly the distal) vessels until the embolus can be treated. The relief of pain is essential because it is severe and constant. Embolectomy and thrombolysis are the treatments available for patients with limb emboli.

**Embolectomy**

Local or general anaesthesia may be used. The artery (usually the femoral), bulging with clot, is exposed and held in slings. Through a longitudinal or transverse incision, the clot begins to extrude and is removed, together with the embolus (Figure 56.28), with the help of a Fogarty balloon catheter. The catheter, with its balloon tip, is introduced both proximally and distally until it is deemed to have passed the limit of the clot. The

---

**Figure 56.25** The symptoms and signs of embolism (four Ps). The fifth feature, anaesthesia, is often stated to be paraesthesia (the fifth P) but, in truth, complete loss of sensation in the toes and feet is characteristic.

**Figure 56.26** Aortic bifurcation embolus. Source of embolus is a recent myocardial infarct or atrial fibrillation. This causes severe, dramatic symptoms.

**Figure 56.27** Aortic bifurcation thrombosis. No source of embolus but previous claudication. Claudication worse but no dramatic event.

**Brain.** The middle cerebral artery (or its branches) is most commonly affected, resulting in major or minor (TIA) stroke.

**Retina.** Amaurosis fugax is fleeting blindness caused by a minute thrombus emanating from an atheromatous plaque in the carotid artery passing into the central retinal artery. Lasting obstruction causes permanent blindness.
balloon is inflated and the catheter withdrawn slowly, together with any obstructing material (Figure 56.29). The procedure is repeated until back bleeding occurs. An angiogram may be performed in the operating theatre at the end of the procedure to ensure that flow to the distal leg has been restored. Postoperatively, heparin therapy is continued until long-term anticoagulation with warfarin is established to reduce the chance of further embolism.

**Compartment syndrome**

In limbs that have been subject to sudden ischaemia followed by revascularisation, oedema is likely. Muscles swell within fixed fascial compartments and this can itself be a cause of ischaemia, with both local muscle necrosis and nerve damage due to pressure, and distal effects such as renal failure secondary to the liberation of muscle breakdown products. The treatment is urgent fasciotomy to release the compression. The usual site for fasciotomy is the calf (especially the anterior tibial compartment), but compartment syndrome may occasionally affect the thigh and the arm.

**Intra-arterial thrombolysis**

If ischaemia is not so severe that immediate operation is essential, it may be possible to treat either embolus or thrombosis by intra-arterial thrombolysis (Figure 56.30). At arteriography of the ischaemic limb (usually via the common femoral artery), a narrow catheter is passed into the occluded vessel and left embedded within the clot. Tissue plasminogen activator (TPA) is infused through the catheter and regular arteriograms are carried out to check on the extent of lysis, which, in successful cases, is achieved within 24 hours. The method should be abandoned if there is no progression of dissolution of clot with time. There are several contraindications to thrombolysis, the most important of which are recent stroke, bleeding diathesis and pregnancy, and results in those over 80 years old are poor.

**Acute mesenteric ischaemia**

Acute mesenteric occlusion may be either thrombotic (following atheromatous narrowing) or embolic. Embolic occlusion results in sudden, severe abdominal pain, with bowel emptying (vomiting and diarrhoea) and a source of emboli present (usually cardiac). Unfortunately, the diagnosis is often only made at laparotomy with widespread infarction of the small and large bowel present; in this situation, it is fatal. Occasionally, the degree of bowel infarction is more limited; resection of the dead bowel and embolectomy of the superior mesenteric artery, or bypass surgery can reduce the otherwise high mortality rate in these patients. A 'second look' laparotomy 24 hours later to check the viability of the bowel is often indicated.

**Other forms of emboli**

Infective emboli of bacteria or an infected clot may cause mycotic aneurysms, sepsicaemia or infected infarcts. Parasitic emboli, caused by the ova of *Taenia echinococcus* and *Filaria sanguinis hominis*, may occur in some countries. Tumour cells (e.g. hypernephroma and cardiac myxoma) are rare causes of emboli. Fat embolism may follow major bony fractures. However, it usually causes venous emboli that travel to the lungs and cause acute respiratory distress syndrome.

**Air embolism**

Air may be accidentally injected into the venous circulation or sucked into an open vein during head and neck surgery or a cut throat. It may also occur following Fallopian tube insufflation or illegal abortion. If a large volume of air reaches the right side of the heart it may form an air lock within the pulmonary artery and cause acute right heart failure.

The treatment of air embolism is to put the patient in a head-down (Trendelenburg) position to encourage the air to enter the veins in the lower part of the body. The patient should also be placed on the left side to help the air to float to the ventricular apex, away from the ostium of the pulmonary artery. In extreme

---

*Gabrielle Falloppio (Fallopius), 1523–1563, Professor of Anatomy, Surgery and Botany, Padua, Italy.*
cases, air may be aspirated from the heart through a needle introduced below the left costal margin.

**Therapeutic embolisation**

This is used to arrest haemorrhage from the gastrointestinal, urinary (Figure 56.31), gynaecological and respiratory tracts, to treat arteriovenous malformations by blocking their arterial supply and to control the growth of unresectable tumours. Arterial embolisation requires accurate selective catheterisation using the Seldinger technique. A variety of materials may be used, including gelfoam sponge, plastic microspheres, balloons, ethyl alcohol, quick-setting plastics and metal coils.

**AMPUTATION**

**General**

Amputation should be considered when part of a limb is dead, deadly or a dead loss. A limb is dead when arterial occlusive disease is severe enough to cause infarction of macroscopic portions of tissue, i.e. gangrene. The occlusion may be in major vessels (atherosclerotic or embolic occlusions) or in small peripheral vessels (diabetes, Buerger’s disease, Raynaud’s disease, inadvertent intra-arterial injection). If the obstruction cannot be reversed and the symptoms are severe, amputation is required.

A limb is deadly when the putrefaction and infection of moist gangrene spreads to surrounding viable tissues. Cellulitis and severe toxæmia are the result. Amputation is required as a life-saving operation. Antibiotic cover should be broad and massive. Other life-threatening situations for which amputation may be required include gas gangrene (as opposed to simple infection), neoplasms (such as osteogenic sarcoma) and arteriovenous fistula.

![Figure 56.31 Before (a) and after (b) therapeutic embolisation of the internal iliac artery in a patient with gross haematuria from an ulcerating bladder carcinoma (courtesy of F McIvor, FRCR, London, UK).](image)

A limb may be deemed a dead loss in the following circumstances: first, when there is relentless severe rest pain without gangrene and reconstruction is not possible – amputation will improve quality of life; second, when a contracture or paralysis makes the limb impossible to use and renders it a hindrance; and third, when there is major unrecoverable traumatic damage (Summary box 56.3).

**Summary box 56.3**

**Indications for amputation**

- Dead limb
  - Gangrene
- Deadly limb
  - Wet gangrene
  - Spreading cellulitis
  - Arteriovenous fistula
  - Other (e.g. malignancy)
- ‘Dead loss’ limb
  - Severe rest pain with unreconstructable critical leg
  - Ischaemia
  - Paralysis
  - Other (e.g. contracture, trauma)

**Distal and transmetatarsal amputation**

In patients with small-vessel disease, typically caused by diabetes, gangrene of the toes may occur with relatively good blood supply to the surrounding tissues. In such circumstances, local amputation of the digits can result in healing. However, if the metatarsophalangeal joint region is involved, a ray excision is required, taking part of the metatarsal and cutting tendons back. Most surgeons leave the wound open. Early mobility aids drainage provided that cellulitis is not present. For less extensive gangrene, if amputation is taken through a joint, healing is improved by removing the cartilage from the joint surface. A transmetatarsal amputation may be required when several toes are affected, but the proximal circulation is adequate. The wound may be closed with a viable long plantar flap (Figure 56.32) or left open.

**Major amputation**

**Choice of operation**

The major choice is between an above- or below-knee operation. A below-knee amputation preserves the knee joint and gives the best chance of walking again with a prosthesis. However, an above-knee amputation is more likely to heal and may be appropriate if the patient has no prospect of walking again. If the femoral pulse is absent, the amputation should be above the knee. Unfortunately, the presence of a femoral pulse does not guarantee healing of a below-knee amputation and sometimes a

Sir William Ferguson (1808–1877), surgeon, Royal Infirmary, Edinburgh, later Professor of Surgery, King’s College Hospital, London, said that amputation is ‘one of the meanest, and yet one of the greatest operations in surgery: mean, when resorted to where better may be done – great, as the only step to give comfort and prolong life’.

Sir Edward ‘Weary’ Dunlop, a great Australian surgeon. During the Second World War, as a prisoner of war (POW) held by the Japanese while looking after other POWs working on the Burma-Siam Railway, he made prosthetic lower limbs for amputees out of bamboo.

Leo Buerger, 1879–1943, Professor of Urologic Surgery, New York Polyclinic Medical School, New York, NY, USA, described thromboangitis obliterans in 1908.

Maurice Raynaud, 1834–1881, physician, Hospital Lariboisiere, Paris, France, described this condition in 1862.
failed below-knee amputation may require revision to an above-knee procedure.

For above- or below-knee amputations with a good stump shape, it is possible to hold a prosthesis in place simply by suction, without any cumbersome and unsightly straps. The stump should be of sufficient length to give the required leverage, i.e. not less than 8 cm below the knee (preferably 10–12 cm) and not less than 20 cm above the knee.

Below-knee amputations

Two types of skin flap are commonly used: long posterior flap and skew flap (described by KP Robinson). For both methods, the total length of flap must be at least one and a half times the diameter of the leg at the point of bone section.

The long posterior flap technique is the older method and remains the more popular probably because of its relative simplicity (Figure 56.33). Anteriorly, the incision is deepened to bone and the lateral and posterior incisions are fashioned to leave the bulk of the gastrocnemius muscle attached to the flap, muscle and skin being transected together at the same level. If bleeding is inadequate, the amputation is refashioned at a higher level. Blood vessels are identified and ligated. Nerves are not clamped, but pulled down gently and transected as high as possible. Vessels in nerves are ligated. The fibula is divided 2 cm proximal to the level of tibial division using bone cutters. The tibia is cleared and transected at the desired level, the anterior aspect of the bone being sawn obliquely before the cross-cut is made. This, with filing, gives a smooth anterior bevel, which prevents pressure necrosis of the flap. The long muscle/skin flap is tapered after removing the bulk of the soleus muscle (much of the gastrocnemius may be left, unless it is very bulky). The area is washed with saline to remove bone fragments and the muscle and fascia are sutured with an absorbable material to bring the flap over the bone ends. A suction drain is placed deep to the muscle and brought out through a stab incision in the skin. The skin flap should lie in place with all tension taken by the deep sutures. Interrupted skin sutures are inserted. Gauze, wool and crepe bandages are usually used for the stump dressing.

The skew flap amputation makes use of anatomical knowledge of the skin blood supply. Equally long flaps are developed; they join anteriorly 2.5 cm from the tibial crest, overlying the anterior tibial compartment, and posteriorly at the exact opposite point on the circumference of the leg. After division of bone and muscle in a fashion similar to that described above, the gastrocnemius flap is sutured over the cut bone end to the anterior tibial periosteum with absorbable sutures. Finally, drainage and skin sutures are inserted and the limb dressed as for the long posterior flap operation.

Above-knee amputation

The site is chosen as indicated above, but may need to be higher if bleeding is poor on incision of the skin. Equal curved anterior and posterior skin flaps are made of sufficient total length. Skin, deep fascia and muscle are transected in the same line. Vessels are ligated. The sciatic nerve is pulled down and transected cleanly as high as possible and the accompanying artery ligated.
Muscle and skin are retracted and the bone cleared and sawn at the point chosen. Haemostasis is achieved. The muscle ends are united over the bone by absorbable sutures incorporating the fascia. A suction drain deep to the muscle is brought out through the skin clear of the wound. The fascia and subcutaneous tissues are further brought together so that the skin can be apposed by interrupted sutures. Gauze, wool and crepe bandages form the stump dressing.

Postoperative care of an amputee

Opiate pain relief should be given regularly. Care of the good limb must not be forgotten as a pressure ulcer on the remaining foot will delay mobilisation, despite satisfactory healing of the stump. Exercise and mobilisation are of the greatest importance. After surgery, flexion deformity must be prevented and exercises started to build up muscle power and coordination. Mobility is progressively increased with walking between bars and the use of an inflatable artificial limb, which allows weight-bearing to be started before a pylon or temporary artificial limb is ready (Figure 56.34). Early assessment of the home is part of the programme; it allows time for minor alterations, such as the addition of stair rails, movement of furniture to give support near doors and provision of clearance in confined passages.

Complications

Early complications include haemorrhage (which requires return to the operating theatre for haemostasis), haematoma (which requires evacuation) and infection (usually in association with a haematoma). Any abscess must be drained and appropriate antibiotics given. Gas gangrene can occur in a mid-thigh stump from faecal contamination. Wound dehiscence and gangrene of the flaps are caused by ischaemia; a higher amputation may be necessary. Amputees are at risk of deep vein thrombosis and pulmonary embolism in the early postoperative period and prophylaxis with subcutaneous heparin is essential.

Later complications include pain resulting from unresolved infection (sinus, osteitis, sequestrum), a bone spur, a scar adherent to bone and an amputation neuroma. Patients frequently remark that they can feel the amputated limb (phantom limb) and sometimes remark that it is painful (phantom pain). The surgeon’s attitude should be one of firm reassurance that this sensation will almost certainly disappear with time; amitriptyline or gabapentin may help. Other late complications include ulceration of the stump because of pressure effects of the prosthesis or increased ischaemia.

ANEURYSM

General

Dilatations of localised segments of the arterial system are called ‘aneurysms’. They can either be true aneurysms, containing the three layers of the arterial wall (intima, media, adventitia) in the aneurysm sac, or false aneurysms, having a single layer of fibrous tissue as the wall of the sac, e.g. aneurysm following trauma. Aneurysms can also be grouped according to their shape (fusiform, saccular) or their aetiology (atheromatous, traumatic, mycotic, etc.). The term ‘mycotic’ is a misnomer because, although it indicates infection as the cause of the aneurysm, it is due to bacteria, not fungi. Aneurysms may occur in the aorta, iliac, femoral, popliteal, subclavian, axillary, carotid, cerebral, mesenteric, splenic and renal arteries and their branches. The majority are true fusiform atherosclerotic aneurysms (Summary box 56.4).

Summary box 56.4

**Classification of aneurysms**

- **Wall**
  - True (three layers: intima, media, adventitia)
  - False (single layer of fibrous tissue)
- **Morphology**
  - Fusiform
  - Saccular
- **Aetiology**
  - Atheromatous
  - Mycotic (bacterial rather than fungal)
  - Collagen disease
  - Traumatic

**Clinical features**

All aneurysms can cause symptoms, as a result of compression of surrounding structures, thrombosis, rupture or the release of emboli. The symptoms relate to the vessel affected and the tissues it supplies. Many aneurysms of clinical significance can be palpated and, typically, an expansile pulsation is felt. Transmitted pulsation through a mass lesion, cyst or abscess lying adjacent to a large artery may be mistaken for aneurysmal pulsation. Before incising a swelling believed to be an abscess, it is essential to make sure that it does not pulsate. Finally, a tortuous (and often ectatic) artery, usually the innominate or carotid, may seem like an aneurysm to the inexperienced clinician.
Abdominal aortic aneurysm

Abdominal aortic aneurysm is by far the most common type of large vessel aneurysm and is found in 2 per cent of the population at autopsy; 95 per cent have associated atheromatous degeneration and 95 per cent occur below the renal arteries. Most remain asymptomatic until rupture occurs; the risk of rupture increases with increasing size (diameter) of the aneurysm. Asymptomatic aneurysms are found incidentally on physical examination, radiography or ultrasound investigation. It may be appropriate to screen for abdominal aortic aneurysms with ultrasound; a national screening programme has recently started in England and offers an ultrasound scan to men in their 65th year. Symptomatic aneurysms may cause minor symptoms, such as back and abdominal discomfort, before sudden, severe back and/or abdominal pain develops from expansion and rupture.

Asymptomatic abdominal aortic aneurysm

An asymptomatic abdominal aortic aneurysm (Figure 56.35) in an otherwise fit patient should be considered for repair if >55 mm in diameter (measured by ultrasonography). The annual incidence of rupture rises from 1 per cent or less in aneurysms that are <55 mm in diameter to a significant level, perhaps as high as 20 per cent, in those that are 70 mm in diameter. Assuming open elective surgery (transabdominal) carries a 5 per cent mortality rate, the balance is in favour of elective operation once the diameter is >55 mm, provided there is no major comorbidity. Regular ultrasonographic assessment is indicated for asymptomatic aneurysms <55 mm in diameter.

Investigations

Full blood count, electrolytes, liver function tests, coagulation tests and blood lipid estimation should be performed. Blood should be crossmatched a few days prior to surgery. Many patients now have an anaesthetic assessment and the need for cardiac and respiratory function tests are decided at this time. An electrocardiogram and chest radiograph are essential; further assessment may include echocardiography or isotope ventriculography, cardiopulmonary exercise testing and spirometry.

The morphology of the aneurysm is best assessed by CT scan (Figures 56.36 and 56.37). Fifty per cent of aneurysms are suitable for endovascular (minimally invasive) repair usually via the femoral arteries in the groin. If lower limb pulse is absent, there may be associated arterial occlusive disease which should be assessed by duplex scanning initially. Further assessment with CT, MR or digital subtraction angiography may be required and angioplasty may be appropriate. The aneurysm is often filled with circumferential clot (Figure 56.38a), which produces a falsely narrowed appearance on digital subtraction angiography (Figure 56.38b); this method should not therefore be used to assess aneurysm size.

Choice of operation – open or endovascular repair

Open surgical procedure

Under general anaesthesia, with the patient lying supine, a full-length midline or supraumbilical transverse incision is made. The small bowel is lifted to the patient’s right and the aorta identified. The posterior peritoneum overlying the aorta is opened and the upper limit of the aneurysm identified. The aorta immediately above the dilatation is exposed; this is generally just inferior to the left renal vein and renal arteries (Figure 56.39).
Figure 56.37 (a) Spiral computed tomogram showing an infrarenal abdominal aortic aneurysm; (b) with the bony elements subtracted.

Figure 56.38 (a) Thrombus removed from an abdominal aortic aneurysm; this thrombus is the reason an angiogram may give a false impression of aneurysm diameter on digital subtraction angiography (b).

Figure 56.39 Operative appearance of a huge, non-ruptured infrarenal abdominal aortic aneurysm.
The common iliac arteries are then exposed and clamps applied above and below the lesion. Many surgeons give systemic heparin before clamping. The aneurysm is opened longitudinally and back-bleeding from lumbar and mesenteric vessels controlled by sutures placed from within the sac. Upper and lower aortic necks are prepared to which an aortic prosthesis is then sutured end to end inside the sac with a monofilament non-absorbable suture (Figure 56.40). Clamps are released slowly to prevent sudden hypotension. If haemostasis is satisfactory at this point, the aneurysm sac is closed around the prosthesis to exclude both it and the suture lines from the bowel to reduce the risk of adherence and potential fistula formation. The abdomen is then closed. Occasionally, when the iliac vessels are also involved with dilatation or severe atheroma, it is necessary to construct an aortobi-iliac or aortobifemoral bypass, rather than use a simple aorto-aortic tube.

**Endovascular aneurysm repair**

Endovascular aneurysm repair (EVAR) is now established in clinical practice and has been shown to have reduced mortality compared to open repair over the first six years. Currently, about 50 per cent of infrarenal aneurysms are suitable for EVAR which is dependent on the morphology of the aneurysm when assessed by CT scan. Common causes of unsuitability include a short, flared or angulated neck and difficult iliac artery access because of narrowing or tortuosity. The usual technique is to expose both femoral arteries (under general or local anaesthetic) which allows access to the aorta. Then, under radiological control, guidewires and catheters are used to cross the aneurysm and an angiogram performed to mark the level of the renal arteries.

The endovascular prosthesis (often termed a 'stent graft') is usually made up of three separate parts – a main body (Figure 56.41a) and two limbs which are enclosed in separate delivery catheters (Figure 56.41b). Some types have only two pieces – a main body with ipsilateral limb attached and a separate contralateral limb. The prosthesis is made from Dacron or PTFE with integral metallic stents for support. The delivery catheter is inserted in the aneurysm sac and the stent graft deployed by withdrawal of the delivery system. Most systems now have hooks or barbs to anchor the prosthesis in the aortic wall and some surgeons inflate a moulding balloon catheter in the stent graft to ensure the hooks and barbs are engaged and a good seal is obtained (Figure 56.42). Although the top edge of the fabric of the stent graft has to be deployed below the renal arteries (infrarenal fixation), some systems have additional bare metal stents at the proximal end of the main body which lie across

---

**Figure 56.40** (a) Aneurysm sac opened. Note that the posterior wall of the aorta immediately above and below the sac is not divided. A Dacron tube graft is laid in place within the sac ready for suture. (b) Graft sutured in place and vascular clamps removed.
an endoleak which means that the aneurysm is not excluded from the circulation and may still expand and rupture. Patients who undergo EVAR require life-long follow-up and surveillance with duplex or CT scans to detect endoleak, disconnection of the components and migration of the stent graft, all of which predispose to late rupture (Figure 56.43).

**Ruptured abdominal aortic aneurysm**

Abdominal aortic aneurysms can rupture anteriorly into the peritoneal cavity (20 per cent) or posterolaterally into the retroperitoneal space (80 per cent). Less than 50 per cent of patients with rupture survive to reach hospital. Anterior rupture results in free bleeding into the peritoneal cavity; very few patients reach hospital alive. Posterior rupture on the other hand produces a retroperitoneal haematoma (Figure 56.44). Often a brief period ensues when a combination of moderate hypotension and the resistance of the retroperitoneal tissues arrests further haemorrhage and may allow transport to hospital. The patient may remain conscious, but in severe pain. If no operation is performed, death is virtually inevitable. Operative mortality is around 50 per cent and the overall combined mortality (community and hospital) is around 80–90 per cent.

Ruptured abdominal aortic aneurysm is a surgical emergency; it should be suspected in a patient with the triad of severe abdominal and/or back pain, hypotension and a pulsatile abdominal mass. If there is doubt about the presence of an aneurysm an ultrasound scan may help, but this cannot diagnose rupture. CT scanning is performed in an increasing number of patients to establish the diagnosis and to determine whether an endovascular repair is possible.

Good venous access is needed for infusion of saline or volume expanding fluids, but the systolic blood pressure should not be raised any more than is necessary to maintain consciousness and permit cardiac perfusion (<100 mmHg). Many surgeons now adopt a policy of permissive hypotension where fluids are withheld if the patient is conscious (and cerebral perfusion is therefore adequate), in order to avoid provoking further uncontrolled haemorrhage. After CT scanning, the patient should be transferred immediately to an operating theatre where a urinary

PART 10  |  VASCULAR

Symptomatic abdominal aortic aneurysm

These patients most commonly present with abdominal and/or back pain, but the aneurysm is not ruptured on CT scan. Pain may also occur in the thigh and groin because of nerve compression. Gastrointestinal, urinary and venous symptoms can also be caused by pressure from an abdominal aneurysm. About 3 per cent of all aneurysms cause pain as a result of inflammation of the aneurysm itself (Figure 56.45). Finally, a few cause symptoms from distal embolisation of fragments of their intraluminal thrombus. An operation is usually indicated in patients who are otherwise reasonably fit. Pain may be a warning sign of stretching of the aneurysm sac and imminent rupture; surgery should be performed as soon as possible (usually on the next available operating list). The operative mortality of symptomatic aneurysms is usually higher than elective cases.

Postoperative complications

The most common complications after open repair are cardiac (ischaemia and infarction) and respiratory (atelectasis and lower lobe consolidation). A degree of colonic ischaemia because of a lack of a collateral blood supply occurs in about 10 per cent of patients, but fortunately this usually resolves spontaneously. Renal failure is an uncommon event after elective procedures but may complicate procedures undertaken for rupture. Renal

catheter and arterial line are usually inserted. If the patient appears stable, surgery may be delayed until cross-matched blood is available, but surgery should commence immediately if haemodynamic instability develops and the patient collapses. The abdomen is usually prepared and draped with the patient awake. It should always be remembered that the treatment of ruptured aneurysm is operation, not monitoring and resuscitation (Summary box 56.5).

Summary box 56.5

Management of ruptured abdominal aortic aneurysm

- Early diagnosis (abdominal/back pain, pulsatile mass, shock)
- Immediate resuscitation (oxygen, intravenous replacement therapy, central line)
- Maintain systolic pressure, but not >100 mmHg, consider permissive hypotension
- Urinary catheter
- Cross-match six units of blood
- Rapid transfer to the operating theatre

Figure 56.45 An inflammatory abdominal aortic aneurysm. Note the white ‘icing’ effect. Such lesions can be technically difficult to manage.
failure is more likely if there is preoperative renal impairment or considerable intraoperative blood loss. Neurological complications include sexual dysfunction and spinal cord ischaemia. An aortoduodenal fistula is an uncommon but treatable complication of abdominal aortic replacement surgery. It should be suspected whenever haematemesis or melaena occurs in the months or years after operation. Prosthetic graft infection is also uncommon; it may require removal of the graft and limb revascularisation by insertion of an axillofemoral bypass.

Cardiac, respiratory, renal and neurological complications are less common after endovascular repair. However, there are complications that are unique to EVAR such as endoleak, graft migration, metal strut fracture and graft limb occlusion. Life-long surveillance with duplex or CT (together with plain abdominal x-ray for strut fracture) is required to detect endoleak and migration. High pressure endoleaks may require repeat ballooning or a proximal cuff or distal limb extension to reseat the endograft. Migration may also require extension of the graft. Overall, 10–20 per cent of patients with EVAR will require secondary interventions to treat complications at some future date, although many of the interventions can be performed via a percutaneous approach via the femoral artery in the angiography suite.

Peripheral aneurysm

Popliteal aneurysm

Popliteal artery aneurysm accounts for 70 per cent of all peripheral aneurysms; two-thirds are bilateral. Examination of the abdominal aorta is indicated if a popliteal aneurysm is found because one-third are accompanied by aortic dilatation. Popliteal aneurysms present as a swelling behind the knee or with symptoms caused by complications, such as severe ischaemia following thrombosis or distal ischaemia as a result of emboli. The diagnosis is usually confirmed with duplex scanning, but assessment of the distal vessels (with CT, MR or DSA) is important prior to repair if the foot pulses are diminished or absent. An asymptomatic aneurysm should be considered for elective repair to prevent future complications, especially if it exceeds 25 mm in diameter. Some surgeons would also offer elective repair if the sac contained thrombus because this may predispose to distal emboli. Surgery usually involves a medial approach to the above-knee popliteal arteries, ligation of the aneurysm and restoration of flow to the foot with a bypass graft using saphenous vein. An alternative is a posterior approach and an inlay graft.

In the acute situation, the presentation is usually with a thrombosed aneurysm and an ischaemic foot. Surgery is often unsuccessful because the distal vessels are thrombosed and difficult to clear. Attempts should be made with a Fogarty catheter and intra-arterial thrombolysis. The limb loss rate is high (50 per cent).

Femoral aneurysm

True aneurysm of the femoral artery is uncommon. Complications occur in less than 3 per cent so conservative treatment is generally indicated, but it is important to look for aneurysms elsewhere as over half are associated with abdominal or popliteal aneurysms. Large aneurysms should be repaired. False aneurysm of the femoral artery occurs in 2 per cent of patients after arterial surgery at this site. Local repair may involve reanastomosis of the bypass in the groin under suitable antibiotic cover. However, if infection is the cause, the treatment may involve excision of the infected graft and insertion of a further bypass routed around the infected area. In the latter case, the failure rate is high, and limb loss may be unavoidable. For false aneurysms caused by femoral artery puncture, thrombin injection under ultrasound guidance may be successful and avoids surgery; the alternative is arterial repair and suturing the puncture site in the artery.

iliac aneurysm

This usually occurs in conjunction with aortic aneurysm and only rarely on its own. On its own, it is difficult to diagnose clinically so about half present already ruptured. Open surgery usually involves an inlay graft, but some iliac aneurysms may be suitable for endovascular repair.

Arteriovenous fistula

Communication between an artery and a vein (or veins) may be either a congenital malformation or the result of trauma. Arteriovenous fistulae for haemodialysis access are also created surgically. All arteriovenous communications have a structural and a physiological effect. The structural effect of arterial blood flow on the veins is characteristic; they become dilated, tortuous and thick walled (arterialised). The physiological effect, if the fistula is big enough, is an increase in cardiac output. In extreme circumstances, this can cause left ventricular enlargement and even cardiac failure. A pulsatile swelling may be present if the lesion is superficial. A thrill is detected on palpation and auscultation reveals a buzzing continuous bruit (‘machinery murmur’). Dilated veins may be seen, in which there is rapid blood flow. Pressure on the artery proximal to the fistula reduces the swelling and the thrill and bruit cease.

Duplex scan and/or angiography confirms the lesion, which is noteworthy for the speed with which venous filling occurs.

Management

Treatment is by embolisation. Excisional surgery can be advocated only rarely, perhaps for severe deformity or recurrent haemorrhage; the assistance of a plastic surgeon is wise. It is important to realise that ligation of a ‘feeding’ artery on its own is of no lasting value and is actually detrimental as it may preclude treatment by embolisation.

ARTERITIS AND VASOSPASTIC CONDITIONS

Thromboangiitis obliterans (Buerger’s disease)

This is characterised by occlusive disease of small- and medium-sized arteries (plantar, tibial, radial, etc.), thrombophlebitis of the superficial or deep veins, and Raynaud’s syndrome; it occurs in male smokers, usually under the age of 30 years. Often, only one or two of the three manifestations are present. Histologically, there are inflammatory changes in the walls of arteries and veins, leading to thrombosis. Treatment is total abstinence from smoking, which arrests, but does not reverse, the disease. Established arterial occlusions are treated as for atheromatous disease, but amputations may eventually be required.
**ARTERIAL DISORDERS**

**Other types of arteritis**

Arteritis occurs in association with many connective tissue disorders, e.g. rheumatoid arthritis, systemic lupus erythematosus and polyarteritis nodosa. This is usually the province of the specialist physician, but the surgeon may be called on to carry out minor amputations. Sympathectomy has previously been used, but is usually ineffective.

Temporal arteritis is a disease in which localised infiltration with inflammatory and giant cells leads to arterial occlusion, ischaemic headache and tender, palpable, pulseless (thrombosed) arteries in the scalp. Irreversible blindness occurs if the ophthalmic artery becomes occluded. The surgeon may be required to perform a temporal artery biopsy, but this should not delay immediate steroid therapy to arrest and reverse the process before the ophthalmic artery is involved. The length of the biopsy should be at least 1 cm.

Takayasu’s disease is an arteritis that obstructs major arteries, particularly the large vessels coming off the aortic arch. It usually pursues a relentless course.

**Cystic myxomatous degeneration**

This is typified by an accumulation of clear jelly (like a synovial ganglion) in the outer layers of a main artery, especially the popliteal artery. The lesion may narrow the vessel causing claudication. Duplex scan is the investigation of choice. Decompression, by removal of the myxomatous material, is often all that is required, but the ‘ganglion’ may recur, necessitating excision of part of the artery with interposition vein graft repair.

**Raynaud’s disease**

This idiopathic condition usually occurs in young women and affects the hands more than the feet. There is abnormal sensitivity in the arteriolar response to cold. These vessels constrict and the digits (usually the fingers) turn white and become incapable of fine movements. The capillaries then dilate and fill with slowly flowing deoxygenated blood, resulting in the digits becoming swollen and dusky. As the attack passes off, the arterioles relax, oxygenated blood returns into the dilated capillaries and the digits become red. Thus, the condition is recognised by the characteristic sequence of blanching, dusky cyanosis and red engorgement, often accompanied by pain. Superficial necrosis is very uncommon. This condition must be distinguished from Raynaud’s syndrome, which has similar features (see below). Treatment of Raynaud’s disease consists of protection from cold and avoidance of pulp and nailbed infection. Calcium antagonists, such as nifedipine, may also have a role to play and electrical heating gloves can be useful in winter. Sympathectomy has previously been used in the past, but it is either ineffective or its effects are short-lived.

**Raynaud’s syndrome**

Although peripheral vasospasm may be noted in atherosclerosis, thoracic outlet syndrome, carpal tunnel syndrome, etc., the term ‘Raynaud’s syndrome’ is most often used for a peripheral arterial manifestation of a collagen disease, such as systemic lupus erythematosus or rheumatoid arthritis. The clinical features are as for Raynaud’s disease, but they may be much more aggressive. Raynaud’s syndrome may also follow the use of vibrating tools.

Treatment is directed primarily at the underlying condition, although the conservative measures outlined above are often helpful. The syndrome when secondary to collagen disease leads frequently to necrosis of digits and multiple amputations. Sympathectomy yields disappointing results and is not recommended. Nifedipine, steroids and vasospastic antagonists may all have a role in treatment. Patients with vibration white finger should avoid vibrating tools.

**Acrocyanosis**

Acrocyanosis may be confused with Raynaud’s disease, but it is painless and not episodic. It tends to affect young women and the mottled cyanosis of the fingers and/or toes may be accompanied by paraesthesia and chilblains.

**Cervical sympathectomy**

Open cervical sympathectomy was previously performed for vasospastic conditions affecting the hands and to treat palmar (sometimes axillary) hyperhidrosis. The operation is now obsolete, having been replaced by endoscopic transthoracic sympathetic sympathectomy. Furthermore, it has been increasingly recognised that the vasospastic conditions do not respond to this form of treatment, rendering the endoscopic intervention a therapy that is suitable solely for hyperhidrosis.

An endoscope, often a rigid cystoscope, is used. The ipsilateral lung may be deflated by the anaesthetist and a cannula inserted into the chest wall to permit easy access for the scope. The sympathetic chain is visualised and a coagulating electrode used to ablate the ganglia below the stellate. The scope and cannula are then removed, the lung inflated and the small chest wound closed.

**Lucbar sympathectomy**

Lumbar sympathectomy has been used to treat chronic lower limb ischaemia in the past. Lumbar sympathectomy by open operation has, however, been obsolete for several years and even chemical sympathectomy, its minimally invasive equivalent, can now be regarded as outdated. Chemical sympathectomy requires the injection of small quantities of a sclerosant into the lumbar sympathetic chain under radiographic control.

*Mikito Takayasu, 1860–1938, Japanese ophthalmologist described this disease in 1908.*
THE ANATOMY OF THE VENOUS SYSTEM OF THE LIMBS

Arterial blood flows through the main axial arteries of the upper and lower limbs before returning via the deep and superficial veins. All of the veins of the upper and lower limbs contain valves, which ensure that blood flows towards the heart.

The superficial venous trunks in the leg are the greater (long) and lesser (short or small) saphenous veins (Figure 57.1a and b), which lie above the muscle fascia of the limb. The cephalic and basilic veins are the superficial venous trunks of the arm (Figure 57.1c and d). Although the long saphenous vein is classically said to join the femoral vein at the saphenofemoral junction, a fixed point in the groin 2.5 cm below and lateral to the pubic tubercle, it is usually encountered somewhat higher. The lesser saphenous vein joins the popliteal vein at the saphenopopliteal junction at a variable site in the popliteal fossa but generally proximally to the knee joint crease. Blood passing up the superficial veins enters the deep veins at the saphenopopliteal and saphenofemoral junctions.

In the calf and thigh there are a number of valved perforating (communicating) veins that join the superficial to the deep veins at inconstant sites and which allow blood to flow from the superficial to the deep venous system. The most important of these are the direct perforating veins of the medial and lateral calf and the communicating veins around the knee and in the mid-thigh.

The deep veins of the lower limb include three pairs of venae commitantes, which accompany the three crural arteries (anterior and posterior tibial and peroneal arteries). These six veins intercommunicate and join in the popliteal fossa to form the popliteal vein, which also receives the soleal and gastrocnemius veins.

The popliteal vein passes up through the adductor hiatus to enter the subsartorial canal as the superficial femoral vein, which receives the deep (profunda) femoral vein (or veins) in the femoral triangle to become the common femoral vein, which then changes its name to the external iliac vein as it passes behind the inguinal ligament. The internal iliac vein joins with the external iliac vein in the pelvis to form the common iliac vein. The left common iliac vein passes behind the right common iliac artery to join the right common iliac vein on the right side of the abdominal aorta to form the inferior vena cava.

VENOUS PATHOPHYSIOLOGY

Blood enters the lower limb through the femoral arteries before passing through arterioles into the capillaries, which have a pressure of about 32 mmHg at their arterial ends. This pressure is reduced along the course of the capillaries and is approximately 12 mmHg at the venular end of the capillary. The pressure continues to fall in the main veins and is as low as −5 mmHg at the upper end of the vena cava where it enters the right atrium.

The venous pressure in a foot vein on standing is equivalent to the height of a column of blood extending from the heart to the foot, e.g. approximately 100 mmHg (Figure 57.2). To enable blood to be returned against gravity in the standing position, an auxiliary pump is required in the lower limb. This is the calf muscle pump, which is augmented to a lesser extent by the thigh and foot pumps. The deep veins of the calf are capacious and are joined by blind-ending sacks called the soleal sinuses, which force blood into the popliteal and crural veins during calf muscle pump contraction, e.g. walking. The foot pump also ejects blood from the plantar veins during walking. As the calf muscles contract, the veins are compressed and the valves only allow blood to pass in the direction of the heart. The pressure within the calf compartment rises to 200–300 mmHg during muscle contraction. During muscle relaxation the pressure falls and blood from the superficial veins enters the deep veins through the saphenous junctions and the perforating veins. Each time this occurs the pressure falls in the superficial venous compartment until a threshold is reached, when the venous inflow keeps pace with ejection from the deep veins. This is normally around 30 mmHg, a fall of approximately two-thirds of the resting venous pressure. The net reduction in the pressure of the superficial system is dependent on the presence of patent deep veins, perforating veins and superficial veins, which must contain competent valves. Ambulatory venous hypertension is a consequence of...
Figure 57.1 (a and b) Anatomy of the superficial and deep veins of the lower limb. [c and d] Anatomy of the superficial and deep veins of the upper limb. The innumerable branch veins and those lying within muscle are omitted. The tibial and peroneal veins of the leg are usually paired veins uniting in their upper parts.
Varicose veins

Varicose veins are defined as dilated, usually tortuous, subcutaneous veins ≥3 mm in diameter measured in the upright position with demonstrable reflux.

Epidemiology

The adult prevalence of visible varicose veins is 25–30 per cent in women and 15 per cent in men. Factors affecting prevalence include:

- gender: the vast majority of studies report a higher prevalence in women than men, the Edinburgh Vein Study being the main exception;
- age: the prevalence of varicose veins increases with age. In the Edinburgh Vein Study, the prevalence of trunk varicosities in the age groups 18–24 years, 25–34 years, 35–44 years, 45–57 years and 55–64 years was 11.5, 14.6, 28.8, 41.9 and 55.7 per cent, respectively;
- ethnicity: does seem to influence the prevalence of varicose veins;
- body mass and height: increasing body mass index and height may be associated with a higher prevalence of varicose veins;
- pregnancy: appears to increase the risk of varicose veins;
- family history: evidence supports familial susceptibility to varicose veins;
- occupation and lifestyle factors: there is inconclusive evidence regarding increased prevalence of varicose veins in smokers, patients who suffer constipation and occupations which involve prolonged standing.

Classification

The CEAP (clinical – etiology – anatomy – pathophysiology) classification for chronic venous disorders is widely utilised.

Clinical classification

- C0: no signs of venous disease
- C1: telangiectasia or reticular veins
- C2: varicose veins
- C3: oedema
- C4a: pigmentation or eczema
- C4b: lipodermatosclerosis or atrophie blanche
- C5: healed venous ulcer
- C6: active venous ulcer

Each clinical class is further characterised by a subscript depending upon whether the patient is symptomatic (S) or asymptomatic (A) e.g. C2S.

Etiologic classification

- Ec: congenital
- Ep: primary
- Es: secondary (post-thrombotic)
- En: no venous cause identified

Anatomical classification

- As: superficial veins
- Ap: perforator veins
- Ad: deep veins
- An: no venous location identified

Pathophysiological classification

- Pr: reflux
- Po: obstruction
- Pr,o: reflux and obstruction
- Pn: no venous pathophysiology identifiable

Clinical features

Symptoms

Varicose veins frequently cause symptoms, the most common being aching or heaviness, which typically increases throughout the day or with prolonged standing and is relieved by elevation or compression hosiery. Other less common symptoms include ankle swelling and itching while complications (bleeding, superficial thrombophlebitis, eczema,
lipodermatosclerosis and ulceration) represent important indications for investigation and intervention. The Edinburgh Vein Study failed to show any evidence that the extent of valvular incompetence was related to the severity of symptoms.

**Signs**

The presence of tortuous dilated subcutaneous veins are usually clinically obvious. These are confined to the long and lesser saphenous systems in approximately 60 and 20 per cent of cases, respectively. The distribution of varicosities may indicate which superficial system is defective; medial thigh and calf varicosities suggest long saphenous incompetence (Figure 57.3a), posterolateral calf varicosities are suggestive of short saphenous incompetence (Figure 57.3b), whereas anterolateral thigh and calf varicosities may indicate isolated incompetence of the proximal anterolateral long saphenous tributary (Figure 57.3c). Percussion over the varices may elicit an impulse tap by the fingers placed over the dilated trunk.

Other signs commonly found include:

- Telangiectasia, which are essentially a confluence of dilated intradermal venules <1 mm in diameter. These may be mild or severe (Figure 57.4). Synonyms include spider veins, thread veins and hyphen webs.
- Reticular veins are dilated, subdermal veins, 1–3 mm in diameter. The presence of telangiectasia and reticular veins are of dubious significance, are not necessarily associated with major varicose veins and are purely a cosmetic problem.
- In saphena varix (Figure 57.5), there is a large groin varicosity which presents as a (usually painless) lump, emergent when standing and disappearing when recumbent. Gentle palpation over the varix during coughing may elicit a thrill.
- Atrophie blanche (Figure 57.6) is localised white atrophic skin frequently surrounded by dilated capillaries and hyperpigmentation, usually seen around the ankle.
- Corona phlebectasia are fan-shaped patterns of small intradermal veins on the medial or lateral aspects of the ankle or foot. Synonyms include malleolar or ankle flares.

![Figure 57.3 Varicose veins.](image)

(a) Left leg varicose veins in the distribution of an incompetent long saphenous vein (marked for intervention). (b) Right leg varicose veins in the distribution of the short saphenous system with a recent episode of phlebitis. (c) Varicose veins in distribution of an isolated incompetent proximal anterolateral tributary of the long saphenous system with associated gaiter area skin changes.
Pigmentation (Figure 57.7) is usually a brown discolouration (because of haemosiderin deposition) of the skin, most frequently affecting the gaiter area, and may be associated with phlebitis and ulceration.

Eczema (Figure 57.8a); this is an erythematous dermatitis which may progress to blistering, weeping or scaling eruption of the skin, not to be confused with contact dermatitis (Figure 57.8b).

Dependent pitting oedema as a result of increase in volume of fluid in skin and subcutaneous tissue characteristically increases throughout the day, and is relieved by elevation and compression hosiery/bandaging. The oedema is usually confined to the ankle area but may extend to the foot and rest of the leg.

Lipodermatosclerosis (Figure 57.9) is a localised chronic inflammation and fibrosis of the skin and subcutaneous tissues of the leg, a sign of severe chronic venous disease.

Ulceration (Figure 57.10) is a full thickness epidermal defect, most frequently affecting the gaiter area.

Investigation
Tourniquet tests have now largely been abandoned. There is good evidence to support the policy of duplex ultrasound scanning for all patients with varicose veins prior to any intervention. This policy facilitates a more accurate surgical approach, reduces the incidence of varicose vein recurrence, and allows assessment regarding suitability for endovenous intervention. Clinical acumen combined with continuous wave hand-held Doppler examination will miss up to 30 per cent of important connections between superficial and deep veins and information...
on affected veins when compared to duplex scanning; thus, it
should only be utilised as the basis for intervention when duplex
scanning is not available.

Hand-held continuous wave Doppler emits a sound when
blood flows past the transmitting and receiving crystals. A uni-
phasic signal indicates flow in one direction. Forward and reverse
flow produces a biphasic signal which is indicative of blood reflux-
ing through incompetent valves. A biphasic signal following a calf
squeeze performed with the Doppler probe over the saphenofemo-
ral junction suggests the presence of junctional incompetence.
A biphasic signal over the saphenopopliteal junction or lesser
saphenous vein is not an accurate method of establishing incom-
petence of the lesser saphenous vein as its termination is variable
and it is difficult to separate lesser saphenous incompetence from
popliteal valvular incompetence. In all cases of biphasic lesser
saphenous signal a duplex scan should be performed.

**Duplex ultrasound imaging**

Duplex ultrasound imaging has become the main stay of inves-
tigation for varicose veins. A high-frequency linear array trans-
ducer of 7.5–13 MHz is appropriate for the majority of lower
limbs in order to obtain good quality images. The B mode set-
ing (depth, focal zone, overall gain and dynamic gain) should
be optimised to ensure the area of interest is in the centre and
occupies the majority of the image, and that the lumen of the
vein appears as a dark void in the subcutaneous and deep tissues.
The pulsed wave spectral or colour Doppler settings should be
optimised for the low flow velocities encountered within veins.
It is conventional to use blue to represent antegrade venous flow
towards the heart and red for the reverse. Visible venous flow
can be augmented by a calf squeeze.

The aim of the duplex scan in patients with varicose veins is
to establish:

- which saphenous junctions are incompetent and their
locations;
- the extent of reflux in the saphenous veins and their diameters;
- the number, location and diameter of incompetent perforating
veins;

Figure 57.8 Excema. (a) Erythematous dermatitis; (b) contact dermatitis.

Figure 57.9 Lipodermatosclerosis of the calf skin.

Figure 57.10 A venous ulcer.
other relevant veins that demonstrate reflux;
• the source of all superficial varices if not from the veins already described;
• the competence and evidence of previous venous thrombosis in the deep venous system.

In order to standardise measurements of venous diameter and reflux, it is recommended that examination of the superficial veins is performed with the patient standing. Venous reflux is defined as retrograde flow in the reverse direction to physiological flow lasting for more than 0.5 seconds. Reflux may be elicited by release of a calf or foot squeeze for proximal or calf varicosities respectively, manual compression over varicosity clusters, pneumatic calf cuff deflation, active foot dorsiflexion and relaxation or the Valsalva manoeuvre.

The patient should stand facing towards the examiner with the leg rotated outwards, heel on the ground and weight on the opposite limb (Figure 57.11). The scan should begin in the groin, using a transverse view to identify the long saphenous vein and common femoral vein lying medial to the common femoral artery (the 'Micky Mouse' sign – Figure 57.12). Saphenofemoral junction (SFJ) competence is assessed in the transverse view and potential destinations for reflux including the greater or long saphenous vein (LSV), the accessory anterior saphenous vein and other major thigh tributaries superficial to the saphenous fascia are noted. The full length of the LSV within its fascial compartment, known as the 'saphenous eye', should be examined (Figure 57.13), and its diameter measured just below the SFJ, mid-thigh, above and below the knee joint, mid-calf and ankle. The groin is next examined for reflux in the longitudinal plane in the common femoral vein, superficial femoral vein and SFJ using spectral and/or colour Doppler (Figure 57.14). The presence and competence of thigh and calf perforators should be noted. For examination of the lesser or short saphenous vein (SSV) and posterior thigh extension of the SSV (Giacomini vein), the patient is positioned facing away, knee slightly flexed, heel on the ground and the weight taken on the opposite leg. If the saphenopopliteal junction (SPJ) is incompetent, the level of the SPJ in relation to the knee crease and whether the SSV joins the popliteal vein posteriorly, medially or laterally is noted. In the transverse view, the SSV vein is followed distally, checking its competence and diameter in the proximal, mid and distal
calf. Finally, the patency and competence of the popliteal vein is assessed.

Very occasionally, investigations other than duplex are required, usually when duplex demonstrates reflux in superficial varicosities but fails to identify any site of junctional incompetence. Varicography involves injection of contrast directly into superficial varices which allows detailed mapping of the varices to their termination. This can be useful in patients with recurrent varicose veins or with complex anatomy (Figure 57.15). Descending intravenous venography where contrast is injected via the deep veins or magnetic resonance venography is useful when lower limb varicosities appear to arise from pelvic vein incompetence.

**Management**

Patients who have asymptomatic varicose veins can simply be reassured. Indications for referral to a vascular surgeon include C2 disease associated with bleeding, superficial thrombophlebitis or symptoms which are impairing quality of life, or C3–6 disease.

**Compression hosiery**

Compression hosiery relies on graduated external pressure to improve deep venous return. Compression hosiery can be knee length or thigh length; there is no evidence which length of stocking is more effective and hence below-knee stockings are usually prescribed as they are easier to don and have much better patient acceptance. Compression hosiery is classified according to the pressure exerted, and the British classification class 1 stockings exert pressure of 14–17 mmHg, class 2 exert 18–24 mmHg and class 3 exert 25–35 mmHg. Compression hosiery significantly improves varicose vein symptoms but is not popular with patients with compliance rates and long-term tolerance being universally poor. There is no evidence to suggest that compression hosiery prevents the occurrence or progression of varicose veins. Finally, the incorrect application of compression hosiery can have serious consequences (pressure necrosis, tourniquet effects); thus assessment, prescription and application of compression hosiery should be limited to those with the appropriate skills and training.

**Ultrasound-guided foam sclerotherapy**

Ultrasound-guided foam sclerotherapy involves the injection of detergent directly into the superficial veins. The most commonly used (and only sclerosant recognised for treatment in the UK) is sodium tetradecyl sulphate although others are available on a named patient basis. The detergent destroys the lipid membranes of endothelial cells causing them to shed, leading to thrombosis, fibrosis and obliteration (sclerosis). The procedure commences with the patient standing, and the sites of venous cannulation are selected and marked using ultrasound. Then, with the patient supine, the major venous trunks and superficial varicosities to be treated are all cannulated using ultrasound guidance (Figure 57.16). This is performed before injection as the injection quickly spreads through the superficial varicosities making further cannulation difficult. Once all injection sites are cannulated the injection can be prepared. The most widely used method is that of Tessari, which utilises two syringes connected using a three-way tap. A 1:3 or 1:4 ratio mixture of sclerosant and air is drawn into one syringe, and is then oscillated vigorously between the two syringes about 10 or 20 times (Figure 57.17). The foam produced in this way is stable for about 2 minutes so it

---

Carlo Giacomini, 1840–1898, anatomist, Turin, Italy, on his death left his skeleton to the Anatomical Museum in Turin.

Lorenzo Tessari, born 1949, an Italian physician.

William George Fegan, 1921–2007, Emeritus Professor of Surgery, Trinity College, Dublin, Ireland.
should be injected as soon as it has been made. The leg is then elevated to empty the veins of blood, and injection of foam commences first with superficial varicosities and ends with injection of the LSV or SSV. Only 1 or 2 mL of foam should be injected at a time and the distribution of the foam should be monitored and massaged with the ultrasound probe. When the foam is visualised at the site of junctional incompetence no further foam should be injected. The maximum volume of foam which should be injected at a single session should not exceed 10–12 mL as the incidence of complications are directly related to the volume of foam injected. Compression bandaging or hosiery is then applied and left in situ for 7–10 days. Sclerotherapy improves varicose vein-related symptoms, but recurrence rates and the need for reintervention are relatively high. Foam is superior to liquid sclerotherapy, as popularised by George Fegan, in achieving LSV obliteration at two years. Some complications (phlebitis, pigmentation, headache, visual disturbance, chest tightness, cough) are relatively common. There is no robust randomised controlled trial data to influence choice of sclerosant, local pressure dressings, or duration of postsclerotherapy compression. Short-term bandaging is better tolerated than more prolonged bandaging.

**Endovenous laser ablation**

Endovenous laser ablation (EVLA) as a treatment for varicose veins was first described in 2001, and involves the insertion of a laser fibre into the lumen of an incompetent truncal vein, with subsequent thermal ablation of the vein. The vast majority of patients with primary and recurrent varicose veins are suitable for EVLA, with success reported in treating the long, short and anterior saphenous veins, perforators and varicosities themselves. The factors which may preclude EVLA pertain to either the patient (unsuitable for local anaesthesia, e.g. needle phobia) or the vein (excess tortuosity, thrombophlebitis).

The procedure begins with ultrasound-guided marking of the truncal vein to be treated and the site of proposed cannulation. The varicosities are also marked at this stage if concomitant treatment (phlebectomy, foam sclerotherapy) is to be undertaken. The patient is then positioned on the procedure couch in the reverse Trendelenburg position. For the LSV, the patient is supine with the hip of the leg to be treated externally rotated and slightly flexed. A pillow under the contralateral hip/lower back may improve patient comfort. For the SSV, the patient is positioned in the prone position. The vein is then cannulated percutaneously under ultrasound guidance, at the lowest point of reflux. A wire is then passed through the needle into the superficial vein through the site of junctional incompetence into the deep vein. The catheter is then passed over the wire and positioned within 1 cm of the site of junctional incompetence. Accurate positioning of the catheter tip (and thus the laser fibre tip) with ultrasound is crucial (Figure 57.18). Following the administration of perivenous tumescent anaesthesia (Figure 57.19a and b), the laser fibre is introduced into the catheter (Figure 57.20), passed to the catheter tip and laser energy is used to ablate the vein.

The tumescent anaesthesia during EVLA provides analgesia and compresses the vein, increasing the contact area between the vein wall and laser fibre. It also protects adjacent structures (skin, nerves) by causing hydrodissection and acting as a heat sink. Dilute lidocaine with adrenaline and bicarbonate warmed to body temperature is recommended. It is important not to exceed the recommended dose.
As EVLA treats only junctional and truncal incompetence, debate exists regarding the management of varicosities. These can be managed concomitantly or sequentially by either phlebectomy or sclerotherapy. Concomitant phlebectomies (Figure 57.21) result in a more rapid improvement in disease-specific quality of life, and allow the vast majority of patients to complete treatment in a single visit. Compression and analgesia are usually recommended in the early postoperative period.

**Radiofrequency ablation**

Radiofrequency ablation (RFA) is a minimally invasive endovascular therapy that uses a bipolar catheter to generate thermal energy to ablate the vein. Preoperative planning and consent, patient positioning, tumescent anaesthesia administration and postoperative management are identical to EVLA. The main differences include vein cannulation and method of ablation. The vein to be treated is cannulated with a 7FG sheath using ultrasound guidance and the catheter is introduced through the sheath and the catheter tip positioned not within 2 cm of the incompetent junction (Figure 57.22). The catheter generates temperatures of 85–120°C, typically using a power of 2–4 W, to ablate the vein. The thermal energy can be applied continuously using a continuous pull-back technique or sequentially over 7-cm segments depending on the RFA catheter of choice. Recent trials comparing RFA and EVLA suggest the former may be associated with less pain and bruising.

The incidence of complications following endovenous interventions are low but include thromboembolic complications (<1 per cent), phlebitis (<5 per cent – reduced with non-steroidal anti-inflammatory drugs (NSAIDs) and skin burns (<2 per cent – the majority occurring in patients not given tumescence).

**Surgery**

The principles of the operation are to ligate the point of junctional incompetence and to remove the refluxing trunk and dilated tributaries. Preoperatively, a careful consent is taken, explaining the risks of infection, minor nerve injury and recurrence, and the varicose veins must be tramlined using an indelible marker pen to enable accurate identification varicosities during surgery. The operation is usually performed under general anaesthesia but locoregional anaesthesia is possible.

**Saphenofemoral ligation and long saphenous stripping**

An oblique groin incision is made at the level of and lateral to the pubic tubercle. The long saphenous vein is identified and dissected to the SFJ, which should be clearly established before the vein is divided to avoid disasters (Figure 57.23). Six LSV tributaries are normally encountered close to the SFJ, the superficial inferior epigastric vein and superficial circumflex iliac vein laterally, the deep and superficial external pudendal veins medially, and usually more distally the anterolateral and posteriomedial thigh veins, which should be ligated and divided. A flush SFJ ligation is then performed and the LSV retrogradely...
stripped to the knee. The tributary varicosities should then be avulsed through small incision along Langer’s lines, using small hooks or mosquito forceps. Closure of the cribriform fascia, with sutures or synthetic patches, over the ligated SFJ, has not been demonstrated to reduce groin recurrence. Stripping the LSV reduces the rate of reintervention for recurrent varicose veins, but it should only be stripped to knee level, as stripping to the ankle does not improve symptomatic relief, but significantly increases the risk of saphenous nerve injury.

**Saphenopopliteal junction ligation and lesser saphenous stripping**

Preoperative duplex to mark the position of the SPJ is highly recommended (Figure 57.24). The patient is positioned in the prone position, a transverse incision is made over the premarked SPJ, the fascia is divided and the SSV is exposed. The SPJ can then be formally dissected with a flush ligation or the SSV can be gently retracted and ligated as proximally as possible. No good evidence exists to favour one technique over the other, but proponents of the flush ligation would argue that it avoids leaving a stump of SSV, a common source of recurrence, while proponents of the simple SSV ligation technique argue it reduces the incidence of the most common serious complications, nerve injury and popliteal vein injury. The SSV can then either be stripped or the proximal section of the vein can be resected. Those who strip argue it reduces the incidence of recurrence while opponents feel it increases the incidence of sural nerve injury. There are no randomised trials comparing these techniques.

**Perforator ligation**

The majority of studies assessing the role of perforator ligation have been in patients with venous ulcers analysing the effects on ulcer healing, and even in this situation randomised controlled data are lacking. The role of perforator ligation in patients with uncomplicated varicose veins is even less clear. The traditional procedure described by Linton and Cockett has fallen out of favour due to the associated high incidence of wound complications. In uncomplicated varicose veins, perforators may be ligated through a small, duplex-guided incision, while in patients with skin changes, subfascial endoscopic perforator ligation may be preferred, although the benefits are unproven.

**Phlebectomies**

These may be performed following treatment of junctional incompetence and axial vein reflux or as sole treatment under...
local anaesthetic in patients with isolated tributary incompetence. Phlebectomies are usually performed through small stab incisions using small mosquito forceps and/or phlebectomy hooks which have been demonstrated to be superior in terms of bruising, pain and generic quality of life than transilluminated-powered phlebectomy (TIPP).

Complications of standard varicose vein surgery
Complications (minor and major) are reported in up to 20 per cent of patients who undergo traditional varicose vein surgery. Wound infections, the most common complication, are reduced by prophylactic antibiotics. Nerve injury is the most common serious complication. The incidence of saphenous nerve neuralgia is up to 7 per cent following LSV stripping to the knee (the incidence is higher with stripping to the ankle). The incidence of sural nerve neuropraxia and common peroneal nerve injury may be as high as 20 and 4 per cent, respectively, following SSV surgery. The incidence of venous thromboembolic complications is approximately 0.5 per cent following varicose vein surgery, however patient risk factors must be individually assessed and appropriate prophylaxis administered according to guidelines.

Comparison of interventions
Endovenous and traditional surgery for varicose veins appear equally beneficial in improving generic and disease-specific quality of life in the short to medium term. However in the early postoperative period, traditional surgery is associated with higher pain scores and analgesic requirement, and more severe disability in terms of physical, social and psychological quality of life although the clinical significance of this is unclear. Thus endovenous interventions, by minimising the immediate postoperative quality of life impairment, result in a more rapid return to work and normal activities. Adequately powered, long-term comparisons of recurrence rates following surgery and endovenous interventions are awaited.

Recurrent varicose veins
Approximately 10–20 per cent of patients who present to hospital with varicose veins have had previous intervention. Prospective data on long-term results following intervention for recurrent varicose veins are sparse and the criteria for defining recurrence are variable.

Significant clinical recurrence five to ten years following varicose vein surgery occurs in 10–35 per cent of patients, but minor/duplex detected recurrence is much more common being in the order of 70 per cent. Causes of recurrence are controversial but include: neo-revascularisation; reflux in residual axial vein; inadequate initial surgery; and new junctional reflux. Recurrence is more common following short than long saphenous vein surgery and in patients with high BMI (body mass index), while stripping of the incompetent axial vein reduces recurrence rates. Limited data suggest recurrence rates following endovenous thermal ablation may be lower and of different aetiology (axial vein recannalisation) than following surgery. Recurrent varicose veins often have an atypical distribution and duplex assessment is mandatory (Figures 57.25 and 57.26). Surgery for recurrent varicose veins is associated with a high (40 per cent) complication rate, the most common being lymph leak and wound infection, thus endovenous interventions would seem to offer an attractive alternative, where feasible.

Pelvic congestion syndrome
Pelvic congestion syndrome (PCS) is among the differential diagnoses to be considered in female patients presenting with chronic pelvic pain. PCS sufferers are typically premenopausal, multiparous women aged 20–45 years, who present with severe dull aching pelvic pain thought to be the direct result of ovarian and pelvic varicosities. The pain is usually non-cyclical, and may be precipitated by prolonged standing. Other symptoms include dysmenorrhoea, menorrhagia, rectal discomfort or urinary frequency. Signs may include tenderness over the uterus/ovaries, vulval varicosities and haemorrhoids. There may be vulval and...
Venous thrombosis

Venous thrombosis is the formation of a semi-solid coagulum within the venous system and may occur in the superficial system (usually described as superficial thrombophlebitis) or the deep system (deep venous thrombosis or DVT). Venous thrombosis of the deep veins of the leg may be complicated by the immediate risk of pulmonary embolus and sudden death. Subsequently, patients are at risk of developing a post-thrombotic limb (Figure 57.28) and venous ulceration. While DVT may occur in the upper limb, it is the leg that gives rise to the vast majority of the morbidity and subsequent complications of this condition.

Aetiology

The three factors described by Virchow over a century ago are still relevant in the development of venous thrombosis. These are:

- changes in the vessel wall (endothelial damage);
- stasis, which is diminished blood flow through the veins;
- coagulability of blood (thrombophilia).

There are many predisposing causes for venous thrombosis. These are listed in Table 57.1. The most important factor is hospital admission for the treatment of a medical or surgical condition. Injury, especially fractures of the lower limb and pelvis, pregnancy and the oral contraceptive pill are other well-recognised predisposing factors. Endothelial damage is now known to be critically important. The interaction of the endothelium with inflammatory cells, or previous deep vein damage, renders the endothelial surface hypercoagulable and less fibrinolytic.

Stasis is a predisposing factor seen in many of the conditions described in Table 57.1, especially in the postoperative period, in patients with heart failure and in those with arterial ischaemia.
A number of conditions are associated with increased coagulability of the blood (thrombophilia) (Table 57.2). Deficiencies of antithrombin, activated protein C and protein S have all been shown to predispose to venous thrombosis in young patients. Activated protein C deficiency is associated with inheritance of the factor V Leiden gene and may account for the higher incidence of venous thrombosis in Caucasian populations (being present in 6–7 per cent). It results in a small increase in the risk of venous thrombosis, although it may act in concert with some of the other predisposing factors. A thrombophilic cause should be sought in any patient presenting with an episode of venous thrombosis who gives a family history of deep vein thrombosis or in whom there is no other predisposing factor.

Although the development of deep vein thrombosis is probably multifactorial, immobility (and hence stasis) remains one of the most important factors. Deep vein thrombosis is recognised as a complication of long-haul flights and other forms of travel.

A thrombus often develops in the soleal veins of the calf, initially as a platelet aggregate. Subsequently, fibrin and red cells form a mesh until the lumen of the vein wall occludes. The coralline thrombus then progresses as a propagated loose red fibrin clot containing many red cells (Figure 57.29). This is likely to extend up to the next large venous branch and it is possible for the clot to break off and embolise to the lung as a pulmonary embolism. In this situation the embolus arising from the lower leg veins becomes detached, passes through the large veins of the limb and vena cava, through the right heart and lodges in the pulmonary arteries. This may totally occlude perfusion to all or part of one or both lungs (pulmonary embolism). Acute right heart obstruction may lead to sudden collapse and death. Lung infarction is rare as the lung has a dual blood supply (bronchial and pulmonary arteries). Moderate-sized emboli can cause pyramidal-shaped infarcts.

Pathology

A thrombus often develops in the soleal veins of the calf, initially as a platelet aggregate. Subsequently, fibrin and red cells form a mesh until the lumen of the vein wall occludes. The coralline thrombus then progresses as a propagated loose red fibrin clot containing many red cells (Figure 57.29). This is likely to extend up to the next large venous branch and it is possible for the clot to break off and embolise to the lung as a pulmonary embolism. In this situation the embolus arising from the lower leg veins becomes detached, passes through the large veins of the limb and vena cava, through the right heart and lodges in the pulmonary arteries. This may totally occlude perfusion to all or part of one or both lungs (pulmonary embolism). Acute right heart obstruction may lead to sudden collapse and death. Lung infarction is rare as the lung has a dual blood supply (bronchial and pulmonary arteries). Moderate-sized emboli can cause pyramidal-shaped infarcts.
Diagnosis

The most common presentation of a deep vein thrombosis is pain and swelling, especially in the calf – usually in one lower limb; however, bilateral deep vein thromboses are common, occurring in up to 30 per cent. When the swelling is bilateral, deep vein thromboses must be differentiated from other causes of systemic oedema, such as hypoproteinaemia, renal failure and heart failure. Some patients have no symptoms of thrombosis and may first present with signs of a pulmonary embolism, e.g. pleuritic chest pain, haemoptysis and shortness of breath. Patients may also develop shortness of breath from chronic pulmonary hypertension. Sometimes the leg appears cellulitic and, very occasionally, it may be white or cyanosed: phlegmasia alba dolens and phlegmasia cerulia dolens (Figure 57.30). Patients who present with venous gangrene (Figure 57.31) often have an underlying neoplasm.

Clinical examination for DVT is unreliable. Physical signs may also be absent. Mild pitting oedema of the ankle, dilated surface veins, a stiff calf and tenderness over the course of the deep veins should be sought. Leg pain occurs in about 50 per cent of patients with DVT but is non-specific. Homans’ sign – resistance (not pain) of the calf muscles to forcible dorsiflexion – is not specific and should not be elicited. Tenderness occurs in 75 per cent of patients but is also found in 50 per cent of patients without objectively confirmed DVT. The pain and tenderness associated with DVT does not usually correlate with the size, location or extent of the thrombus. Clinical signs and symptoms of pulmonary embolism occur in about 10 per cent of patients with confirmed DVT.

A low-grade pyrexia may be present, especially in a patient who is having repeated pulmonary emboli. Patients may have signs of cyanosis, dyspnoea, raised neck veins, a fixed split second heart sound and a pleural rub if they are having pulmonary emboli causing right heart strain, although these signs may be subtle or lacking.

Investigation

The diagnosis of deep vein thrombosis and pulmonary embolism should be established by special investigations as the symptoms and signs are non-specific and may be entirely lacking. In addition, treatment with anticoagulation is not without risk and the diagnosis must be made with reasonable certainty.

Patients who present to an Accident and Emergency department with an idiopathic thrombosis usually have a d-dimer measurement where the modified Wells score is less than 4 or there is clinical suspicion (Table 57.3). If this is greater than the normal range there is no indication for further investigation but, if raised, a duplex compression ultrasound examination of the deep veins should be performed. The deep veins of the lower limb are located and compressed. Filling defects in flow and a lack of compressibility indicate the presence of a thrombosis (Figure 57.32). This is accurate and reliable for femoral and popliteal clots but less certain in tibial vein clots.

Ascending venography, which shows a thrombus as a filling defect, is now rarely required unless other measures are being considered (Figure 57.33). Magnetic resonance imaging

---

John Homans, 1877–1957, Professor of Clinical Surgery, Harvard University Medical School, Boston, MA, USA.
William Morrant Baker, 1839–1896, surgeon, St Bartholomew’s Hospital, London, UK, described these cysts in 1877.

Pulmonary embolism is diagnosed definitively by computed tomography (CT) scanning of the pulmonary arteries, which can show filling defects in the pulmonary arteries (Figure 57.34). Pulmonary angiography is rarely required unless interventional treatment is being considered. Radionucleotide imaging has now been superseded by CT pulmonary angiography and should not normally be used.

The differential diagnosis of a deep vein thrombosis includes a ruptured Baker’s cyst, a calf muscle haematoma, a ruptured plantaris muscle, a thrombosed popliteal aneurysm and arterial ischaemia. Duplex scanning will detect many of these conditions but often patients present with non-specific pain in the calf that resolves with no firm diagnosis being made. The differential diagnosis of a pulmonary embolism includes myocardial infarction, pleurisy and pneumonia.

**Prophylaxis**

Patients who are being admitted for surgery can be graded as low, moderate or high risk (Table 57.4). Patients in the medium or high risk groups should be considered for anticoagulation prophylaxis.

Prophylactic methods can be divided into mechanical and pharmacological. A variety of mechanical methods have been tried but only the use of graduated elastic compression stockings and external pneumatic compression have been shown to be worthwhile by reducing the incidence of thrombosis.

DVT, deep venous thrombosis; PE, pulmonary embolism.
Pharmacological methods are more effective than mechanical methods at risk reduction although they carry an increased risk of bleeding. In the past, low-dose unfractionated heparin was used both intravenously and subcutaneously. Most patients now start on low molecular weight heparin given subcutaneously, with the dose based on the patient’s weight. This does not require monitoring and has a reduced risk of heparin-induced thrombocytopenia. It can be given once a day and has a lower risk of bleeding complications. Unfractionated heparin and warfarin are now rarely used in the prophylaxis of deep vein thrombosis. A combination of mechanical and pharmacological treatment with heparin can be used in patients considered at high risk.

**Treatment of a deep vein thrombosis**

Patients who are confirmed to have a deep vein thrombosis on duplex imaging should be started on subcutaneous low molecular weight heparin and rapidly anticoagulated with warfarin unless there is a specific contraindication. Warfarin is usually started at a dose of 10 mg on day 1, 10 mg on day 2 and 5 mg on day 3. A prothrombin time taken on days 2 and 3 along with a warfarin dose algorithm guides the maintenance dose of warfarin.

The great majority of patients are treated with heparin and warfarin in this way. Thrombolysis should be considered, however, in patients with an iliac vein thrombosis, especially if they are seen early and the limb is extremely swollen. Very few surgeons now carry out surgical venous thrombectomy, although it may still be attempted in patients with threatened venous gangrene and phlegmasia cerulea dolens. If performed, a venous thrombectomy should be accompanied by an arteriovenous fistula to increase venous flow through the vein that has had the thrombus removed, however the results are, at best, modest.

During thrombolysis, tissue plasminogen activator (or more usually urokinase in the United States) is administered directly into the thrombus, either via the popliteal vein or by direct puncture in the groin. New devices are being marketed that physically disrupt the thrombus at the same time as local lysis is carried out. Some thrombi can be compressed by stent grafting, allowing the venous lumen to be opened, especially in the iliac region. This technique is most useful in patients who have a malignant cause for their venous obstruction.

**Treatment of pulmonary embolus**

Most pulmonary emboli can be treated by anticoagulation and observation but severe right heart strain and shortness of breath indicate the need for fibrinolytic treatment or radiologically guided catheter embolectomy. Rarely, patients who are on the point of cardiac arrest should undergo surgical pulmonary embolectomy.

**Prophylaxis against pulmonary embolism**

In patients who are considered at high risk of embolism or when anticoagulants are contraindicated, an inferior vena cava filter may be inserted to prevent the onward passage of any emboli. Filters can also be placed in patients who continue to have pulmonary emboli despite adequate anticoagulation. A large number of different types of filter are now available, some of which are removable (temporary filters). There are no good randomised trials to determine which filter is best.

**Superficial thrombophlebitis**

This is a superficial venous thrombosis. The term ‘thrombophlebitis’ implies a major inflammatory component; however, this is rarely seen. Common causes include external trauma (especially to varicose veins), venepunctures and infusions of hyperosmolar solutions and drugs. The presence of an intravenous cannula for longer than 24–48 hours often leads to local thrombosis. Some systemic diseases, such as thrombocytopenia, malignancy, especially of the pancreas, can lead to a flitting thrombophlebitis (thrombophlebitis migrans), affecting different veins at different times. Finally, coagulation disorders, such as polycythemia, thrombocytosis and sickle cell disease are often associated, as is a concomitant thrombosis within the deep veins.

The surface vein feels solid and is tender on palpation. The overlying skin may be attached to the vein and in the early stages may be erythematous before gradually turning brown. A linear segment of vein of variable length can be easily palpated once the inflammation has died down.

A full blood count, coagulation screen and duplex scan of the deep veins should usually be obtained. Any suggestion of an associated malignancy should be investigated using appropriate endoscopy and imaging studies, such as an abdominal CT scan.

Most patients are treated with NSAIDs and the condition resolves spontaneously. Rarely, infected thrombi require incision or excision. Ligation to prevent propagation into the deep veins is almost never required, although some authors advocate saphenofemoral ligation when the thrombus is seen on ultrasound to be at the saphenofemoral junction. Associated deep vein thrombosis or thrombophlebitias are treated by anticoagulation.

**LEG ULCERATION**

Venous disease is responsible for between 60 and 70 per cent of all ulcers in the lower leg. There are many other causes of leg ulcers and these must be excluded in any patient presenting with ulceration:

- venous disease: superficial incompetence; deep venous damage (post-thrombotic);
- arterial ischaemic ulcers;
- rheumatoid ulcers;
- traumatic ulcers;
- neuropathic ulcers (diabetes);
- neoplastic ulcers (squamous cell carcinoma and basal cell carcinoma);
- infections, especially in Third World countries.

Up to 20 per cent of patients have evidence of arterial disease, which may be the sole cause of ulceration or may be a mixed factor in the development of an ulcer in association with venous disease.

**Aetiology of ulceration**

The exact pathophysiology of ulcer development has not been established. Originally, it was thought that static blood within the superficial veins led to hypoxia, which caused tissue death (stasis ulcers). This was not confirmed by investigation of venous oxygen saturation, which was found to be higher in ulcerated limbs. This led to the concept of arteriovenous fistulae, which were thought to develop in response to the high venous pressure; however, this could not be confirmed. High venous pressure was found to be associated with a pericapillary infiltrate. This includes fibrin and other proteins, which are known to lead to fibrosis. It was hypothesised that these ‘cuffs’ could act as a diffusion block.
Leukocytes were found to decrease in the venous effluent coming out of dependent limbs. This decrease in leukocyte passage was shown to increase if short-term venous hypertension was induced by application of a tourniquet. This led to the concept of white cell 'trapping', which, however, has not been confirmed by further investigation. Polymorphonuclear leukocytes were not found within the tissues but increased numbers of mast cells, monocytes and lymphocytes have been found in perilesional tissues.

Reactive oxygen species are increased in the ulcer environment and these may generate free radicals, leading to tissue damage. Proteolytic enzymes are also increased in ulcers and the fibrinolasts in the ulcer surrounds are also abnormal, being in a 'senescent' state. Growth factors may be inhibited, leading to poor repair, and their absence may also lead to ulceration. It is proving difficult to show whether any of these factors is the cause of or the result of an ulcer.

At present, ambulatory venous hypertension is the only accepted underlying cause of ulceration. This also explains why venous ulcers are never seen in the upper limb. It is important to try and define the exact mechanism of ulcer development. Venous hypertension may be the result of primary valve incompetence of the saphenous veins, incompetence of the perforating veins or incompetence or obstruction of the deep veins.

**Clinical features**

The ulcer must be carefully examined. A venous ulcer usually has a gently sloping edge and the floor contains granulation tissue covered by a variable amount of slough and exudate. Any significant elevation of the ulcer edge should indicate the need for a biopsy to exclude a carcinoma (usually a squamous cell).

The venous ulcer of the leg characteristically develops in the skin of the gaiter region, the area between the muscles of the calf and the ankle. This is the region where many of the Cockett perforators join the posterior tibial vein to the surface vein, known as the posterior arch vein. The majority of ulcers develop on the medial side of the calf but ulcers associated with lesser saphenous incompetence may develop on the lateral side of the leg. Ulcers can develop on any part of the calf skin in patients with post-thrombotic legs; however, venous ulcers rarely extend onto the foot or into the upper calf and, if there is ulceration at these sites, other diagnoses should be seriously considered. Ulcers often develop in response to minor trauma; many patients notice some itching, perhaps associated with mast cell degranulation, before the ulcers develop. Almost all venous ulcers have surrounding haemosiderosis (seen as pigmentation) and the more chronic ulcers develop lipodermatosclerosis with associated fibrosis of the subcutaneous tissue (Figure 57.10). This is manifest as thickening, pigmentation, inflammation and induration of the calf skin. The thickening comes from haemosiderin and melanin and the haemosiderin itself may be an important factor in the ulcer development.

A full examination of the front and back of the limbs with the patient standing should be carried out to assess the presence of varicosities and truncal incompetence of the saphenous systems (note that venous ulcers are not always accompanied by varicose veins).

All patients should have their pulses palpated and, if there is any doubt, their Doppler pressures should be measured. Sensation and proprioception should be assessed to exclude neuropathy, especially in diabetic patients. A careful examination of the hand and other joints may confirm the presence of rheumatoid arthritis or osteoarthritis.

**Investigation**

Most vascular surgeons will carry out a duplex scan when the patient with an ulcer is first seen to assess the state of the deep and superficial veins. The presence of reflux in these veins does not confirm a venous ulcer but supports the diagnosis in the absence of another cause and helps direct treatment.

All patients presenting for the first time with a new leg ulcer should have a full blood count, blood glucose, erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) and sickle cell test if they have an appropriate racial background. Anaemia can both cause ulcers (e.g. sickle cell disease and pernicious anaemia) and be a result of ulceration (e.g. iron deficiency anaemia and the anaemia of chronic disease). Polycythaemia is a rare cause of ulceration. An antibody screen should be obtained if the ulcer appears 'atypical' or there is any suggestion of joint disease (e.g. rheumatoid arthritis). All patients presenting with a new ulcer should have their Doppler pressures measured, unless the foot pulses are easily palpable and have been confirmed as such by a vascular specialist.

**Management**

When the diagnosis of a 'probable venous ulcer' has been made, patients are initially treated by a compression bandaging regimen, which can be applied in a specialised clinic or by a trained district or practice nurse. Patients with new ulcers should ideally be assessed in a specialised ulcer clinic to confirm the diagnosis and agree the correct treatment regimen.

Many bandaging regimens have been described but three types usually suffice. A multilayered elastic compression bandaging system has been shown to be effective (Charing Cross four-layer bandage), as has a rigid multilayered system (Steripaste™ three-layer bandage). A low-compression regimen is desirable for mixed venous/arterial ulcers. The alternative to these bandaging regimens is to apply a bland absorbent leak-proof dressing beneath a graduated elastic compression stocking (class II). Recent data suggest that this regimen may be equally effective in attaining ulcer healing.

These compression regimens are ideally applied by trained staff on a bi-weekly or weekly basis until the ulcer is starting to heal and the amount of exudate is reduced. Longer periods between dressing changes can then be instituted. At each attendance ulcer size must be measured to monitor improvement. Antibiotics do not speed ulcer healing in the absence of cellulitis and all other specific ulcer-healing drugs are of dubious validity. Failure to heal an ulcer may indicate that it has another or coexisting cause (e.g. malignancy, rheumatoid arthritis or arterial ischaemia). Biopsies are indicated if malignancy is suspected and it is important to remember that a Marjolin’s type of ulcer (a squamous cell or basal cell carcinoma) can develop in a chronic long-standing venous ulcer (Figure 57.35). Once these factors have been excluded, consideration may be given to healing the ulcer by excision and grafting in appropriate cases. A number of biological dressings have been developed, including fetal keratinocytes and collagen meshes, which have been shown to improve healing; however, they are not cost-effective for the majority of ulcers.

---

**A gaiter** is a leather or cloth covering for the lower leg and ankle. The name is derived from the French ‘gante’ for the same piece of clothing.

Frank Bernard Cockett, formerly surgeon, St Thomas’s Hospital, London, UK.

Jean-Nicholas Marjolin, 1780–1850, surgeon, Paris, France, described the development of carcinomatosus ulcers in scars in 1828.

Charing Cross. This method of treating venous ulcers was introduced at Charing Cross Hospital, London, UK.
ulcer excision with mesh grafting have been shown to provide good early healing with moderate long-term results (50 per cent healed at five years).

The Eschar trial has confirmed that surgery to sites of superficial venous incompetence does not speed ulcer healing and this practice should be abandoned unless new evidence is provided of its efficacy.

**Prevention of recurrence**

Once an ulcer has healed the patient must be re-evaluated in an attempt to prevent recurrence. Patients with normal deep veins should be offered treatment to obliterate any sites of saphenous or perforator reflux. The Eschar study has confirmed the results of other studies showing that this treatment is effective in reducing the incidence of ulcer recurrence in patients with normal deep veins. Some patients will decline treatment and others will be considered unsuitable for major interventions on their veins.

Elastic stockings (normally class II) should be prescribed for all patients with evidence of post-thrombotic deep vein damage and these remain an alternative treatment for patients with superficial venous disease who decline intervention. Although ideally these should be above-knee stockings in many cases, the pragmatist will prescribe below-knee stockings as most patients will otherwise not comply. Stockings need to be worn during the day and are a lifelong prescription. Used effectively, they will reduce the incidence of any further DVTs and reduce although not eliminate the chance of further ulceration. Studies are required to determine whether laser ablation and foam sclerotherapy are as satisfactory as surgery in achieving prolonged ulcer-free periods.

**Prognosis**

Nearly all venous ulcers can be healed but, even in those who have successful surgery or wear their stockings religiously, there is a 20–30 per cent incidence of recuralercation by five years. The greatest risk of reulceration is in the post-thrombotic leg.

**CONGENITAL VENOUS ANOMALIES**

There are four main types of anomaly:

1. aplasia;
2. hypoplasia;
3. duplication;
4. persistence of vestigial vessels.

Aplasia is most commonly seen in the inferior vena cava and has a similar presentation to the post-thrombotic limb. Membranous occlusion of the left common iliac vein (May–Thurner–Cockett syndrome) often develops where the vein passes behind the right common iliac artery (iliac vein compression syndrome). This leads to an iliac vein thrombosis, which most commonly affects the left common and external iliac veins. Membranes may also narrow the hepatic veins, which can become totally occluded, leading to a Budd–Chiari syndrome.

Hypoplasia results in a narrow vein.

Duplications are quite common, with double vena cava, femoral and renal veins; they often present as an incidental finding.

**Klippel–Trenaunay syndrome**

This is a combined anomaly of a cutaneous naevus, persistent vestigial veins with varicose veins, and soft tissue and bone hypertrophy. The condition is a mesodermal abnormality that is not familial (Figure 57.36).

Segments of the deep veins are hypoplastic or aplastic and there may be an associated obstruction of the lymphatics. The condition must be distinguished from the Parkes Weber syndrome, in which there are multiple arteriovenous fistulae causing venous hypertension, ulceration and high-output cardiac failure.

Virtually all patients with Klippel–Trenaunay syndrome should be treated conservatively with elastic compression hosiery; however, some will benefit from laser ablation of the naevus, stapling of the bones to avoid leg length discrepancy and occasional removal of large superficial varicose veins, provided the deep veins are normal. Low molecular weight heparin should be given to all patients having surgery as this syndrome is associated with an increased risk of deep vein thrombosis.

**ENTRAPMENT OF VEINS**

The axillary vein and the popliteal vein are the two veins that are most commonly compressed. The former is compressed at the thoracic outlet between the first rib and the clavicle, where it usually presents as an axillary vein thrombosis (see below) (Figure 57.37a). The latter is compressed by an abnormal insertion of the gastrocnemius muscles. Entrapment may cause discomfort and swelling of the limb during exercise before thrombosis develops. Treatment is by surgical decompression, excising the first rib or dividing the abnormal musculature of the gastrocnemius insertion.

**AXILLARY VEIN THROMBOSIS**

Thrombosis of the axillary vein may occur following excessive exercise in a patient with an anatomically abnormal thoracic outlet but is also associated with excessive muscle bulk as found

---

**Figure 57.35 A Marjolin’s ulcer (a squamous cell cancer arising in a chronic venous ulcer; arrow).**

**Figure 57.37**

George Budd, 1808–1882, Professor of Medicine, King’s College Hospital, London, UK, described this syndrome in 1845.

Hans Chiari, 1851–1916, Professor of Pathological Anatomy, Strasbourg, Germany (Strasbourg was returned to France after the end of World War I, in 1918), gave his account of this condition in 1898.
in weightlifters. The vein may be compressed by a cervical rib if this is present (Figure 57.37b). The arm is swollen and painful and, at an early stage, the thrombus can be removed by thrombolysis delivered through one of the arm veins. The vein must then be imaged to see if there is any compression on elevation of the arm. Thoracic outlet decompression can be carried out by resecting the cervical rib or first rib if this is confirmed.

VENOUS INJURY

Blunt or penetrating trauma almost always damages some small and medium-sized veins, which can be safely ignored or ligated without causing any problems. Larger axial venous channels have, in the past, been ligated when injured, but it is now recognised that these axial veins should be repaired whenever possible to reduce subsequent morbidity (pain and swelling in the tissues being drained) and limb loss when associated with a concomitant arterial injury. Many venous injuries remain undiagnosed at the time of injury (e.g. crural vein damage associated with a fractured tibia) and only present many years later when post-thrombotic changes become apparent. Venous injuries occur from both civilian and military trauma but the incidence of venous military injuries has been particularly well documented. In total, 40–50 per cent of arterial injuries have concomitant venous injuries, especially in the popliteal fossa.

Classification

Venous injuries may be lacerated, contused or torn apart by stretching (Figure 57.38). Iatrogenic injuries result from damage at the time of surgery and from punctures caused by catheter insertion by radiologists and physicians. Thrombosis, haemor-
Venous tumours

Investigations are rarely helpful and rapid exploration is usually required except in the case of unstable pelvic fractures where external fixation has dramatically improved the outcome of these injuries by stabilising the injury. Embolisation and stent grafting can have a limited role, especially if the venous injury is relatively inaccessible or an arteriovenous fistula has developed.

The patient must be adequately resuscitated, have blood cross-matched and have good intravenous access obtained via a central venous pressure line if possible, provided that there are no injuries around the neck or thorax. Gentle wound exploration, under tourniquet control when possible, should assess the extent of the injuries before the vessels are dissected out and clamped. Different types of repair are shown in Figure 57.39; the type of repair carried out depends on the extent of the venous injury, including how much venous wall has been lost or damaged. Lateral sutures and vein patches are ideal methods of repair and end-to-end anastomosis is satisfactory provided that it is not carried out under tension.

Vein replacement should be by autogenous tissue whenever possible, using vein harvested from another site, e.g. the internal jugular vein or the long saphenous vein from an undamaged limb. Artificial grafts, such as polytetrafluoroethylene (PTFE) grafts, are likely to get infected in contaminated wounds and have given poor results in recent conflicts. The use of anti-coagulants and an arteriovenous fistula to reduce the risk of thrombosis in the vein graft are controversial and depend on the associated injuries that are present. In contaminated wounds, tetanus, toxoid and antibiotics should be given. A fasciotomy should always be considered if there is a concomitant arterial and venous injury.

**Prognosis**

It is now recognised that repair of a major axial vein can be carried out with a 70–80 per cent success rate, reducing the morbidity of a combined arterial and venous injury considerably (especially limb loss). Complex repairs should not, however, be carried out if a patient’s life is at risk, when ligation may have to suffice in the short term.

**VENOUS TUMOURS**

Cystic degeneration of the vein wall is an uncommon cause of venous occlusion. It may be detected by ultrasound. The cyst may be deroofed or the venous segment excised.

**Venous malformation cavernous angioma/haemangioma**

These malformations are common, representing one end of a spectrum of arteriovenous malformations. They often affect the skin but also extend into the deep tissues, including bones and joints. They usually present with variable swelling and dilated veins beneath the skin. Occasionally, there is no visible mass and the complaint is one of pain. Haemorrhage and thrombo-phlebitis may exacerbate the pain. A soft compressible mass, which is venous in colour especially if it is under the skin, is usually present (Figure 57.40a). A dark blue tinge is often apparent even if the malformation is deeply situated. Nodules within the mass usually represent previous episodes of thrombosis. The size and extent of the haemangioma are best visualised by nuclear magnetic resonance with a short tau inversion recovery (STIR) sequence (Figure 57.40b) or CT scanning with contrast...
Venography rarely shows an abnormality, but direct puncture with contrast injection shows the connections of the malformation.

Treatment is a highly specialised area. Treatment options nowadays rarely initially involve surgical excision as once this is done future embolisation and sclerotherapy is very difficult. No treatment is entirely curative because it is difficult to remove all of the angiomatous tissue or sclerose the angioma completely. Sclerosis can be dangerous when the veins connect to the deep system, particularly near the central nervous system.

**Leiomyomas and leiomyosarcomas of the vein wall**

These are extremely rare tumours that are usually slow growing. They present with pain and a mass with signs of venous obstruction, e.g. oedema and distended veins. Duplex scanning, CT (Figure 57.41) and magnetic resonance imaging show a filling defect within the vein wall. Treatment is by resection with replacement by autogenous vein taken from another site. Rarely, a PTFE graft is required. When the tumour affects the vena cava it must be resected and replaced with a prosthetic graft.

**Figure 57.40** (a) Venous angioma of the leg. (b) Magnetic resonance with a short tau inversion recovery sequence showing angioma in white throughout the limb.

CHAPTER 58

Lymphatic disorders

LEARNING OBJECTIVES

To understand:
- The main functions of the lymphatic system
- The development of the lymphatic system
- The various causes of limb swelling
- The aetiology, clinical features, investigations and treatment of lymphoedema

INTRODUCTION

The lymphatic system was first described by Erasistratus in Alexandria more than 2000 years ago. William Hunter, in the late eighteenth century, was the first to describe the function of the lymphatic system. Starling’s pioneering work on the hydrostatic and haemodynamic forces controlling the movement of fluid across the capillary provided further insights into the function of the lymphatics. However, there is much about the lymphatic system that is not understood and debate continues over the precise aetiology of the most common abnormality of the system, namely lymphoedema.

ANATOMY AND PHYSIOLOGY OF THE LYMPHATIC SYSTEM

Functions

The principal function of the lymphatics is the return of protein-rich fluid to the circulation through the lymphaticovenous junctions in the jugular area. Thus, water, electrolytes, low molecular weight moieties (polypeptides, cytokines, growth factors) and macromolecules (fibrinogen, albumin, globulins, coagulation and fibrinolytic factors) from the interstitial fluid (ISF) return to the circulation via the lymphatics. Intestinal lymph (chyle) transports cholesterol, long-chain fatty acids, triglycerides and the fat-soluble vitamins (A, D, E and K) directly to the circulation, bypassing the liver. Lymphocytes and other immune cells also circulate within the lymphatic system.

Development and macroanatomy

In the human embryo lymph sacs develop at 6–7 weeks’ gestation as four cystic spaces, one on either side of the neck and one in each groin. These cisterns enlarge and develop communications that permit lymph from the lower limbs and abdomen to drain via the cisterna chyli into the thoracic duct, which in turn drains into the left internal jugular vein at its confluence with the left subclavian vein. Lymph from the head and right arm drains via a separate lymphatic trunk, the right lymphatic duct, into the right internal jugular vein. Lymphatics accompany veins everywhere except in the cortical bony skeleton and central nervous system, although the brain and retina possess cerebrospinal fluid and aqueous humour, respectively.

The lymphatic system comprises lymphatic channels, lymphoid organs (lymph nodes, spleen, Peyers patches, thymus, tonsils) and circulating elements (lymphocytes and other mononuclear immune cells). Lymphatic endothelial cells are derived from embryonic veins in the jugular and perimesonephric areas from where they migrate to form the primary lymph sacs and plexus. Both transcription (e.g. Prox1) and growth (e.g. VEGF-C) factors are essential for these developmental events.

Microanatomy and physiology

Lymphatic capillaries

Lymphatics originate within the ISF space from specialised endothelialised capillaries (initial lymphatics) or non-endothelialised channels such as the spaces of Disse in the liver. Initial lymphatics are unlike arteriovenous capillaries in that:
- they are blind-ended;
- they are much larger (50 µm);
- they allow the entry of molecules of up to 1000 kDa in size because the basement membrane is fenestrated, tenuous or even absent and the endothelium itself possesses intra- and intercellular pores;
- they are anchored to interstitial matrix by filaments. In the resting state, initial lymphatics are collapsed. When ISF volume and pressure increases, initial lymphatics and their pores are held open by these filaments to facilitate increased drainage.

Terminal lymphatics

Initial lymphatics drain into terminal (collecting) lymphatics
that possess bicuspid valves and endothelial cells rich in the contractile protein actin. Larger collecting lymphatics are surrounded by smooth muscle. Valves partition the lymphatics into segments (lymphangions) that contract sequentially to propel lymph into the lymph trunks.

**Lymph trunks**
Terminal lymphatics lead to lymph trunks, which have a structure similar to that of veins, namely a single layer of endothelial cells, lying on a basement membrane overlying a media comprising smooth muscle cells that are innervated with sympathetic, parasympathetic and sensory nerve endings. About 10 per cent of lymph arising from a limb is transported in deep lymphatic trunks that accompany the main neurovascular bundles. The majority, however, is conducted against venous flow from deep to superficial in epifascial lymph trunks. Superficial trunks form lymph bundles of various sizes, which are located within strips of adipose tissue, and tend to follow the course of the major superficial veins.

**Starling’s forces**
The distribution of fluid and protein between the vascular system and ISF depends on the balance of hydrostatic and oncotic pressures between the two compartments (Starling’s forces), together with the relative impermeability of the blood capillary membrane to molecules over 70 kDa. In health there is net capillary filtration, which is removed by the lymphatic system.

**Transport of particles**
Particles enter the initial lymphatics through interendothelial openings and vesicular transport through intraendothelial pores. Large particles are actively phagocytosed by macrophages and transported through the lymphatic system intracellularly.

**Mechanisms of lymph transport**
Resting ISF is negative (−2 to −6 mmH2O), whereas lymphatic pressures are positive, indicating that lymph flows against a small pressure gradient. It is believed that prograde lymphatic flow depends upon three mechanisms:

1. transient increases in interstitial pressure secondary to muscular contraction and external compression;
2. the sequential contraction and relaxation of lymphangions;
3. the prevention of reflux because of valves.

Lymphangions are believed to respond to increased lymph flow in much the same way as the heart responds to increased venous return in that they increase their contractility and stroke volume. Contractility is also enhanced by noradrenaline, serotonin, certain prostaglandins and thromboxanes, and endothelin-1. Pressures of up to 30–50 mmHg have been recorded in normal lymph trunks and up to 200 mmHg in severe lymphoedema. Lymphatics may also modulate their own contractility through the production of nitric oxide and other local mediators. Transport in the thoracic and right lymph ducts also depends upon intrathoracic (respiration) and central venous (cardiac cycle) pressures. Therefore, cardiorespiratory disease may have an adverse effect on lymphatic function.

In summary, in the healthy limb, lymph flow is largely due to intrinsic lymphatic contractility, although this is augmented by exercise, limb movement and external compression. However, in lymphoedema, when the lymphatics are constantly distended with lymph, these external forces assume a much more important functional role.

**ACUTE INFLAMMATION OF THE LYMPHATICS**
Acute lymphangitis is an infection, often caused by *Streptococcus pyogenes* or *Staphylococcus aureus*, which spreads to the draining lymphatics and lymph node (lymphadenitis) where an abscess may form. Eventually this may progress to bacteraemia or septicaemia. The normal signs of infection (rubor, calor, dolor) are present and a red streak is seen in the skin along the line of the inflamed lymphatic (Figure 58.1). The part should be rested to reduce lymphatic drainage and elevated to reduce swelling, and the patient should be treated with intravenous antibiotics based upon actual or suspected sensitivities. Failure to improve within 48 hours suggests inappropriate antibiotic therapy, the presence of undrained pus or the presence of an underlying systemic disorder (malignancy, immunodeficiency). The lymphatic damage caused by acute lymphangitis may lead to recurrent attacks of infection and lymphoedema; patients with lymphoedema are prone to so-called acute inflammatory episodes (see below).

![Figure 58.1](image)

**LYMPHOEDEMA**

**Definition**
Lymphoedema may be defined as abnormal limb swelling caused by the accumulation of increased amounts of high protein ISF secondary to defective lymphatic drainage in the presence of (near) normal net capillary filtration.

**The scope of the clinical problem**
At birth, 1 in 6000 people will develop lymphoedema with an overall prevalence of 0.13–2 per cent. The condition is not only associated with significant physical symptoms and complications but is also a frequent cause of emotional and psychological distress, which can lead to difficulties with relationships, education and work (Summary box 58.1).

Despite this significant impact on quality of life, many sufferers choose not to seek medical advice because of embarrassment and a belief that nothing can be done. Patients who do come
The ISF compartment (10–12 litres in a 70-kg man) constitutes a reservoir of fluid, proteins, growth factors, and other active substances. However, in contrast to true lymphoedema, when the primary problem is in the lymphatics, capillary filtration is normal and the oedema fluid is relatively high in protein. Of course, in a significant number of patients with oedema there is both abnormal capillary filtration and abnormal lymphatic drainage, as in chronic venous insufficiency (CVI) for example.

Lymphoedema results from lymphatic aplasia, hypoplasia, dysmaturity (reduced contractility with or without valvular insufficiency), obliteration by inflammatory, infective or neoplastic processes, or surgical extirpation. Whatever the primary abnormality, the resultant physical and/or functional obstruction leads to lymphatic hypertension and distension, with further secondary impairment of contractility and valvular competence. Lymphostasis and lymphotension lead to the accumulation in the ISF of fluid, proteins, growth factors and other active peptide moieties, glycosaminoglycans and particulate matter, including bacteria. As a consequence, there is increased collagen production by fibroblasts, an accumulation of inflammatory cells (predominantly macrophages and lymphocytes) and activation of keratinocytes. The end result is protein-rich oedema fluid, increased deposition of ground substance, subdermal fibrosis and dermal thickening and proliferation. Lymphoedema, unlike all other types of oedema, is confined to the epifascial space. Although muscle compartments may be hypertrophied because of the increased work involved in limb movement, they are characteristically free of oedema.

**Summary box 58.2**

**What every patient with lymphoedema should receive**

- An explanation of why the limb is swollen and the underlying cause
- Guidance on skin hygiene and care and the avoidance of acute infective episodes
- Antifungal prophylactic therapy to prevent athlete’s foot
- Rapid access to antibiotic therapy if necessary, hospital admission for acute infective episodes
- Appropriate instructions regarding exercise therapy
- Manual lymphatic drainage (MLD)
- Multilayer lymphoedema bandaging (MLLB)
- Compression garments and, if appropriate, specialised footwear
- Advice on diet
- Access to support services and networks

The severity of unilateral limb lymphoedema can be classified as:

- Mild: <20 per cent excess limb volume;
- Moderate: 20–40 per cent excess limb volume;
- Severe: >40 per cent excess limb volume.

**Pathophysiology**

The ISF compartment (10–12 litres in a 70-kg man) constitutes 50 per cent of the wet weight of the skin and subcutaneous tissues and, in order for oedema to be clinically detectable, its volume has to double. About 8 litres (protein concentration approximately 20–30 g/L, similar to ISF of lymph) is produced each day and travels in efferent lymphatics to lymph nodes. There, the volume is halved and the protein concentration doubled, resulting in 4 litres of lymph re-entering the venous circulation each day via efferent lymphatics. In one sense, all oedema is lymphoedema in that it results from an inability of the lymphatic system to clear the ISF compartment. However, in most types of oedema this is because the capillary filtration rate is pathologically high and overwhelms a normal lymphatic system, resulting in the accumulation of low-protein oedema fluid. In contrast, in true lymphoedema, when the primary problem is in the lymphatics, capillary filtration is normal and the oedema fluid is relatively high in protein. Of course, in a significant number of patients with oedema there is both abnormal capillary filtration and abnormal lymphatic drainage, as in chronic venous insufficiency (CVI) for example.

Lymphoedema results from lymphatic aplasia, hypoplasia, dysmaturity (reduced contractility with or without valvular insufficiency), obliteration by inflammatory, infective or neoplastic processes, or surgical extirpation. Whatever the primary abnormality, the resultant physical and/or functional obstruction leads to lymphatic hypertension and distension, with further secondary impairment of contractility and valvular competence. Lymphostasis and lymphotension lead to the accumulation in the ISF of fluid, proteins, growth factors and other active peptide moieties, glycosaminoglycans and particulate matter, including bacteria. As a consequence, there is increased collagen production by fibroblasts, an accumulation of inflammatory cells (predominantly macrophages and lymphocytes) and activation of keratinocytes. The end result is protein-rich oedema fluid, increased deposition of ground substance, subdermal fibrosis and dermal thickening and proliferation. Lymphoedema, unlike all other types of oedema, is confined to the epifascial space. Although muscle compartments may be hypertrophied because of the increased work involved in limb movement, they are characteristically free of oedema.

**Classification**

Two main types of lymphoedema are recognised:

1. **Primary lymphoedema**, in which the cause is unknown (or at least uncertain and unproven); it is thought to be caused by 'congenital lymphatic dysplasia'.
2. **Secondary or acquired lymphoedema**, in which there is a clear underlying cause.

Primary lymphoedema is usually further subdivided on the basis of the presence of family history, age of onset and lymphangiographic findings (Tables 58.1 and 58.2) (see below).

**Risk factors for lymphoedema**

Although the true risk factor profile for lymphoedema is not currently known, a number of factors are thought to predispose an individual to its development and predict progression, severity and outcome of the condition (Table 58.3).

**Symptoms and signs**

In most cases, the diagnosis of primary or secondary lymphoedema can be made and the condition can be differentiated from other causes of a swollen limb on the basis of history and exami-
Unlike other types of oedema, lymphoedema characteristically involves the foot (Figure 58.2). The contour of the ankle is lost through infilling of the submalleolar depressions, a ‘buffalo hump’ forms on the dorsum of the foot, the toes appear ‘square’ because of confinement of footwear and the skin on the dorsum of the toes cannot be pinched because of subcutaneous fibrosis (Stemmer’s sign). Lymphoedema usually spreads proximally to knee level and less commonly affects the whole leg (Figure 58.3). In the early stages, lymphoedema will ‘pit’ and the patient will report that the swelling is down in the morning. This represents a reversible component to the swelling, which can be controlled. Failure to do so allows fibrosis, dermal thickening and hyperkeratosis to occur. In general, primary lymphoedema progresses more slowly than secondary lymphoedema. Chronic eczema fungal infection of the skin (dermatophytosis) and nails (onychomycosis), fissuring, verrucae and papillae (warts) are frequently seen in advanced disease. Ulceration is unusual, except in the presence of chronic venous insufficiency.

Ab igne is Latin for ‘from fire’.
William Morrant Baker, 1839–1896, surgeon, St Bartholomew’s Hospital, London, UK, described these cysts in 1877.
Norman Treves, 1894–1964, an American surgeon. He had a special interest in male breast cancer.
Stewart and Treves reported this condition in a joint paper in 1948.

Lymphangiomas are dilated dermal lymphatics that ‘blister’ onto the skin surface. The fluid is usually clear but may be blood-stained. In the long term, lymphangiomas thrombose and fibrose, forming hard nodules that may raise concerns about malignancy. If lymphangiomas are <5 cm across, they are termed lymphangioma circumscriptum, and if they are more widespread, they are termed lymphangioma diffusum. If they form a reticulate pattern of ridges then it has been termed lymphoedema ab igne. Lymphangiomas frequently weep (lymphorrhoea, chylorrhoea), causing skin maceration, and they act as a portal for infection. Protein-losing diarrhoea, chylous ascites, chylorrhoea, chyluria and discharge from lymphangiomas suggest lymphangectasia (megalymphatics) and chylous reflux.

Ulceration, non-healing bruises and raised purple-red nodules should lead to suspicion of malignancy. Lymphangiosarcoma was originally described in postmastectomy oedema (Stewart–Treves’ syndrome) and affects around 0.5 per cent of patients at a mean onset of ten years. However, lymphangiosarcoma can develop in any long-standing lymphoedema, but usually takes longer to manifest (20 years). It presents as single or multiple bluish/red skin and subcutaneous nodules that spread to form satellite lesions, which may then become confluent. The diagnosis is usually made late and confirmed by skin biopsy. Amputation offers the best chance of survival but, even then, most patients live for less than three years. It has been suggested that lymphoedema leads to an impairment of immune surveillance and so predisposes to other malignancies, although the causal association is not as definite as it is for lymphangiosarcoma (Summary box 58.3).

Fred Waldorf Stewart, 1894–1991, Chairman of Pathology, Memorial Sloan-Kettering Hospital, New York, NY, USA. An annual award was instituted in his name by the Department of Pathology called the Fred Waldorf Stewart Award.

**Ab igne** is Latin for ‘from fire’.
William Morrant Baker, 1839–1896, surgeon, St Bartholomew’s Hospital, London, UK, described these cysts in 1877.
Norman Treves, 1894–1964, an American surgeon. He had a special interest in male breast cancer.
Stewart and Treves reported this condition in a joint paper in 1948.
It has been proposed that all cases of primary lymphoedema are due to an inherited abnormality of the lymphatic system, sometimes termed 'congenital lymphatic dysplasia'. However, it is possible that many sporadic cases of primary lymphoedema occur in the presence of a (near-)normal lymphatic system and are actually examples of secondary lymphoedema for which the triggering events have gone unrecognised. These might include seemingly trivial (but repeated) bacterial and/or fungal infections, insect bites, barefoot walking (silica), deep venous thrombosis (DVT) or episodes of superficial thrombophlebitis. In animal models, simple excision of lymph nodes and/or trunks leads to acute lymphoedema, which resolves within a few weeks, presumably because of the development of collaterals. The human condition can only be mimicked by inducing extensive lymphatic obliteration and fibrosis. Even then, there may be considerable delay between the injury and the onset of oedema. Primary lymphoedema is much more common in the legs than the arms. This may be because of gravity and a bipedal posture.
the fact that the lymphatic system of the leg is less well developed, or the increased susceptibility of the leg to trauma and/or infection. Furthermore, loss of the venoarteriolar reflex (VAR), which protects lower limb capillaries from excessive hydrostatic forces in the erect posture, with age and disease (CVI, diabetes), may be important.

Classification

Primary lymphoedema is usually classified on the basis of apparent genetic susceptibility, age of onset or lymphangiographic findings. None of these is ideal and the various classification systems in existence can appear confusing and conflicting as various terms and eponyms are used loosely and interchangeably. This has hampered research and efforts to gain a better understanding of underlying mechanisms, the effectiveness of therapy and prognosis.

Genetic susceptibility

Primary lymphoedema is often subdivided into those cases in which there appears to be a genetic susceptibility or element to the disease, and those in which there is not. The former may be further divided into those cases that are familial (hereditary), when typically the only abnormality is lymphoedema and there is a family history, and those cases that are syndromic, when the lymphoedema is only one of several congenital abnormalities and is either inherited or sporadic. Syndromic lymphoedema may be sporadic and chromosomal (Turner’s (XY karyotype), Klinefelter’s (XXY), Down’s (trisomy 21) syndrome) or clearly inherited and related to an identified or presumed single-gene defect (lymphoedema-distichiasis (autosomal dominant defect in FOXC2 gene)), or of uncertain genetic aetiology (yellow-nail and Klippel–Trenaunay–Weber’s syndromes). Familial (hereditary) lymphoedema can be difficult to distinguish from non-familial lymphoedema because a reliable family history may be unobtainable, the nature of the genetic predisposition is unknown and the genetic susceptibility may only translate into clinical disease in the presence of certain environmental factors. Although the distinction may not directly affect treatment, the patients are often concerned lest they be ‘passing on’ the disease to their children.

Two main forms of familial (hereditary) lymphoedema are recognised – Nonne–Milroy (type I) and Letessier–Meige (type II) – although it is likely that both eponymous diseases overlap and represent more than a single disease entity and genetic abnormality. Milroy’s disease is estimated to be present in 1 in 6000 live births and is probably inherited in an autosomal dominant manner with incomplete (about 50 per cent) penetrance. In some families, the condition may be related to abnormalities in the gene coding for a vascular endothelial growth factor receptor 3 (VEGFR3) on chromosome 5. The disease is characterised by brawny lymphoedema of both legs (and sometimes the genitalia, arms and face), which develops from birth or before puberty. The disease has been associated with a wide range of lymphatic abnormalities on lymphangiography. Meige’s disease is similar to Milroy’s disease, except that the lymphoedema generally develops between puberty and middle age (30 years). It usually affects one or both legs but may involve the arms. Some, but not all, cases appear to be inherited in an autosomal dominant manner. Lymphangiography generally shows aplasia or hypoplasia.

Age of onset

Lymphoedema congenita (onset at or within two years of birth) is more common in males and is more likely to be bilateral and involve the whole leg. Lymphoedema praecox (onset from 2 to 35 years) is three times more common in females, has a peak incidence shortly after menarche, is three times more likely to be unilateral than bilateral and usually only extends to the knee. Lymphoedema tarda develops, by definition, after the age of 35 years and is often associated with obesity, with lymph nodes being replaced with fibrofatty tissue. The cause is unknown. Lymphoedema developing for the first time after 50 years should prompt a thorough search for underlying (pelvic, genitalia) malignancy. It is worth noting that, in such patients, lymphoedema often commences proximally in the thigh rather than distally (Figure 58.4).

Lymphangiographic classification

Browse has classified primary lymphoedema on the basis of lymphangiographic findings (Table 58.5 and Figures 58.5 and 58.6). These findings may be related to the clinical presentations described above. Some patients with lymphatic hyperplasia possess megalymphatics in which lymph or chyle refluxes freely under the effects of gravity against the physiological direction of flow. The megalymphatics usually end in thin-walled vesicles on the skin, serous surfaces (chylous ascites, chylothorax), intestine (protein-losing enteropathy), kidney or bladder (chyluria) (Figure 58.7).

SECONDARY LYMPHOEDEMA

This is the most common form of lymphoedema. There are several well-recognised causes including infection, inflammation, neoplasia and trauma (Table 58.6).

Figure 58.4 This patient, in her sixth decade, presented with rapid onset of lymphoedema of the right leg. On further investigation she was found to have locally advanced bladder carcinoma. Note that unlike most cases of lymphoedema the swelling is greater proximally than distally.

Sir Norman Leslie Browse, formerly Professor of Surgery, the United Medical and Dental Schools of Guy’s and St Thomas’s Hospitals, London, UK; former President of the Royal College of Surgeons of England.

Filariasis
This is the most common cause of lymphoedema worldwide, affecting up to 100 million individuals. It is particularly prevalent in Africa, India and South America where 5–10 per cent of the population may be affected. The viviparous nematode *Wuchereria bancrofti*, whose only host is man, is responsible for 90 per cent of cases and is spread by the mosquito. The disease is associated with poor sanitation. The parasite enters lymphatics from the blood and lodges in lymph nodes, where it causes fibrosis and obstruction, due partly to direct physical damage and partly to the immune response of the host. Proximal lymphatics become grossly dilated with adult parasites. The degree of oedema is often massive, in which case it is termed elephantiasis (Figure 58.8). Immature parasites (microfilariae) enter the blood at night and can be identified on a blood smear, in a centrifuged specimen of urine or in lymph itself. A complement fixation test is also available and is positive in present or past infection. Eosinophilia is usually present. Diethylcarbamazine destroys the parasites but does not reverse the lymphatic changes, although there may be some regression over time. Once the infection has been cleared, treatment is as for primary lymphoedema. Public health measures to reduce mosquito breeding, protective clothing and mosquito netting may be usefully employed to combat the condition (Summary box 58.4).

- Funiculo-epididymo-orchitis

Chronic
- Lymphoedema of legs (arm, breast)
- Hydrocele
- Abdominal lymphatic varices
- Chyluria
- Lymphuria

Endemic elephantiasis (podoconiosis)

This is common in the tropics and affects more than 500,000 people in Africa. The barefoot cultivation of soil composed of alkaline volcanic rocks leads to destruction of the peripheral lymphatics by particles of silica, which can be seen in macrophages in draining lymph nodes. Plantar oedema develops in childhood and rapidly spreads proximally. The condition is prevented and its progression is slowed by the wearing of shoes.

Bacterial infection

Lymphangitis and lymphadenitis can cause lymphatic destruction that predisposes to lymphoedema complicated by further acute inflammatory episodes. Interestingly, in such patients, lymphangiography has revealed abnormalities in the contralateral, unaffected limb, suggesting an underlying, possibly inherited, susceptibility. Lymphatic and lymph node destruction by tuberculosis is also a well-recognised cause of lymphoedema, especially in developing countries.

Malignancy and its treatment

Treatment (surgery, radiotherapy) for breast carcinoma is the most common cause of lymphoedema in developed countries, but is decreasing in incidence as surgery becomes more conservative (see Chapter 53). Lymphoma may present with lymphoedema, as may malignancy of the pelvic organs and external genitalia. Kaposi’s sarcoma developing in the course of human immunodeficiency virus (HIV)-related illness may cause lymphatic obstruction and is a growing cause of lymphoedema in certain parts of the world.
VASCULAR LYMPHATIC DISORDERS

Trauma
It is not unusual for patients to develop chronic localised or generalised swelling following trauma. The aetiology is often multifactorial and includes disuse, venous thrombosis and lymphatic injury or destruction. Degloving injuries and burns are particularly likely to disrupt dermal lymphatics. Tenosynovitis can also be associated with localised subcutaneous lymphoedema, which can be a cause of troublesome persistent swelling following ankle and wrist ‘sprains’ and repetitive strain injury.

Lymphoedema and chronic venous insufficiency
It is important to appreciate the relationship between lymphoedema and CVI as both conditions are relatively common and so often coexist in the same patient, and it can be difficult to unravel which components of the patient’s symptom complex are caused by each. There is no doubt that superficial venous thrombophlebitis (SVT) and DVT can both lead to lymphatic destruction and secondary lymphoedema, especially if recurrent. Lymphoedema is an important contributor to the swelling of the postphlebitic syndrome. It has also been suggested that lymphoedema can predispose to DVT, and possible SVT, through immobility and acute inflammatory episodes. Certainly, tests of venous function (duplex ultrasonography, plethysmography) are frequently abnormal in patients with lymphoedema.

Miscellaneous conditions
Rheumatoid and psoriatic arthritis (chronic inflammation and lymph node fibrosis), contact dermatitis, snake and insect bites, and retroperitoneal fibrosis are all rare but well-documented causes of lymphoedema. Pretibial myxoedema is due to the obliteration of initial lymphatics by mucin.

Conditions mimicking lymphoedema
Factitious lymphoedema
This is caused by application of a tourniquet (a ‘rut’ and sharp cut-off is seen on examination) or ‘hysterical’ disuse in patients with psychological and psychiatric problems.

Immobility
Generalised or localised immobility of any cause leads to chronic limb swelling that can be misdiagnosed as lymphoedema, for example the elderly person who spends all day (and sometimes all night) sitting in a chair (armchair legs), the hemiplegic stroke patient and the young patient with multiple sclerosis.

Lipoedema
This presents almost exclusively in women and comprises bilateral, usually symmetrical, enlargement of the legs and, sometimes, the lower half of the body because of the abnormal deposition of fat. It may or may not be associated with generalised obesity. There are a number of features that help to differentiate the condition from lymphoedema but, of course, lipoedema may coexist with other causes of limb swelling. It has been proposed that lipoedema results from, or at least is associated with, fatty obliteration of lymphatics and lymph nodes (Summary box 58.5).

INVESTIGATION OF LYMPHOEDEMA

Are investigations necessary?
It is usually possible to diagnose and manage lymphoedema purely on the basis of history and examination, especially when the swelling is mild and there are no apparent complicating features. In patients with severe, atypical and multifactorial swelling, investigations may help confirm the diagnosis, inform management and provide prognostic information.

‘Routine’ tests
These include a full blood count, urea and electrolytes, creati-
nine, liver function tests, thyroid function tests, plasma total protein and albumin, fasting glucose, C-reactive protein, urine dipstick including observation for chyluria, blood smear for microfilariae, chest radiograph and ultrasound.

**Lymphangiography**

Direct lymphangiography involves the injection of contrast medium into a peripheral lymphatic vessel and subsequent radiographic visualisation of the vessels and nodes. It remains the 'gold standard' for showing structural abnormalities of larger lymphatics and nodes (Figure 58.9). However, it can be technically difficult, it is unpleasant for the patient, it may cause further lymphatic injury and, largely, it has become obsolete as a routine method of investigation. Few centres now perform this technique and those that do generally reserve it for preoperative evaluation of the rare patient with megalymphatics who is being considered for bypass or fistula ligation. Indirect lymphangiography involves the intradermal injection of water-soluble, non-ionic contrast into a web space, from where it is taken up by lymphatics and then followed radiographically. It will show distal lymphatics but not normally proximal lymphatics and nodes.

**Isotope lymphoscintigraphy**

This has largely replaced lymphangiography as the primary diagnostic technique in cases of clinical uncertainty. Radioactive technetium-labelled protein or colloid particles are injected into an interdigital web space and specifically taken up by lymphatics, and serial radiographs are taken with a gamma camera. The technique provides a qualitative measure of lymphatic function rather than quantitative function or anatomical detail. Quantitative lymphoscintigraphy is performed using a dynamic (exercise) component in addition to the static test and provides information on lymphatic transport.

**Computed tomography**

A single, axial computed tomography (CT) slice through the midcalf has been proposed as a useful diagnostic test for lymphoedema (coarse, non-enhancing, reticular ‘honeycomb’ pattern in an enlarged subcutaneous compartment), venous oedema (increased volume of the muscular compartment) and lipoeedema (increased subcutaneous fat). CT can also be used to exclude pelvic or abdominal mass lesions.

**Magnetic resonance imaging**

Magnetic resonance imaging (MRI) can provide clear images of lymphatic channels and lymph nodes, and can be useful in the assessment of patients with lymphatic hyperplasia. MRI can also distinguish venous and lymphatic causes of a swollen limb, and detect tumours that may be causing lymphatic obstruction.

**Ultrasound**

Ultrasound can provide useful information about venous function including DVT and venous abnormalities.

Figure 58.9 Lymphangiographic patterns of primary lymphoedema.
Pathological examination
In cases in which malignancy is suspected, samples of lymph nodes may be obtained by fine-needle aspiration, needle core biopsy or surgical excision. Skin biopsy will confirm the diagnosis of lymphangiosarcoma.

Limb volume measurement
While not helpful in the diagnosis of lymphoedema, limb volume measurement is a useful tool to determine severity of lymphoedema, guide management and assess response to treatment. Limb volume is typically measured at diagnosis, following intensive treatment and at follow up. In unilateral limb swelling the affected side can be compared to the contralateral unaffected limb. In bilateral swelling the volume of both limbs is tracked with time. Measurements are recorded in millilitres or expressed as a percentage of the normal limb. Water plethysmography (water displacement) is the ‘gold standard’ method but is limited by practicalities of measurement and hygiene issues. Other options include circumferential limb measurements and perometry (infrared light beams measure the outline of the limb to calculate volume).

MANAGEMENT OF LYMPHOEDEMA

Overview
The evaluation of the lymphoedema patient needs to be ‘holistic’ and their care delivered by a multiprofessional team comprising physical therapists, nurses, orthotists, physicians (dermatologists, oncologists, palliative care specialists), surgeons and social service professionals. Although surgery itself has a very small role, surgeons (especially those with breast and vascular interests) are frequently asked to oversee the management of these patients. Early diagnosis and institution of management are essential because at that stage relatively simple measures can be highly effective and will prevent the development of disabling late-stage disease, which is extremely difficult to treat. There is often a latent period of several years between the precipitating event and the onset of lymphoedema. The identification, education and treatment of such ‘at-risk’ patients can slow down, even prevent, the onset of disease. In patients with established lymphoedema, the three goals of treatment are to relieve pain, reduce swelling and prevent the development of complications (Summary box 58.6).

Relief of pain
On initial presentation, 50 per cent of patients with lymphoedema complain of significant pain. The pain is usually multifactorial and its severity and underlying cause(s) will vary depending on the aetiology of the lymphoedema. For example, following treatment for breast cancer, pain may arise from the swelling itself (radiation and surgery induced); nerve (brachial plexus and intercostobrachial nerve), bone (secondary deposits, radiation necrosis) and joint (arthritis, bursitis, capsulitis) disease; and recurrent disease. Treatment involves the considered use of non-opioid and opioid analgesics, corticosteroids, tricyclic antidepressants, muscle relaxants, anti-epileptics, nerve blocks, physiotherapy and adjuvant anticancer therapies (chemo-, radio- and hormonal therapy), as well as measures to reduce swelling if possible. In patients with non-cancer-related lymphoedema, the best way to reduce pain is to control swelling and prevent the development of complications. Whatever the cause, pain is a somatopsychic experience that is affected by mood and morale. These issues are important in patients with both cancer-related lymphoedema, who are concerned about recurrent disease, and non-cancer-related disease, who often have poor self-esteem and problems with body image and perception.

Control of swelling
Physical therapy for lymphoedema comprising bed rest, elevation, bandaging, compression garments, massage and exercises was first described at the end of the nineteenth century, and through the twentieth century various eponymous schools developed. Although there is little doubt that physical therapy can be highly effective in reducing swelling, its general acceptance and practice has been hampered by a lack of proper research and confusing terminology. The current preferred term is decongestive lymphoedema therapy (DLT), which comprises two phases. The first is a short intensive period of therapist-led care and the second is a maintenance phase in which the patient uses a self-care regimen with occasional professional intervention. The intensive phase comprises skin care, manual lymphatic drainage (MLD) and multi-layer lymphoedema bandaging (MLLB), and exercises. The length of intensive treatment will depend upon the disease severity, the degree of patient compliance and the willingness and ability of the patient to take more responsibility for the maintenance phase. However, weeks rather than months should be the goal.

Skin care
The patient must be carefully educated in the principles and practice of skin care. The patient should inspect the affected skin daily, with special attention paid to skinfolds, where maceration may occur. The limb should be washed daily; the use of bath oil, e.g. Balneum, is recommended as a moisturiser and the limb must be carefully dried afterwards. A hair drier on low heat is more effective and hygienic, and less traumatic, than a towel. If the skin is in good condition daily application of a bland emollient, e.g. aqueous cream, is recommended to keep the skin hydrated. If the skin is dry and flaky then a bland ointment, e.g. 50:50 white soft paraffin/liquid paraffin (WSP/LP), should be used twice daily and, if there is marked hyperkeratosis, a keratolytic agent, such as 5 per cent salicylic acid, should be added. Many
commercially available soaps, creams and lotions contain sensitisers, e.g. lanolin in E45 cream, and are best avoided as patients with lymphoedema are highly susceptible to contact dermatitis (eczema). Apart from causing intense discomfort, eczema acts as an entry point for infection. Management comprises avoidance of the allergen (patch testing may be required) and topical corticosteroids. Fungal infections are common, difficult to eradicate and predispose to acute inflammatory episodes. Chronic application of antifungal creams leads to maceration and it is better to use powders in shoes and socks. Ointment containing 3 per cent benzoic acid helps prevent athlete’s foot and can be used to use powders in shoes and socks. Ointment containing 3 per cent benzoic acid helps prevent athlete’s foot and can be used to use powders in shoes and socks.

Lymphorrhoea is uncommon and predispose to acute inflammatory episodes. Chronic applica-
tion of antifungal creams leads to maceration and it is better to use powders in shoes and socks. Ointment containing 3 per cent benzoic acid helps prevent athlete’s foot and can be used to use powders in shoes and socks. Ointment containing 3 per cent benzoic acid helps prevent athlete’s foot and can be used to use powders in shoes and socks.

Antibiotics with them and self-medicate at the first hint of antibiotic. Hospital admission is required for patients with: signs of septicaemia; continuing or deteriorating systemic signs after 48 hours of antibiotic treatment; unresolving or deteriorating local signs despite trials of first- and second-line antibiotics. Intravenous amoxycillin or benzyl penicillin with clindamycin in penicillin-allergic patients or as second-line therapy is most commonly recommended. Bed rest will reduce lymphatic drainage and the spread of infection, elevation will reduce the oedema and heparin prophylaxis will reduce the risk of DVT. Analgesia is often required but non-steroidal anti-
inflammatories (NSAIDs) should be avoided as they have been associated with increased complications including necrotising fasciitis. Any lymphatic massage should be ceased in the presence of active infection. Amoxycillin can be taken by patients who self-medicate. The use of long-term prophylactic antibiotics is not evidence based, but penicillin V 500 mg daily is probably reasonable in patients who suffer two or more attacks per year. However, the benefits of scrupulous compliance with physical therapy and skin care cannot be underestimated.

Summary box 58.7

Skin care

- Protect hands when washing up or gardening; wear a thimble when sewing
- Never walk barefoot and wear protective footwear outside
- Use an electric razor to depilate
- Never let the skin become macerated
- Treat cuts and grazes promptly (wash, dry, apply antiseptic and a plaster)
- Use insect repellent sprays and treat bites promptly with antiseptics and antihistamines
- Seek medical attention as soon as the limb becomes hot, painful or more swollen
- Do not allow blood to be taken from, or injections to be given into, an affected arm (and avoid blood pressure measurement)
- Protect the affected skin from sun (shade, high-factor sun block)
- Consider taking antibiotics if going on holiday

Apart from lymphangiosarcoma, acute inflammatory episodes are probably the most serious complications of lymphoedema and frequently lead to emergency hospital admission. About 25 per cent of primary and 5 per cent of secondary lymphoedema patients are affected. Acute inflammatory episodes start rapidly, often without warning or a precipitating event, with tingling, pain and redness of the limb. Patients feel ‘viral’ and severe attacks can lead to the rapid onset of fever, rigors, headache, vomiting and delirium. Patients who have suffered previous attacks can usually predict the onset and many learn to carry antibiotics with them and self-medicate at the first hint of trouble. This may stave off a full-blown attack and prevent the further lymphatic injury that each acute inflammatory episode causes. It is rarely possible to isolate a responsible bacterium but the majority are presumed to be caused by group A β-haemolytic streptococci and/or staphylococci. The diagnosis is usually obvious but dermatitis, thrombophlebitis and DVT are in the differential diagnosis. Oral amoxycillin is the treatment of choice with erythromycin or clarithromycin in those with penicillin allergy. Flucloxacinil should be added for those with evidence of S. aureus infection (folliculitis, crusted dermatitis). Oral clindamycin is a second line agent for those with failure to respond to initial therapy. Hospital admission is required for patients with: signs of septicaemia; continuing or deteriorating systemic signs after 48 hours of antibiotic treatment; unresolving or deteriorating local signs despite trials of first- and second-line antibiotics. Intravenous amoxycillin or benzyl penicillin with clindamycin in penicillin-allergic patients or as second-line therapy is most commonly recommended. Bed rest will reduce lymphatic drainage and the spread of infection, elevation will reduce the oedema and heparin prophylaxis will reduce the risk of DVT. Analgesia is often required but non-steroidal anti-
inflammatories (NSAIDs) should be avoided as they have been associated with increased complications including necrotising fasciitis. Any lymphatic massage should be ceased in the presence of active infection. Amoxycillin can be taken by patients who self-medicate. The use of long-term prophylactic antibiotics is not evidence based, but penicillin V 500 mg daily is probably reasonable in patients who suffer two or more attacks per year. However, the benefits of scrupulous compliance with physical therapy and skin care cannot be underestimated.

Manual lymphatic drainage

Several different techniques of MLD have been described and the details are beyond the scope of this chapter. However, they all aim to evacuate fluid and protein from the interstitial space and stimulate lymphangion contraction with decongestion of impaired lymphatic pathways and development of collateral routes. The therapist should perform MLD daily; they should also train the patient (and/or carer) to perform a simpler, modified form of massage termed simple lymphatic drainage (SLD). In the intensive phase, SLD supplements MLD and, once the maintenance phase is entered, SLD will carry on as daily massage.

Multilayer lymphoedema bandaging and compression garments

Elastic bandages provide compression, produce a sustained high resting pressure and ‘follow in’ as limb swelling reduces. However, the sub-bandage pressure does not alter greatly in response to changes in limb circumference consequent upon muscular activity and posture. By contrast, short-stretch bandages exert support through the production of a semi-rigid casing where the resting pressure is low but changes quite markedly in response to movement and posture. This pressure variation produces a massaging effect within the limb and stimulates lymph flow. Whether the aim is to provide support or compression, the pressure exerted must be graduated (100 per cent ankle/foot, 70 per cent knee, 50 per cent mid-thigh, 40 per cent groin).

Non-invasive assessment of the ankle–brachial pressure index (ABPI) using a hand-held Doppler ultrasound device is usually necessary prior to commencing any form of compression therapy, as it is rarely possible to feel pulses in the lymphoedema-tous limb. Standard MLLB and compression is used in patients with ABPI ≥0.8 and modified techniques with lower pressures in those with moderate arterial disease (ABPI 0.5–0.8). MLLB is contraindicated in severe arterial insufficiency (ABPI <0.5), uncontrolled heart failure and severe peripheral neuropathy. It is generally believed that non-elastic MLLB is preferable (and arguably safer) in patients with severe swelling during the intensive phase of DLT (Summary box 58.8), whereas compression (hosiery, sleeves) is preferable in milder cases and during the maintenance phase. MLLB is highly skilled and to be effective and safe it needs to be applied by a specially trained therapist. It is also extremely labour intensive, needing to be changed daily.
Effects of MLLB

- Reduces oedema
- Restores shape to the affected area
- Reduces skin changes (hyperkeratosis, papillomatosis)
- Eliminates lymphorrhoea
- Supports inelastic skin
- Softens subcutaneous tissues

Compression garments form the mainstay of management in most clinics. The control of lymphoedema requires higher pressures (30–40 mmHg arm, 40–60 mmHg leg) than are typically used to treat CVI. These may be reduced to 15–25 mmHg in those with moderate arterial insufficiency (Figure 58.10). Confusingly, the British (classes I: 14–17 mmHg; II: 18–24 mmHg; III: 25–35 mmHg) and international (USA) (classes I: 20–30 mmHg; II: 30–40 mmHg; III: 40–50 mmHg; IV: 50–60 mmHg) standards are different. The patient should put the stocking on first thing in the morning before rising. It can be difficult to persuade patients to comply. Putting lymphoedema-grade stockings on and off is difficult and many patients find them intolerably uncomfortable, especially in warm climates. Furthermore, although intellectually they understand the benefits, emotionally they may find wearing them presents a greater body image problem than the swelling itself.

Enthusiasm for pneumatic compression devices has waxed and waned. Unless the device being used allows the sequential inflation of multiple chambers up to >50 mmHg, it will probably be ineffective for lymphoedema. The benefits to the patient are maximised and complications are minimised if these devices are used under the direction of a physical therapist as part of an overall package of care.

Exercise

Lymph formation is directly proportional to arterial inflow and 40 per cent of lymph is formed within skeletal muscle. Vigorous exercise, especially if it is anaerobic and isometric, will tend to exacerbate lymphoedema and patients should be advised to avoid prolonged static activities, for example carrying heavy shopping bags or prolonged standing. In contrast, slow, rhythmic isotonic movements (e.g. swimming) and massage will increase venous and lymphatic return through the production of movement between skin and underlying tissues (essential to the filling of initial lymphatics) and augmentation of the muscle pumps. Exercise also helps to maintain joint mobility. Patients who are unable to move their limbs benefit from passive exercises. When at rest, the lymphoedematous limb should be positioned with the foot/hand above the level of the heart. A pillow under the mattress or blocks under the bottom of the bed will encourage the swelling to go down overnight.

Drugs
There are considerable, and scientifically inexplicable, differences in the use of specific drugs for venous disease and lymphoedema between different countries. The benzopyrones are a group of several thousand naturally occurring substances, of which the flavonoids have received the most attention. Enthusiasts will argue that a number of clinical trials have shown benefit from these compounds, which are purported to reduce capillary permeability, improve microcirculatory perfusion, stimulate interstitial macrophage proteolysis, reduce erythrocyte and platelet aggregation, scavenge free radicals and exert an anti-inflammatory effect. Detractors will argue that the trials are small and poorly controlled with short follow up and ‘soft’ end points, and that any benefits observed can be explained by a placebo effect. In the UK, oxerutins (Paroven®) are the only such drugs licensed for venous disease and none has a license for lymphoedema. Diuretics are of no value in pure lymphoedema. Their chronic use is associated with side effects, including electrolyte disturbance, and should be avoided.

With increasing understanding of lymphangiogenesis pathways there is hope that specific pharmacological targets or gene therapy may become available in the future but this remains in the very early stages at present.

Surgery
Only a small minority of patients with lymphoedema benefit from surgery. Operations fall into three categories: bypass procedures, liposuction and reduction procedures.

Bypass procedures
The rare patient with proximal ilioinguinal lymphatic obstruction and normal distal lymphatic channels might benefit, at least in theory, from lymphatic bypass. A number of methods have been described including the omental pedicle, the skin bridge (Gillies), anastomosing lymph nodes to veins (Neibulowitz) and the ileal mucosal patch (Kinmonth). More recently, direct lymphaticovenular anastomosis (LVA) has been carried out on vessels of 0.3–0.8 mm diameter using supermicrosurgical techniques. The procedures are technically demanding and not without morbidity. They are more often attempted in the upper limb following lymph node resection or radiotherapy for breast cancer. The outcomes are best in patients with earlier stages of lymphoedema for whom the majority can be controlled with best medical therapy alone. In those with later stage disease who have failed conservative management, the outcomes of LVA have generally been disappointing.

Liposuction
Liposuction has been used in the treatment of chronic lymphoedema. It is usually reserved for patients who have progressed to non-pitting oedema. Case series reported thus far have shown promising results with more than 100 per cent reduction in limb oedema volume which can be maintained by ongoing use of compression hosiery for at least one year. While liposuction appears to be safe, results of long-term efficacy and effects on the incidence of future lymphoedema complications (e.g. infection) are awaited.

Limb reduction procedures
These are indicated when a limb is so swollen that it interferes with mobility and livelihood. These operations are not ‘cosmetic’ in the sense that they do not create a normally shaped leg and are usually associated with significant scarring. Four operations have been described.

Sistrunk
A wedge of skin and subcutaneous tissue is excised and the wound closed primarily. This is most commonly carried out to reduce the girth of the thigh.

Homans
First, skin flaps are elevated, and then subcutaneous tissue is excised from beneath the flaps, which are then trimmed to size to accommodate the reduced girth of the limb and closed primarily. This is the most satisfactory operation for the calf (Figure 58.11). The main complication is skin flap necrosis. There must be at least six months between operations on the medial and lateral sides of the limb and the flaps must not pass the midline. This procedure has also been used on the upper limb, but is contraindicated in the presence of venous obstruction or active malignancy.

Figure 58.11 Homans’ procedure involves raising skin flaps to allow the excision of a wedge of skin and a larger volume of subcutaneous tissue down to the deep fascia. Surgery to the medial and lateral aspects of the leg must be separated by at least six months to avoid skin flap necrosis.

John Bernard Kinmonth, 1916–1982, surgeon, St Thomas’s Hospital, London, UK
Sir Harold Delf Gilles, 1882–1960, plastic surgeon, St Bartholomew’s Hospital, London, UK. Born in New Zealand, widely considered the ‘Father of Plastic Surgery’, started his career to better the lives of the victims of the First World War. Later he became a pioneer in ‘gender reassignment (sex change) surgery’. He was joined in private practice by his cousin, the other world famous plastic surgeon, Sir Archibald McIndoe. He excelled in most sports – cricket, rowing, golf, and was an accomplished painter.

Walter Ellis Sistrunk, 1880–1934, a surgeon in The Indian Medical Service.

Major-General Sir Richard Havelock Charles, 1887–1934, a surgeon in The Indian Medical Service.

Frederick Thompson, 1910–1975, plastic surgeon, The Middlesex Hospital, London, UK.
Thompson
This is a modification of the Homans’ procedure aimed to create new lymphatic connections between the superficial and deep systems. One skin flap is denuded (shaved of epidermis), sutured to the deep fascia and buried beneath the second skin flap (the so-called ‘buried dermal flap’) (Figure 58.12). This procedure has become less popular as pilonidal sinus formation is common. The cosmetic result is no better than that obtained with the Homans’ procedure and there is no evidence that the buried flap establishes any new lymphatic connections.

Figure 58.12 A cross-sectional representation of Thompson’s reduction operation; red arrows illustrate the buried dermal flap sutured to deep fascia.

Charles
This operation was initially designed for filariasis and involved excision of all of the skin and subcutaneous tissues down to the deep fascia, with coverage using split-skin grafts (Figure 58.13). This leaves a very unsatisfactory cosmetic result and graft failure is not uncommon. However, it does enable the surgeon to reduce greatly the girth of a massively swollen limb.

Chylous ascites and chylothorax
These are associated with megalymphatics. The diagnosis may be obvious if accompanied by lymphoedema and lymphangiomata. However, some patients develop chylous ascites and/or chylothorax in isolation, in which case the diagnosis can be confirmed by aspiration and the identification of chylomicrons in the aspirate. Cytology for malignant cells should also be carried out. A CT scan may show enlarged lymph nodes and CT with guided biopsy, laparoscopy or even laparotomy and biopsy may be necessary to exclude lymphoma or other malignancy. Lymphangiography may indicate the site of a lymphatic fistula that can be surgically ligated. Even if no localised lesion is identified, it may be possible to control leakage at laparotomy or even remove a segment of affected bowel. If the problem is too diffuse to be corrected surgically, a peritoneal venous shunt may be inserted, although occlusion and infection are important complications. Medical treatment comprising the avoidance of fat in the diet and the prescription of medium-chain triglycerides (which are absorbed directly into the blood rather than via the lymphatics) may reduce swelling. Chylothorax is best treated by pleurodesis, but this may lead to death from lymph-logged lungs as the excess lymph has nowhere to drain.

Chyluria
Filariasis is the most common cause, with chyluria occurring in 1–2 per cent of cases 10–20 years after initial infestation. It usually presents as painless passage of milky white urine, particularly after a fatty meal. The chyle may clot, leading to renal colic, and hypoproteinaemia may result. Chyluria may also be caused by ascarisis, malaria, tumour and tuberculosis. Intravenous urography and/or lymphangiography will often demonstrate the lymphourinary fistula. Treatment includes a low-fat and high-protein diet, increased oral fluids to prevent clot colic, and laparotomy and ligation of the dilated lymphatics. Attempts have also been made to sclerose the lymphatics either directly or via instrumentation of the bladder, ureter and renal pelvis.

INTRODUCTION
Abdominal symptoms are possibly the most frequent of all symptoms encountered in surgical practice. Most symptoms arise from intra-abdominal organs or systems while some may originate extra-abdominally and are then referred to the abdomen.

GATHERING INFORMATION
The first step is to obtain a history from the patient. But even before that, initial observations provide clues to the direction which the history should take; general appearance, gait, position in bed, facial expression, tone of the speech, all provide useful hints. The patient will be frightened and may well be in severe pain; therefore, the clinician should try to comfort the patient and gain their confidence, especially in cases of abdominal pain presenting as an emergency.

Obtaining a history
During the initial part of the interview with the patient, it is best to encourage the patient to explain their problem without interruption. After that, leading questions are used to fill any gaps left in the patient’s history.

Presenting complaint
One should start with an open question inviting the patient to explain their reason for seeking medical advice.

Duration of the presenting complaint
The duration of symptoms will profoundly affect the differential diagnosis. For example, abdominal pain, which lasts for a few hours, may be ureteric colic whereas long-standing abdominal pain may be more suggestive of peptic ulceration.

History of the presenting complaint
Once the patient has finished explaining their problem, leading questions should be used to support or exclude the likely diagnoses. One way to do this is to enquire exactly when the patient last felt well and then ask about all that has happened since. At this stage it should be possible to identify a likely organ or system responsible for the patient’s symptoms and come to a differential diagnosis. For example, a patient who presents with episodic loose stools, left-sided abdominal pain and sense of incomplete evacuation of bowel is likely to have pathology in the colon or rectum. In this case the relevant questions would be whether there was blood and mucus in the stools, and if there were constitutional symptoms suggestive of anaemia, malignancy and a family history of colon cancer.

Some patients may volunteer information that at first may not sound relevant but must be heeded. This is particularly important in the Asian subcontinent where people do resort to alternative medicines, which may have their own side effects.

Past history
The past history is important as it may have a bearing on the diagnosis and management. For example, control of diabetes will be difficult in the presence of intra-abdominal suppuration until the pus is drained. Some symptoms and signs may be due to comorbid conditions. A patient with abdominal pain due to gallstones may also have bilateral ankle oedema due to congestive cardiac failure. A tendency towards depression and anxiety may have an effect on the outcome of surgery.

Drug history and allergies
Some drugs will have an effect on the symptoms and signs or will have to be discontinued prior to surgery if they are not to cause complications. For example, a patient on a beta-blocker with abdominal bleeding will not have tachycardia
proportionate to the blood loss. A patient on long-term steroids will need intravenous steroids to prevent an adrenal crisis in the perioperative period.

**Social history**
The use of alcohol and illicit drugs, smoking and occupation are important. Family background will give an idea as to the possible family support that can be expected after discharge from hospital.

**Family history**
Genetic disorders including adverse reactions to anaesthetics and medications need to be recorded. Any family history of cancer, particularly in a first-degree relative, is especially important.

**Review of the systems**
A system review should highlight any comorbid disease, such as cardiac, vascular, respiratory or endocrine problems (Summary box 59.1).

**CLINICAL PRESENTATION OF ABDOMINAL PROBLEMS**

Pain, dyspepsia and alteration of bowel habit are the three common clinical presentations of pathology in the abdomen. However, it is important to be vigilant about insidious presentations of malignancies. Classic examples are right colon cancers presenting with symptoms of anaemia, malignant infiltrations of the liver with weight loss, gastric cancers with loss of appetite, abdominal lymphomas with weight loss and fever, ovarian cancers with abdominal distension, adrenal cancers with weight gain, and malignant obstructions of the extrahepatic biliary tree presenting with jaundice (Summary box 59.2).

</tr>
</tbody>
</table>

**Abdominal pain**
Pain is the most common of all abdominal symptoms. This may be due to inflammatory, infective or obstructive pathology. These can arise from abdominal viscera or be referred from a site outside the abdomen, such as the lungs as in pneumonia or the heart as in angina. Sometimes there may be abdominal pain for which no organic cause can be found, a situation labelled 'functional abdominal pain' for want of a better term. Common examples are dyspepsia or irritable bowel syndrome (IBS).

**Acute medical conditions**
Acute abdominal pain from medical conditions such as diabetic ketoacidosis and porphyrias may present as apparent surgical emergencies. It is also important to be vigilant about the atypical presentations of life-threatening abdominal problems and hidden malignancies. For example, an elderly man presenting with vague abdominal pain combined with an episode of fainting may have a leaking abdominal aortic aneurysm. Young alcoholics presenting to the Accident and Emergency department with abdominal pain and a recent history of trauma may be developing traumatic acute pancreatitis or a traumatic subcapsular haematoma of the spleen. The elderly patient presenting with a clinical picture of acute appendicitis and anaemia should arouse suspicion of a concomitant caecal cancer as a cause of obstructive appendicitis.

**Abdominal pain and dyspepsia**
The word dyspepsia is used to describe a multitude of symptoms, such as upper abdominal pain, abdominal distension, discomfort, early satiety, nausea, vomiting, heartburn, acid regurgitation and water brash; all these symptoms are referable to the upper gastrointestinal tract. They are called 'organic dyspepsias', the most common cause of which is gastro-oesophageal reflux disease. Other causes are peptic ulcer, gallstones, chronic pancreatitis and oesophagogastric cancer. However, in approximately 50 per cent of patients a definitive diagnosis cannot be made. In these cases the term 'functional dyspepsia' is used.

**Abdominal pain and change of bowel habits**
Alteration in bowel habit makes the colon the likely source of pathology. The onset, nature, duration, type of alteration (constipation or diarrhoea) and its relationship to abdominal pain will help to differentiate organic pathology causing obstruction or inflammation (colon cancer and inflammatory bowel disease) from functional conditions such as IBS. When patients complain of diarrhoea, they may imply different meanings – some use the term for loose stools, while others may mean frequent but normal stools. A long-standing increase in frequency of stools, with left-sided abdominal pain prior to defecation which eases after defecation, all points to IBS. However, if such symptoms are of short duration in an adult and are associated with blood and mucus in the stools with weight loss, a left colonic carcinoma is more likely. If a patient with such symptoms presents as an emergency with worsening abdominal pain and absolute constipation, then the most likely diagnosis is one of acute-on-chronic intestinal obstruction, from a stenotic left colon cancer. If the patient also has a distended abdomen and tenderness over the caecal area, then closed-loop obstruction with impending caecal rupture must be suspected and urgent surgery will be needed. However, a history of previous abdominal surgery changes the situation again; now, adhesions entrapping the small bowel is the most likely source of the symptoms. However, a small incarcerated femoral hernia could also be the cause. This can easily be missed, especially in an obese patient (Summary box 59.3).
PATHOPHYSIOLOGICAL BASIS OF COMMON ABDOMINAL SYMPTOMS AND SIGNS

The abdominal wall and parietal peritoneum are supplied by the somatic nervous system, while the abdominal organs and visceral peritoneum are innervated by the autonomic nervous system. Therefore pain will appear to change in position and nature as the underlying pathology spreads from a local intraperitoneal structure to the parietal peritoneum.

The skin and the muscles of the abdominal wall are supplied by the lateral and anterior cutaneous branches of the lower six intercostal nerves and the iliohypogastric and ilioinguinal nerve (Figure 59.1). The dermatome levels of the xiphoid process, umbilicus and pubis are T7, T10 and T12, respectively. The parietal peritoneum is supplied segmentally by the same nerves that innervate the overlying muscles. The central part of the diaphragmatic peritoneum is supplied by the phrenic nerve (C4); therefore, pain arising in this region is referred to the tip of the shoulder as it has the same segmental supply. The peripheral rim of the diaphragmatic peritoneum is supplied by the intercostal nerves. The obturator nerve is the chief nerve supply of the pelvic parietal peritoneum (Summary box 59.4).

Pain from the viscera is principally due to ischaemia, muscle spasm and stretching of the visceral peritoneum. Unlike somatic pain, autonomic pain is deep and poorly localised. This pain is transmitted via sympathetic fibres and so is referred to the appropriate somatic distribution of that nerve root from T1 to L2 (Figure 59.2). However, when an inflamed organ touches the parietal peritoneum, the pain becomes sharp and localises to the appropriate segmental dermatome of the abdominal wall. Pain arising from the parietal peritoneum may radiate to the back or the front along the appropriate dermatome. This referral pattern is classically seen in acute cholecystitis when an inflamed gall bladder touches the parietal peritoneum. Pain then radiates round to the back along the involved dermatome. The overlying muscle and the skin is supplied by the same nerve root, so when the patient takes a deep breath the tenderness in the right subcostal region is markedly increased, causing the patient to stop breathing; this is Murphy’s sign. In children with abdominal pain, who hold their right hip in a flexed position to obtain relief from the pain, one should suspect retrocaecal appendicitis causing irritation of the psoas muscle.
The pattern of pain distribution from the various regions of the gut is most easily understood by appreciating that the gut develops with its own nerve supply. Pain arising from the foregut is felt in the epigastric region while pain from the mid-gut, which includes the small bowel, appendix and ascending colon, is referred to the periumbilical region (Summary box 59.5).

Summary box 59.5
Specific characteristics of abdominal pain
- Visceral pain arises from ischaemia, muscle spasm and stretching of the visceral peritoneum
- Autonomic pain, deep and poorly localised, is referred to the equivalent somatic distribution of that nerve root from T1 to L2
- When an inflamed organ touches the parietal peritoneum, pain is then localised to the segmental dermatome of the abdominal wall
- The pain in the parietal peritoneum may radiate to back or front along the dermatome

Obstruction
Central colicky abdominal pain is a classical presentation of small bowel obstruction. The central distribution is because of the segmental nerve supply of the mid-gut. When the peristaltic waves hit an obstruction, the contractions increase to overcome the resistance producing the colic. The pain reaches a crescendo and then disappears in minutes when the peristaltic wave passes (Figure 59.3). This is different from that of biliary colic. When the gall bladder contracts against a stone, pain is relatively insidious in onset and reaches its peak in about half an hour and then eases off. A basal pain persists between the bouts of colic (Summary box 59.6).

Rupture and perforation of organs
The urinary bladder, gall bladder and gastrointestinal tract are hollow organs containing fluid. The gastrointestinal system also contains faeces, air and a high concentration of organisms. Trauma and ischaemia may cause perforation, leak of contents and peritonitis. Air leaking from the bowel gets trapped between the liver and abdominal wall; hence the loss of hepatic dullness, a physical sign that supports the diagnosis of perforation of a hollow viscus. Rupture of the bowel causes sudden pain. The initial site of onset of the pain may give a clue as to the organ involved and so help with the differential diagnosis. For example, the diagnosis of a perforated peptic ulcer is supported by a past history of ulcer-type pain followed by sudden onset of upper abdominal pain. In such a patient who has peritonitis the abdominal wall will not move with respiration. The patient will have thoracic respiration with shallow breathing.

The abdomen is divided into nine areas for ease of description (Figure 59.4). These regions are demarcated by the midclavicular lines in the vertical axis and by the transpyloric and transumbilical lines in the horizontal axis. Figure 59.4 also indicates some of the common organs and pathological processes that commonly cause pain experienced in these regions.

EXAMINATION OF THE ABDOMEN
Abdominal examination must be preceded by a detailed general examination of the patient as a whole. Physical examination

Figure 59.3 Time/intensity graph for the pain of obstruction. (From 25th Edition of Bailey and Love, courtesy of Mr Simon Paterson-Brown, Consultant Surgeon, Royal Infirmary of Edinburgh.)

Figure 59.4 Nine sites of abdominal pain: 1, right subcostal; 2, epigastrium; 3, left subcostal; 4, right flank; 5, periumbilical; 6, left flank loin; 7, right iliac fossa; 8, suprapubic/hypogastrium; 9, left iliac fossa. (From 25th Edition of Bailey and Love, courtesy of Mr Simon Paterson-Brown, Consultant Surgeon, Royal Infirmary of Edinburgh.)
should be systematic using the following sequence: inspection, palpation, percussion and auscultation (Summary box 59.7).

### Summary box 59.7

**Inspection of abdomen**

- Kneel beside the bed with eyes level with patient’s anterior abdominal wall
- Look for skin colour changes (Grey Turner and Cullen’s signs)
- Look for surgical scars
- Check for lumps and distended veins and pulsation
- Watch the abdomen move with respiration
- Intra-abdominal lumps vanish or become less prominent when the patient tenses the abdominal wall by lifting the head from the bed

**General examination**

Observation of the patient’s general condition is useful even before starting to take the history, especially in the emergency situation. If a patient resorts to the knee–elbow position to get relief from pain, it indicates that the pain is of pancreatic origin (Figure 59.5). In the outpatient clinic, a patient with loose clothing (most likely caused by significant weight loss) may well have an underlying malignant process. The differential diagnosis will include tuberculosis, Crohn’s disease or chronic pancreatitis. In a patient with anaemia, a clinician should check for nodes in the supraclavicular region from gastric cancer, other nodal masses from lymphoma, as well as a caecal mass and malignant hepatomegaly when the liver will be large with hard nodules. Bilateral lower limb oedema is a significant finding, which may point to heart, liver or renal failure as well as obstruction of the veins in the pelvis (Summary box 59.8).

**Summary box 59.8**

**Sources of physical signs in abdominal examination**

- Malignancy, tuberculosis, Crohn’s disease and chronic pancreatitis should be suspected in a patient who appears to have lost weight
- Occult gastrointestinal bleeding from chronic peptic ulceration and right colon cancers should be excluded in patients with anaemia
- The cause of bilateral lower limb oedema may be in the heart, liver, kidneys or in venous obstruction in the pelvis

**Inspection**

Scars, distension, peristalsis, masses, dilated veins, pulsations and abdominal wall swellings suggestive of hernia should all be carefully sought. In an abdominal emergency look for Grey Turner’s sign – skin discoloration of flanks due to retroperitoneal haemorrhage in severe acute pancreatitis and leaking abdominal aortic aneurysm. The other cause of skin colour change is Cullen’s sign – discoloration around the umbilicus from severe acute pancreatitis, ruptured ectopic pregnancy or trauma to the liver. In these situations blood tracks to the umbilicus along the ligamentum teres (Figure 59.6).

In a patient with acute abdominal pain, always check to see if the abdominal wall moves with respiration. If only the thorax moves then peritonitis should be suspected. Visible abdominal masses, mobility on respiration and peristalsis are all best observed by the clinician kneeling by the patient’s bed so that the observer’s eye is at the level of the patient’s anterior abdominal wall. The same position is useful during palpation for abdominal masses (Figure 59.7).

**Figure 59.5** Classical position adopted to ease pancreatic pain (patient with chronic pancreatitis).

**Figure 59.6** Cullen’s and Grey Turner’s sign of skin discolouration of flanks and around umbilicus (courtesy of Mr Pradip Datta, Honorary Consultant Surgeon, Wick, Scotland).

George Grey Turner, 1877–1951, Professor of Surgery, the University of Durham (1927–1934) and at the Royal Postgraduate Medical School, Hammersmith Hospital, London, UK (1935–1946). He had the surgical club, Grey Turner Surgical Club, named after him. It is said that he dressed shabbily so that when his friends met him they used to ask him to ‘mend the clock’. He had a habit of keeping his cup of tea warm by covering it with his bowler hat!

Thomas Stephen Cullen, 1868–1953, Professor of Gynaecology, the Johns Hopkins University, Baltimore, MD, USA, described the sign in ruptured ectopic pregnancy in 1916.
Palpation

Palpation should be performed in a systematic manner checking all nine regions of the abdomen (Figure 59.4). Palpation is started in the region furthest away from the site of pain. The examiner should observe the patient’s facial expression throughout. It may help to divert the patient’s attention by having a conversation. Watch their face so that you spot discomfort immediately. A relaxed patient with a pillow under the flexed knees makes the procedure easier. A gentle approach and warm hands will allay the patient’s fears. Palpate superficially to identify tender areas then follow this with deep palpation. Take special care wherever tenderness is found in superficial palpation. Finally, palpation during respiration is performed to identify those structures like the liver and spleen which move with respiration.

Signs of parietal peritoneal irritation (tenderness, guarding, rebound tenderness, rigidity)

In the presence of abdominal pain, the degree of abdominal wall rigidity and involuntary guarding should be assessed. Guarding represents contraction of the abdominal wall muscles over the area of pain. This might occur ‘voluntarily’ when the patient wishes to avoid the pain from examination, or ‘involuntarily’ when the muscles go into spasm as the inflamed viscus touches the parietal peritoneum. This produces a reflex spasm of the overlying abdominal wall muscles. The presence of rebound tenderness indicates underlying peritoneal inflammation and is best examined using gentle percussion, although pain on coughing is also found when there is rebound tenderness. When the underlying peritoneal inflammation becomes generalised, the abdomen is ‘board-like rigid’ to palpation, and selective tenderness can no longer be elicited. This sign represents widespread involuntary guarding. The progression from tenderness, guarding, rebound tenderness are all stages in the evolution of generalised peritonitis.

Abdominal masses

A mass arising from the anterior abdominal wall will usually be mobile when the patient is relaxed. On contracting the abdominal wall muscles (ask the patient to lift their legs with the knees extended, or by a Valsalva manoeuvre for laterally placed swellings), lumps superficial to the abdominal wall muscles will become more obvious, and those attached to the deep fascia will become less mobile. Those arising within the muscle layer will become fixed and remain unchanged in site. Lumps arising deep to the abdominal wall (i.e. within the peritoneal cavity or behind the peritoneum) will become impalpable or less prominent on tensing the anterior abdominal wall muscles.

Intraperitoneal lumps in contact with the diaphragm will move on respiration (i.e. swellings arising from liver, gall bladder, spleen, stomach, kidneys and suprarenals). Retroperitoneal masses are usually fixed and certainly do not move with respiration; an enlarged kidney is ‘ballotable’ and bimanually palpable. Normal aortic pulsations can be both seen and felt in a thin abdomen, but expansile pulsation is characteristic of an abdominal aortic aneurysm. This should be differentiated from transmitted pulsation of a mass sitting on the aorta (e.g. pseudocyst of the pancreas).

When ‘palpating during inspiration’, the examining hand is placed distal to the normal site of the organ, and is held there until the edge of the organ descends and touches the examiner’s fingers (Figure 59.8). Liver, spleen, gall bladder and kidneys are best palpated during inspiration.

In the female an abdominal mass, whose lower limit cannot be made out, must be arising from the pelvis. If the mass can be moved in a transverse direction, then it is likely to be an uterine or ovarian mass (Figure 59.9). If the lower limit of an abdominal mass is palpable and it is mobile, then it will be an intra-abdominal mass; the origin of this mass will be dependent upon the site (Figure 59.10) and the pathology dependent upon the clinical features as a whole. If a mass is of recent origin overlying a laparoscopic scar, without any signs of inflammation, consider a secondary metastasis of an intra-abdominal malignancy (Figure 59.11).

Spleen

In a healthy patient the spleen is not palpable. The enlarged spleen descends downwards, forwards and medially. Palpation
for an enlarged spleen is best performed in a supine patient. The examining hand should start in the right lower abdomen, with the tips of the fingers pointing upwards and pressed inwards. The patient is then asked to take a deep breath, and if the spleen is enlarged the lower edge with the characteristic notch will touch the fingers. If it is not palpable, then the hand is gradually moved upwards in the direction of the position of the edge of the normal-sized spleen with each breath. If the spleen is still not palpable, the patient is moved to the right lateral position and the examination repeated.

Liver

In a supine patient, the hand is placed in line with the potential enlarged liver edge lateral to the rectus muscle (Figure 59.8). The patient is then asked to take a deep breath. If the liver is enlarged sufficiently below the costal margin, then surface irregularities can also be felt.

Percussion

Percussion helps to distinguish distension due to bowel gas from free fluid in the abdomen and solid masses. Percussion is most sensitive when the examiner moves from resonant parts of the abdomen to dull ones. In patients with free fluid in the peritoneal cavity, percussion from the centre to the periphery reveals dullness of flanks. Shifting dullness is elicited if the patient is re-examined lying on their side. The margin of dullness is then found to shift when the patient has moved.

Percussion is a very sensitive and refined method of testing for rebound tenderness. If the patient winces with pain on abdominal percussion it denotes underlying peritonitis.

Auscultation

High-pitched bowel sounds are heard during early stages of mechanical intestinal obstruction. Aortic and iliac bruits are heard when blood flows through a stenosis. A succussion splash is a sound like ‘shaking a half-filled bottle with water’ and is found most often in patients with gastric stasis due to gastric outlet obstruction. In generalised peritonitis, bowel sounds will not be heard or be very few and far between.

Inspection of hernial sites, examination of genitalia, inspection of anal region and digital rectal examination

Abdominal examination is not complete until all external hernial sites and the anal area have been carefully inspected, the genitalia examined and a digital rectal examination performed. A vaginal examination will also be needed in females. The spine and renal angles should be examined.

VALUE OF OBSERVATION AND REVIEW

In the case of acute abdominal pain, there will be a group of patients in whom, after full clinical assessment, the surgeon is still uncertain about the need for an urgent operation. This is probably the most difficult group to deal with compared with those in whom an urgent operation is either clearly required, or clearly not required, and undoubtedly the one in which the majority of errors occur. Further urgent investigations are obviously important in this group and these are discussed in some detail elsewhere in this book. However, while these are taking place, a period of observation with regular review is essential. This period of observation has now become an integral part of the early management of patients with acute abdominal pain.
LEARNING OBJECTIVES

To know and understand:
- Basic anatomy of the abdominal wall and its weaknesses
- Causes of abdominal hernia
- Types of hernia and classifications
- Clinical history and examination findings in hernia
- Complications of abdominal hernia
- Nonsurgical and surgical management of hernia
- Complications of hernia surgery
- Other abdominal wall conditions

THE ABDOMINAL WALL

Basic anatomy and function related to pathology

The abdominal wall is a complex structure composed primarily of muscle, bone and fascia. Its major function is to protect the enclosed organs of the gastrointestinal and urogenital tracts but a secondary role is mobility, being able to flex, extend, rotate and vary its capacity. Flexibility requires elasticity and stretch which compromise abdominal wall strength.

The roof of the abdomen is formed by the diaphragm separating the thoracic cavity above with negative pressure from the abdomen below with positive pressure. Weakness of the diaphragm can lead to much of the bowel being drawn into the chest down this pressure gradient. The bony pelvis forms the floor of the cavity but a muscular central portion, the perineum, may also weaken and allow rectum, bladder and gynaecological organs to bulge downwards, a condition called prolapse.

The overall design of the abdominal muscles is best seen on a transverse computed tomography (CT) scan through the mid-abdomen. Posteriorly the muscles are strong, further supported by the vertebral column, ribs and pelvis. Two regions called the posterior triangles represent areas of weakness which can lead to rare lumbar hernias. Laterally there are three thin muscle layers whose fibres criss-cross for strength and flexibility. Surgeons can make use of these layers, by making releasing incisions, separating the layers and then sliding one layer on another to increase girth and allow closure of defects in the centre of the abdomen, e.g. the ‘Ramirez slide’ used in large incisional hernia repair (Figure 60.1).

Anteriorly the two powerful rectus abdominus muscles extend vertically from ribs to pelvis. Herniation through these strong muscles does not occur naturally but their central join, the linea alba, is an area of weakness resulting in epigastric and paraumbilical herniation. Divarification of the recti is the condition where the linea alba stretches laterally as the two rectus muscles separate. It occurs in the upper abdomen in middle-aged, overweight men (Figure 60.2) but also as a result of birth trauma in the female when it occurs below the umbilicus.

Abdominal pressure

The positive pressure within the abdomen is used by a surgeon when drains are placed to allow blood, pus, bile, bowel content and urine to flow outwards down the pressure gradient. However, this constant pressure from within can also lead to the condition of abdominal hernia where tissue, meant to be within the abdominal cavity, is forced outwards through defects in the muscular wall.

ABDOMINAL HERNIA

A hernia is the bulging of part of the contents of the abdominal cavity through a weakness in the abdominal wall.
Anatomical causes of abdominal wall herniation

Despite the complex design of the abdominal wall, the only natural weaknesses caused by inadequate muscular strength are the lumbar triangles and the posterior wall of the inguinal canal (Figure 60.3).

Many structures pass into and out of the abdominal cavity creating weakness which can lead to hernia formation. The most common example is the inguinal canal in the male along which the testis descends from abdomen to scrotum at the time of birth. The testicular artery, veins and vas pass through this canal (the round ligament in the female). The resultant weakness leads to an indirect or lateral-type inguinal hernia. In adult surgery, 80 per cent of all hernia repairs are for inguinal hernia. The evolutionary advantage of testicular descent must outweigh the disadvantage of a high risk of herniation. Other examples are: oesophagus → hiatus hernia, femoral vessels → femoral hernia, obturator nerve → obturator hernia, sciatic nerve → sciatic hernia.

An inguinal hernia (indirect) also occurs through the developmental failure of the processus vaginalis to close. As the testis descends, it pulls a tube of peritoneum along with it. This tube should naturally fibrose and become obliterated but often it fails to fibrose and allows a hernia to form. Recent studies have shown that calcitonin gene-related peptide and hepatocyte growth factor influence the closure of the processus raising the possibility of a hormonal cause of hernia development.

Failure of normal development may lead to weakness of the abdominal wall. Examples are diaphragmatic, umbilical and epi-gastric hernias. Muscles which should unite during development fail to form strong unions with hernia development at birth or in later life.

Herniation at the umbilicus has both components, i.e. weakness due to structures passing through the abdominal wall in fetal life and developmental failure of closure.

The risk of inguinal hernia is related to the anatomical shape of the pelvis and is higher in patients having a wider and shorter pelvis.

Weakness of abdominal muscles may be the result of sharp trauma. Most commonly, this results from abdominal surgery but also occurs after stabbing. A surgical scar, even with perfect wound healing, has only 70 per cent of the initial muscle strength. This loss of strength can result in herniation in at least 10 per cent of surgical incisions. Smaller laparoscopic port-site incisions have a hernia rate of 1 per cent. Increasing use of this surgical approach should lead to a fall in the incidence of incisional hernia.

Muscle damage by blunt trauma or tearing of the abdominal muscles requires exceptional force and is rare.

The sudden presence of a mass in the rectus muscle may be a rectus sheath haematoma, occasionally due to trauma but nowadays more often due to excessive anticoagulation therapy.

Primary muscle pathology and neurological conditions can lead to muscle weakness and occasionally present to the surgeon as a ‘hernia’ (Summary box 60.1).

Summary box 60.1

Causes of hernia
■ Basic design weakness
■ Weakness due to structures entering and leaving the abdomen
■ Developmental failures
■ Genetic weakness of collagen
■ Sharp and blunt trauma
■ Weakness due to ageing and pregnancy
■ Primary neurological and muscle diseases
■ ? Excessive intra-abdominal pressure

Pathophysiology of hernia formation

A normal abdominal wall has sufficient strength to resist high abdominal pressure and prevent herniation of content. Herniation has been attributed to high pressures from constipation, prostatic symptoms, excessive coughing in respiratory disease and obesity. However, it has been shown that hernia is no more common in Olympic weight lifters than the general population, suggesting that high pressure is not a major factor in causing a hernia. Many patients will first notice a hernia after excessive straining.

There is good evidence that hernia is a ‘collagen disease’ and due to an inherited imbalance in the types of collagen. This is supported by histological evidence and relationships between hernia and other diseases related to collagen, such as aortic aneurysm.
Hernia development is more common in pregnancy due to hormonally induced laxity of pelvic ligaments. It is also more common in the elderly due to degenerative weakness of muscles and fibrous tissue. A recent Swedish report has shown that inguinal hernia is less common in obese patients with hernia risk being negatively related to body mass index (BMI) contrary to widespread belief. Hernia is more common in smokers.

**Common principles in abdominal hernia**

An abdominal wall hernia has two essential components, a defect in the wall and content, that is tissue which has been forced outwards through the defect. The weakness may be entirely in muscle, such as an incisional hernia. It may also be in fascia, like an epigastric hernia through the linea alba. It may have a bony component, such as a femoral hernia. The weakness in the wall is usually the narrowest part of the hernia which expands into the subcutaneous fat outside of the muscle. The defect varies in size and may be very small or indeed very large. The nature of the defect is important to understanding the risk of hernia complications. A small defect with rigid walls traps the content and prevents it from freely moving in and out of the defect, increasing the risk of complications.

The content of the hernia may be tissue from the extraperitoneal space alone, such as fat within an epigastric hernia or urinary bladder in a direct inguinal hernia. However, if such a hernia enlarges then peritoneum may also be pulled into the hernia secondarily along with intraperitoneal structures such as bowel or omentum; a good example is a ‘sliding type’ of inguinal hernia.

More commonly, when peritoneum is lying immediately deep to the abdominal wall weakness, pressure forces the peritoneum through the defect and into the subcutaneous tissues. This ‘sac’ of peritoneum allows bowel and omentum to pass through the defect. In most cases, the intraperitoneal organs can move freely in and out of the hernia, a ‘reducible’ hernia, but if adhesions form or the defect is small, bowel can become trapped and unable to return to the main peritoneal cavity, an ‘irreducible’ hernia, with high risk of further complications. The narrowest part of the sac, at the abdominal wall defect, is called the ‘neck of the sac’.

When tissue is trapped inside a hernia it is in a confined space. The narrow neck acts as a constriction ring impeding venous return and increasing pressure within the hernia. Resulting tension leads to pain and tenderness. If the hernia contains bowel then it may become ‘obstructed’, partially or totally. If the pressure rises sufficiently, arterial blood is not able to enter the hernia and the contents become ischaemic and may infarct. The hernia is then said to have ‘strangulated’. The wall of the bowel perforates, releasing infected, toxic bowel content into the tissues and ultimately back into the peritoneal cavity. The risk of strangulation is highest in hernias which have a small neck of rigid tissue leading first to irreducibility and on to strangulation. The term ‘incarcerated’ is not clearly defined and used to imply a hernia which is irreducible and developing towards strangulation (Summary box 60.2).

In a special circumstance (Richter’s hernia) only part of the bowel wall enters the hernia. It may be small and difficult or even impossible to detect clinically. Bowel obstruction may not be present but the bowel wall may still become necrotic and perforate with life-threatening consequences. Femoral hernia may present in this way often with diagnostic delay and high risk to the patient (Figure 60.4).

An interstitial hernia occurs when the hernia extends between the layers of muscle and not directly through them. This is typical of a Spigelian hernia (see below under Spigelian hernia).

An internal hernia is a term used when adhesions form within the peritoneal cavity leading to abnormal pockets into which bowel can enter and become trapped. As there is no defect within the abdominal wall, the term ‘hernia’ is confusing.

**Clinical history and diagnosis in hernia cases**

Patients are usually aware of a lump on the abdominal wall under the skin. Self-diagnosis is common. The hernia is usually painless but patients may complain of an ache or heavy feeling. Sharp, intermittent pains suggest pinching of tissue. Severe pain should alert the surgeon to a high risk of strangulation.

One should determine whether the hernia reduces spontaneously or needs to be helped. The patient should be asked about symptoms which might suggest bowel obstruction.

It is important to know if this is a primary hernia or whether it is a recurrence after previous surgery. Recurrent hernia is more difficult to treat and may require a different surgical approach.

General questions regarding the cardiac and respiratory systems are necessary to assess a patient’s anaesthetic risk.

In a male with a groin hernia, history of prostatic symptoms indicates a high risk of postoperative urinary retention.

Intake of anticoagulants such as warfarin is important as this impacts on future surgery. Many hernia operations can be performed as a day case or single overnight stay, so that suitability for such treatment needs to be assessed, including home support, distance from the hospital, mobility levels, etc.

**Examination for hernia**

The patient should be examined lying down initially and then standing as this will usually increase hernia size. In some
cases no hernia will be apparent with the patient lying. The patient is asked to cough, when an occult hernia may appear. Divarification is best seen by asking a supine patient to simply lift his head off the pillow.

The overlying skin is usually of normal colour. If bruising is present this may suggest venous engorgement of the content. If there is overlying cellulitis then hernia content is strangulating and the case should be treated as an emergency.

In most cases a cough impulse is felt. Gentle pressure is applied to the lump and the patient is asked to cough. If an impulse is felt this is due to increased abdominal pressure being transmitted into the hernia. In cases where the neck is tight and the hernia irreducible there may be no cough impulse. This can lead to failure of diagnosis and is typical of femoral hernia where lack of an impulse leads the clinician to misdiagnose a lymph node. Cough impulse can also occur in a saphena varix (see Chapter 57) which may be referred to a surgeon as a suspected inguinal hernia. It is not unusual for a patient to describe an intermittent swelling but the surgeon finds nothing on examination. This is due to muscle tightening in an anxious patient (Summary boxes 60.3 and 60.4).

If, on lying, the hernia does not reduce spontaneously, the surgeon asks the patient to attempt reduction as he may be well practised in this task while the surgeon might cause unnecessary discomfort. If neither the patient nor surgeon can reduce the hernia then treatment is more urgent. An irreducible hernia may influence the decision between open and laparoscopic surgery. With the hernia reduced, the surgeon assesses the size, rigidity and number of defects. Multiple defects may be present in incisional hernia.

**Investigations for hernia**

For most hernias, no specific investigation is required, the diagnosis being made on clinical examination. However, the patient may have symptoms suggesting a hernia but no hernia is found or have a swelling suggestive of hernia but with clinical uncertainty. It is important to be certain that any symptoms described are due to a hernia and not to coexisting pathology. There may also be a requirement for more detailed information than can be found by examination alone. Plain x-ray of the abdomen is of little value (Figure 60.5) although a hiatus hernia and diaphragmatic hernia may be seen on chest x-ray. Ultrasound scan may be helpful in cases of irreducible hernia, where the differential diagnosis includes a mass or fluid collection, or when the nature of the hernia content is in doubt. Ultrasound is very useful in the early postoperative period when a haematoma or seroma may develop and be difficult to distinguish from an early recurrence. Ultrasound is non-invasive and low cost but operator dependent.

Computed tomography scanning is helpful in complex incisional hernia, determining the number and size of muscle defects, identifying the content, giving some indication of presence of adhesions and excluding other intra-abdominal pathology such as ascites, occult malignancy, portal hypertension, etc. Contrast barium radiology is occasionally useful in the absence of CT. Contrast may also be injected directly into the peritoneum, a herniagram, to identify an occult sac, especially in occult inguinal hernia. Magnetic resonance imaging (MRI) can help in the diagnosis of sportsman’s groin where pain is the presenting feature and the surgeon needs to distinguish an occult hernia from an orthopaedic injury.

Laparoscopy itself may be used. In incisional hernia, initial laparoscopy may determine that a laparoscopic approach is feasible or not depending on the extent of adhesions. In inguinal hernia repair by the transabdominal route, initial laparoscopy can determine the presence of an occult contralateral hernia which has been described in up to 20 per cent of patients (Summary box 60.5).

**Summary box 60.3**

**Checks**
- Reducibility
- Cough impulse
- Tenderness
- Overlying skin colour changes
- Multiple defects/contralateral side
- Signs of previous repair
- Scrotal content for groin hernia
- Associated pathology

**Summary box 60.4**

**Examination**
- A swelling with a cough impulse is not necessarily a hernia
- A swelling with no cough impulse may still be a hernia

**Summary box 60.5**

**Investigations**
- Plain x-ray – of little value
- Ultrasound scan – low cost, operator dependent
- CT scan – incisional hernia
- MRI scan – good in sportsman’s groin with pain
- Contrast radiology – especially for inguinal hernia
- Laparoscopy – useful to identify occult contralateral inguinal hernia
Management principles

An abdominal wall hernia does not necessarily require repair. A patient may request surgery for relief of symptoms of discomfort, cosmesis or to establish the diagnosis when in doubt. The surgeon should recommend repair when complications are likely, the most worrying being strangulation with bowel obstruction and bowel infarction. All cases of femoral hernia, with high risk of strangulation, should be repaired surgically. Any case of irreducible hernia, especially where there is pain and tenderness, should be offered repair unless coexisting medical factors place the patient at very high risk from surgery or anaesthesia. Increasing difficulty in reduction and increasing size are indications for surgery. Surgery should be offered to younger adult patients as symptoms and complications are likely over time (Summary box 60.6).

Summary box 60.6

Management

- Not all hernias require surgical repair
- Small hernias can be more dangerous than large
- Pain, tenderness and skin colour changes imply high risk of strangulation
- Femoral hernia should always be repaired

In reality, most patients with a hernia should be offered repair. In the elderly, if the hernia is asymptomatic, small in size, can be reduced easily and is not causing anxiety then observation alone should be sufficient. This policy, called ‘watchful waiting’ has been studied in asymptomatic inguinal hernia. One study reported such a policy to be safe but a second study was abandoned when a small number of patients developed strangulation. A truss can be used to control a hernia but few surgeons would recommend this approach. Small paraumbilical hernias are often seen. They cause few symptoms and usually contain fat or omentum with a very low risk of complications.

Large incisal hernias, particularly recurrent, present a major problem. Surgical repair is a complex procedure with significant risk of complications and later recurrence. When the neck is wide, the risk of strangulation is low. In the obese and elderly patient, these risks may outweigh the benefits of surgery and it is common for surgeons to adopt a conservative approach.

Any patient who presents with acute pain in a hernia, particularly if irreducible, should be offered surgery. Often, in a patient with an irreducible hernia, after admission to hospital and adequate analgesia, the hernia will reduce due to muscle relaxation. The likelihood of similar episodes is very high and surgery should be recommended at this admission or soon after.

Operative approaches to hernia

All surgical repairs follow the same basic principles:

1. reduction of the hernia content into the abdominal cavity with removal of any non-viable tissue and bowel repair if necessary;
2. excision and closure of a peritoneal sac if present or replacing it deep to the muscles;
3. reapproximation of the walls of the neck of the hernia if possible;
4. permanent reinforcement of the abdominal wall defect with sutures or mesh.

Reduction of hernia content is essential for a successful repair. It is rare that a surgeon fails to reduce the hernia but extensive dissection can lead to bowel injury sometimes requiring bowel resection with subsequent risks of infection and bowel anastomotic complications.

Excision and closure of the peritoneal sac is ideal but not essential. During laparoscopic repair of incisional hernia, surgeons will often leave the sac in situ after reducing hernia contents and simply fix a mesh over the neck to prevent recurrence. There is risk of fluid formation within the sac (seroma). This is a common complication in all forms of hernia repair. In lateral (indirect) inguinal hernia, most surgeons excise the peritoneal sac but some leading experts recommend that it be dissected from surrounding tissue and simply pushed back through the deep inguinal ring. In laparoscopic repair of inguinal hernias, surgeons simply pull the sac back into the abdominal cavity from within and do not excise it.

Closure of the abdominal wall defect is ideal but may not be possible when the defect is large or when tissues are rigid. Plastic surgical techniques have been developed to ‘borrow’ tissue from elsewhere in order to cover large muscle defects but usually at the cost of leaving a weak area elsewhere. Over the past 20 to 30 years, surgeons have realised that simple closure of a hernia defect by sutures alone leads to a high recurrence rate.

Additional reinforcement of the defect with a non-absorbable mesh is now widely practised in most hernia repairs and evidence has shown that recurrence rates have improved but recurrence still remains a problem. A recent large-scale study reported that mesh repair delays but does not prevent recurrence. With improved surgical techniques and new meshes it is hoped that recurrence after surgery will fall further. Mesh repair has become so important in hernia surgery that some understanding of mesh technology is essential for the modern surgeon.

Mesh in hernia repair

The term ‘mesh’ refers to prosthetic material, either a net or a flat sheet which is used to strengthen a hernia repair. Mesh can be used:

- to bridge a defect: the mesh is simply fixed over the defect as a tension-free patch;
- to plug a defect: a plug of mesh is pushed into the defect;
- to augment a repair: the defect is closed with sutures and the mesh added for reinforcement.

A well-placed mesh should have good overlap around all margins of the defect, at least 2 cm but up to 5 cm if possible. Suturing a mesh edge-to-edge into the defect (inlay), with no overlap, is not recommended. Mesh plug repairs have gained some popularity in small defects especially where overlap is hard to achieve. Plug operations are fast but plugs can form a dense ‘meshoma’ of plug and collagen. Other complications include migration, erosion into adjacent organs, fistula formation and chronic pain.

Mesh types

The wide array of meshes available can be classified as follows.

Gross structure

Net meshes are woven or knitted. Flat sheets are not porous but can be perforated with multiple holes. Net meshes allow fibrous tissue in growth between the strands and becoming
adherent and integrated into host tissues within a few months. Initial fixation of the mesh is by glue, sutures or staples which may be absorbable. In laparoscopic inguinal hernia, no fixation is required at all as friction is sufficient to hold the mesh. ‘Sheet’ meshes do not allow host tissue in growth but become encapsulated by fibrous tissue. They always require strong, non-absorbable fixation to prevent mesh migration.

**Synthetic mesh**

The majority of meshes used today are synthetic polymers of polypropylene, polyester or polytetrafluoroethylene (PTFE) (Figure 60.6a,b). They are non-absorbable and provoke little tissue reaction. Polypropylene makes a strong monofilament mesh. It does not have any antibacterial properties but its hydrophobic nature and monofilament microstructure impede bacterial ingrowth. Polyester is a braided filament mesh. This structure may allow infection to take hold, aided by its hydrophilic property. However this property also allows rapid vascular and cellular infiltration within the fibrils aiding host immune responses to infection and providing a stronger host–tissue interface. PTFE meshes are flat sheets and as a result do not allow any tissue ingrowth. They are used as a non-adhesive barrier between tissue layers.

**Weight and porosity**

Synthetic meshes are very strong and early meshes were much stronger than a human abdominal wall so are considered as ‘over-engineered’. All meshes provoke a fibrous reaction. More dense or heavyweight meshes provoke a greater reaction leading to collagen contraction and stiffening. The term ‘mesh shrinkage’ is often used to describe a progressive decrease in size of a mesh over time. It is due to natural contraction of fibrous tissue embedded in the mesh, reducing the area of mesh itself. This can lead to tissue tension and pain, a common complication of mesh repair. It can also lead to hernia recurrence if the mesh no longer covers the defect. Meshes can shrink by up to 50 per cent and, in occasional cases, even more. Meshes with thinner strands and larger spaces between them, ‘lightweight, large-pore meshes’, are preferred as they have better tissue integration, less shrinkage, more flexibility and improved comfort.

The terms ‘light, medium and heavy’ are not precisely defined but meshes less than 40 g/m² are generally referred to as light and meshes more than 80 g/m² are heavy.

**Biological mesh**

There are ‘biological meshes’ which are sheets of sterilised, decellularised, non-immunogenic connective tissue. They derive from human or animal dermis, bovine pericardium or porcine intestinal submucosa. They provide a ‘scaffold’ to encourage neovascular in-growth and new collagen deposition. Host enzymes eventually break down the biological implant which is replaced and remodelled with ‘normal’ host fibrous tissue. The rates of enzymatic degradation and collagen deposition vary between products and also depend on the local environment of the mesh. In the presence of infection, some biological meshes rapidly break down and weaken before remodelling can occur. Others remain strong, their labyrinthine microstructure allowing vascular in-growth to aid infection resistance. The choice of biological mesh depends on the clinical situation for which it is to be used. They are expensive.

**Absorbable meshes**

There are also synthetic absorbable meshes, such as those made from polyglycolic acid fibre. They are used in temporary abdominal wall closure and to buttress sutured repairs. They have no current role in hernia repair as they absorb and induce minimal collagen deposition.

**Tissue-separating meshes**

Most meshes induce fibrosis and, if placed within the peritoneal cavity, promote unwanted adhesions. New meshes have been designed for intraperitoneal use. Most of these have very different surfaces, one being sticky and one being slippery. Good adherence and host–tissue in-growth is required on the parietal (muscle) side of the mesh but the opposite (bowel) side needs to prevent adhesions to bowel. Usually one side of the mesh is coated by material which prevents adhesions (Figure 60.7), such as polyethylene, collagen, PTFE, etc. A recent mesh made entirely of a sheet of condensed PTFE with multiple perforations can be used intraperitoneally as the peritoneum will grow in through its perforations while bowel will not adhere to its inside (Summary box 60.7).

**Positioning the mesh**

The strength of a mesh repair depends on host–tissue in-growth. Meshes should be placed on a firm, well-vascularised tissue bed with generous overlap of the defect. The mesh can be placed:

- just outside of the muscle in the subcutaneous space (onlay);
- within the defect (inlay) – only applies to mesh plugs in small defects;

Figure 60.6 (a) Polypropylene mesh in totally extraperitoneal (TEP) inguinal hernia repair and (b) polytetrafluoroethylene (PTFE) mesh in paraumbilical hernia repair.
• between fascial layers in the abdominal wall (intraparietal or
  sublay);
• immediately extraperitoneally, against muscle or fascia (also
  sublay);
• intraperitoneally.

At open surgery all of these planes are used but laparoscopic
surgeons currently only use intraperitoneal or extraperitoneal
planes (Figure 60.8).

Limitations to the use of mesh
The presence of infection limits the use of mesh, particularly
heavyweight types. If a mesh becomes infected then it often
needs to be removed. Some infected meshes can be salvaged
using a combination of debridement of non-incorporated mesh,
appropriate antibiotics and modern vacuum-assisted dressings.

Meshes are expensive, especially those for intraperitoneal
use, but prices are falling and there are reports of low-cost solu-
tions such as mosquito netting!

SPECIFIC HERNI A TYPES

Hernia sites are shown in Figure 60.9.

Inguinal hernia

The inguinal hernia, often referred to as a ‘rupture’ by patients,
is the most common hernia in men and women but much more
common in men. There are two basic types which are funda-
mentally different in anatomy, causation and complications.
However, they are anatomically very close to one another, sur-
cical repair techniques are very similar and ultimate reinforce-
ment of the weakened anatomy is identical so they are often
referred to together as inguinal hernia (Summary box 60.8).

Summary box 60.8

Inguinal hernia

■ Types – lateral (oblique, indirect); medial (direct), sliding
■ Origin – congenital or acquired
■ Anatomy – inguinal canal
■ Classification – latest European Hernia Society
■ Diagnosis – usually clinical but radiological in special
  circumstances
■ Surgery – open and laparoscopic

Figure 60.8 Diagrammatic representation of the various layers into
which meshes are placed in ventral hernia repair.

Summary box 60.7

Mesh characteristics

■ Woven, knitted or sheet
■ Synthetic or biological – mainly synthetic
■ Light, medium or heavyweight – lightweight becoming more
  popular
■ Large pore, small pore – large pore causes less fibrosis and
  pain
■ Intraperitoneal use or not – non-adhesive mesh on one side
■ Non-absorbable or absorbable – mainly non-absorbable

Figure 60.7 Adhesions to mesh.
The congenital inguinal hernia is known as indirect, oblique or lateral while the acquired hernia is called direct or medial. There is a third ‘sliding’ hernia which is acquired but is lateral in position (see below).

**Basic anatomy of the inguinal canal**

As the testis descends from the abdominal cavity to the scrotum in the male it firsts passes through a defect called the deep inguinal ring in the transversalis fascia, just deep to the abdominal muscles. This ring lies midway between the anterior superior iliac spine and the pubic tubercle, approximately 2–3 cm above the femoral artery pulse in the groin. The inferior epigastric vessels lie just medial to the deep inguinal ring passing from the iliac vessels to the rectus abdominus muscle. Muscle fibres of the innermost two layers of the lateral abdominal wall, the transversus muscle and the internal oblique muscle, arch over the deep inguinal ring from lateral to medial before descending to become attached to the pubic tubercle. These two muscles fuse and become tendinous, hence this arch is referred to as the conjoint tendon. Below this arch there is no muscle but only transversalis fascia and external oblique aponeurosis resulting in weakness (Figure 60.10).

The testis proceeds medially and downwards along the inguinal canal. Anterior to the canal is the aponeurosis of the external oblique muscle whose fibres run downwards and medially. The testis finally emerges through a v-shaped defect in the aponeurosis, the superficial inguinal ring, and descends into the scrotum. The inguinal canal is roofed by the conjoint tendon, its posterior wall is transversalis fascia, an anterior wall is the external oblique aponeurosis which rolls inwards at its lower margin and thickens to become the inguinal ligament (Poupart’s). The inguinal canal in the male contains the testicular artery, veins, lymphatics and the vas deferens. In the female, the round ligament descends in the inguinal ligament (Poupart’s). The inguinal canal is roofed by the conjoint tendon, its posterior wall is transversalis fascia, an anterior wall is the external oblique aponeurosis, the superficial inguinal ring, and descends into the scrotum. Inguinal hernia in neonates and young children is always of this congenital type. However, in other patients, the muscles around the deep inguinal ring are able to prevent a hernia from developing until later in life, when under the constant positive abdominal pressure, the deep inguinal ring and muscles are stretched and a hernia becomes apparent. As the hernia increases in size, the contents are directed down into the scrotum. These hernias can become massive and may be referred to as a scrotal hernia (Figure 60.11).

An indirect hernia is lateral as its origin is lateral to the inferior epigastric vessels. It is also oblique as the hernia passes obliquely from lateral to medial through the abdominal muscle layers.

The second type of inguinal hernia, referred to as direct or medial, is acquired. It is a result of stretching and weakening of the abdominal wall just medial to the inferior epigastric (IE) vessels. Looked at from within the abdominal cavity, there is a triangle referred to as Hasselbach’s triangle, whose three sides are the IE vessels laterally, the lateral edge of the rectus abdominus muscle medially and the pubic bone below (the iliopubic tract) (Figure 60.12). This area is weak as the abdominal wall here only consists of transversalis fascia covered by the external oblique aponeurosis. A direct, medial hernia is more likely in elderly patients.

patients. It is broadly based and therefore unlikely to strangulate. The medially placed bladder can be pulled into a direct hernia (Figure 60.13).

The third type of inguinal hernia is referred to as a sliding hernia. This is also an acquired hernia due to weakening of the abdominal wall but this occurs at the deep inguinal ring lateral to the IE vessels. Retroperitoneal fatty tissue is pushed downwards along the inguinal canal. As more tissue enters the hernia, peritoneum is pulled with it, thus creating a sac. However the sac has formed secondarily, distinguishing it from a classic indirect hernia. On the left side, sigmoid colon may be pulled into a sliding hernia and on the right side the caecum. Surgeons need extra caution during repair as the wall of the large bowel may not be covered by peritoneum and can be damaged.

Occasionally, both lateral and medial hernias are present in the same patient (pantaloon hernia).

Classification
Many surgeons over the past hundred years have attempted to classify inguinal (and femoral) hernias, including Casten, Halverson and McVay, Zollinger, Ponka, Gilbert and Nyhus. The European Hernia Society has recently suggested a simplified system of:

- primary or recurrent (P or R);
- lateral, medial or femoral (L, M or F);
- defect size in finger breadths assumed to be 1.5 cm.

A primary, indirect, inguinal hernia with a 3-cm defect size would be PL2.

Diagnosis of an inguinal hernia
In most cases, the diagnosis of an inguinal hernia is simple and patients often know their diagnosis as they are so common. Usually these hernias are reducible presenting as intermittent swellings, lying above and lateral to the pubic tubercle with an associated cough impulse. Often the hernia will reduce on lying and reappear on standing. With the patient lying down, the patient is asked to reduce the hernia if it has not spontaneously reduced. If the patient cannot then the surgeon gently attempts to reduce the hernia. Once reduced, the surgeon identifies the bony landmarks of the anterior superior iliac spine and pubic tubercle to landmark the deep inguinal ring at the mid-inguinal point. Gentle pressure is applied at this point and the patient asked to cough. If the hernia is controlled with pressure on the deep inguinal ring then it is likely to be indirect/lateral and if the hernia appears medial to this point then it is direct/medial.

Diagnostic difficulties
Confirmation of the diagnosis may not be possible when the patient describes an intermittent swelling but nothing is found on examination. Surgeons will often accept the diagnosis on history alone but re-examination at a later date or investigation by ultrasound scan may be requested.

If an inguinal hernia becomes irreducible and tense there may be no cough impulse. Differential diagnosis would include a lymph node groin mass or an abdominal mass. Such cases require urgent investigation by either ultrasound or CT scan (Figure 60.15).

Large scrotal hernias may be misdiagnosed as a hydrocoele or other testicular swelling. The surgeon should be able to identify the upper limit of a scrotal swelling but a large scrotal hernia has no upper limit as it extends back along the inguinal canal to the

Figure 60.13 This cystogram shows the urinary bladder, part of which has descended into a left direct inguinal hernia.

Figure 60.14 Oblique left inguinal hernia that became apparent when the patient coughed and persisted until it was reduced when he lay down.

Figure 60.15 Malignant mass of nodes.
peritoneal cavity. In cases of doubt, ultrasound scanning should establish the diagnosis.

As inguinal hernia is so common, less-experienced clinicians might suggest this diagnosis when referring cases of femoral hernia or spigelian hernia. Also patients with a saphena varix may present with a swelling which increases in size on standing and with a definite cough impulse and be misdiagnosed as a hernia. The same can be true for a varicocele.

It is essential to examine the scrotal contents to exclude other pathologies and to check that the patient has two testes. It is important to examine the opposite side as contralateral hernia is common. Even if the contralateral side is weak, then bilateral repair should be recommended as the risk of contralateral recurrence is high. Ten per cent of all patients will present with bilateral inguinal hernias and up to 20 per cent more will have an occult contralateral hernia on laparoscopic evaluation. A patient with a single hernia has a lifetime 33 per cent risk of developing a hernia on the other side. Some surgeons have suggested that all patients should be offered bilateral repair especially if laparoscopic surgery is planned, but this is not widespread practice at present.

Investigations for inguinal hernia
Most cases require no diagnostic tests but ultrasound scanning, CT scan and MRI scan are occasionally used. A herniogram involves the injection of contrast into the peritoneal cavity followed by screening which shows the presence of a sac or asymmetric bulging of the inguinal anatomy.

Management of inguinal hernia
It is safe to recommend no active treatment in cases of early, asymptomatic, direct hernia, particularly in elderly patients who do not wish surgical intervention. These patients should be warned to seek early advice if the hernia increases in size or becomes symptomatic. Surgical trusses are not recommended but may be required for occasional patients who refuse any form of surgical intervention.

Elective surgery for inguinal hernia is a common and simple operation. It can be undertaken under local, regional or general anaesthesia with minimal risk even in high-risk patients.

Herniotomy
In children who have lateral hernias with a persistent processus, it is sufficient only to remove and close the sac. This is called a herniotomy. In adult surgery, herniotomy alone has a high recurrence rate and some form of muscle strengthening is added (herniorrhaphy).

Open suture repair
In 1890, Eduardo Bassini described suture repair for inguinal hernia (Figure 60.16). This was a massive leap forward and has been the basis of open repair for over 100 years. The surgeon enters the inguinal canal by opening its anterior wall, the external oblique aponeurosis. The spermatic cord is dissected free and the presence of a lateral or a medial hernia is confirmed. The sac of a lateral hernia is separated from the cord, opened and any contents reduced. The sac is then sutured closed at its neck and excess sac removed. If there is a medial hernia then it is inverted and the transversalis fascia is suture plicated. Sutures are now placed between the conjoint tendon above and the inguinal ligament below, extending from the pubic tubercle to the deep inguinal ring. The posterior wall of the inguinal canal is thus strengthened.

Over 150 modifications to the Bassini operation have been described with little or no benefit except for the Shouldice modification. In this operation, the transversalis fascia is opened by a central incision from the deep inguinal ring to the pubic tubercle and then closed to create a double-thick, two-layered posterior wall (double breasting). The external oblique is closed in similar fashion. Expert centres have reported lifetime failure rates of less than 2 per cent after Shouldice repair but it is a technically demanding operation which, in general hands, gives results identical to the Bassini repair.

Today, when a Bassini-type operation is done, most surgeons use a continuous, non-absorbable nylon or polypropylene suture which is darned between the conjoint tendon and inguinal ligament. This operation was described by Maloney, and recently published large randomised trials have reported excellent results when compared to mesh techniques. It is the most common operation performed in countries where mesh is too expensive.

Suture repair is still under development, and recently, Desarda has described an operation where a 1–2-cm strip of external oblique aponeurosis lying over the inguinal canal is isolated from the main muscle but left attached both medially and laterally. It is then sutured to the conjoint tendon and inguinal ligament, reinforcing the posterior wall of the inguinal canal. As the abdominal muscles contract, this strip of aponeurosis tightening adds further physiological support to the posterior wall. This operation is currently being evaluated.

Open flat mesh repair
Synthetic mesh has been used since the 1950s to reinforce hernia repair, and in the 1980s Lichtenstein described a tension-free, simple, flat, polypropylene mesh repair for inguinal hernia (Figure 60.17). The initial part of the operation is identical to Bassini. Once the hernia sac has been removed and any medial defect closed, a piece of mesh, measuring 8 × 15 cm, is placed over the posterior wall, behind the spermatic cord, and is split to wrap around the spermatic cord at the deep inguinal ring. Loose sutures hold the mesh to the inguinal ligament and conjoint tendon. Two major advantages are claimed: lowered

Eduardo Bassini, 1844–1924, Professor of Surgery, Padua, Italy, described this method of herniorrhaphy in 1889.
hernia recurrence rates and accelerated postoperative recovery. Randomised trials show that hernia recurrence within the first two years is lowered but acute pain scores are similar. Recent research comparing the Lichtenstein repair with laparoscopic surgery has identified chronic pain as the most common complication of open flat mesh repair with rates reported as high as 20 per cent. Nonetheless, today, the Lichtenstein repair is the most common operation for inguinal hernia in the developed world.

Open plug/device/complex mesh repair
Surgeons and industry have been highly creative, attempting to improve on simple flat mesh repair. A surgeon in Europe has over 200 different products and techniques from which to choose. Shaped mesh plugs have gained much attention being simple to insert into the defect and requiring little if any fixation. However, they can become solid (meshoma) and also migrate. Meshes have been designed to be placed beneath the transversalis fascia. The surgeon introduces a finger through the deep inguinal ring and bluntly (and blindly) opens the preperitoneal space deep to the inguinal canal into which a mesh is inserted. A two-layered mesh (‘hernia system’), in which the inner layer is placed deep to transversalis fascia and the outer layer superficial to it, is also gaining popularity. To date, there is little evidence to show any of these techniques is superior to the Lichtenstein operation.

Open preperitoneal repair
This approach was first described by Annandale in 1880, but was largely discarded until the 1950s when Stoppa, a French surgeon, described it with mesh reconstruction. It is useful when multiple attempts at open standard surgery have failed and the hernia(s) keeps recurring. It may now be superseded by the totally extraperitoneal laparoscopic approach which is modelled on the Stoppa operation and first described by Ger, also French.

Laparoscopic inguinal hernia repair
Two techniques are described and have been extensively studied in randomised trials. The totally extraperitoneal (TEP) approach is more widely used than the transabdominal preperitoneal (TAPP) approach. In both, the aim of surgery is to reduce the hernia and hernia sac within the abdomen and then place a 10 × 15 cm mesh just deep to the abdominal wall, extending across the midline into the retropubic space and 5 cm lateral to the deep inguinal ring. The mesh covers Hasselbach’s triangle, the deep inguinal ring and the femoral canal. In TEP, the surgeon is able to create a space just deep to the abdominal muscles without entering the peritoneal cavity whereas, in TAPP, the surgeon enters the peritoneal cavity then incises the peritoneum above the hernia defects and reflects it away from the muscles, essentially entering the same space as in TEP. Once the hernia is reduced, an identical mesh is inserted and the peritoneum closed over the mesh (Figures 60.18 and 60.19).

Over 60 randomised trials have compared laparoscopic surgery with the Lichtenstein repair. They show that, although the laparoscopic operation takes longer to perform, proven advantages are reduced pain both following surgery and up to five years later, more rapid return to full activity and reduced incidence of the wound complications of infection, bleeding and seroma. Laparoscopic surgery is of particular benefit in bilateral cases and in patients with hernia recurrence after open surgery. National statistics show that the proportion of cases performed laparoscopically is slowly rising but all agree that there is a slow learning curve associated with these technically demanding operations (Summary box 60.9).

Emergency inguinal hernia surgery

Ninety-five per cent of inguinal hernia patients present at clinics and only 5 per cent present as an emergency with a painful irreducible hernia which may progress to strangulation and possible bowel infarction. The morbidity and mortality of emergency inguinal hernia surgery is high and surgery needs to be performed rapidly in a well-resuscitated patient with adequate postoperative high dependency or intensive care if necessary. The principles of surgery are the same as in an elective setting. Open surgery is preferred when a hernia is irreducible or if there is any risk of bowel resection. Infection may complicate these cases but most surgeons would still use a lightweight, synthetic mesh repair covered by appropriate antibiotics.

Complications of inguinal hernia surgery

Despite this being a common procedure and technically straightforward, postoperative complications are common. Immediate complications include bleeding (which may be due to accidental damage to the inferior epigastric or iliac vessels) and urinary retention which may require catheterisation. Occasional over-enthusiastic infusion of local anaesthetic may lead to femoral nerve blockade, the patient being unable to move a leg. This usually resolves over 12 hours but is alarming.

Over the next week, seroma formation and wound infection may occur. Seroma is due to an excessive inflammatory response to sutures or mesh and cannot be prevented. In most cases the fluid resolves spontaneously but may require aspiration. After laparoscopic surgery, a seroma may be misdiagnosed as an early recurrence. Wound infection is not uncommon. Many surgeons use routine prophylactic antibiotics but recent studies suggest little benefit even when mesh is used.

In the longer term, hernia recurrence and chronic pain are the main concerns. No operation can guarantee to be recurrence free. Evidence shows that mesh repairs have lower recurrence rates than suture repairs but there is no difference between the various mesh repairs and no difference between open and laparoscopic surgery. There is very strong evidence that specialist hernia surgeons will have lower recurrence rates whatever technique they use.

Chronic pain, defined as pain present three months after surgery, is common after all forms of surgery. It is less common and less severe after laparoscopic surgery. Different types of pain have been described but the most severe is neuralgic pain due to nerve irritation. This may be the result of nerve injury at the time of operation or chronic irritation of nerves by suture material or mesh. Careful identification and protection of all three nerves passing along the inguinal canal reduces the incidence of neuralgic pain. This type of pain is also very uncommon after laparoscopic surgery which is performed at a deeper level away from the nerves. Some contribution to chronic pain may be due to the mesh which can become embedded in a dense collagenous reaction with shrinkage. This causes tissue tension and rigidity.

Rarely, damage to the testicular artery can lead to testicular infarction, perhaps the most serious complication of inguinal hernia surgery. There is no good evidence that hernia surgery has an effect on male fertility despite extensive study in this area (Summary box 60.10).

Summary box 60.10

**Complications**

- Early – pain, bleeding, urinary retention, anaesthetic related
- Medium – seroma, wound infection
- Late – chronic pain, testicular atrophy

Sportsman’s hernia

This specific entity is well described and presents as severe pain in the groin area, extending into the scrotum and upper thigh. It is almost entirely restricted to young men who play contact sports such as football and rugby. The pain can be debilitating and prevent the patient from exercising. On examination there may be some tenderness in the region of the inguinal canal, over the pubic tubercle and over the insertion of the thigh adductor muscles. Usually no hernia can be felt and only occasionally can a true inguinal hernia be found.

In most cases, the pain is due to an orthopaedic injury, such as adductor strain or pubic symphysis diastasis. However, some believe that it can be due to muscle tearing (Gilmore’s groin) or stretching of the posterior wall of the inguinal canal. Other causes of pain should be excluded, such as hip, pelvic or lumbar spinal disease and bladder/prostate problems. MRI scanning is most likely to detect an orthopaedic problem but ultrasound, herniography or even laparoscopy may be used.

There are many anecdotal reports of successful treatment using all types of inguinal hernia surgery, suture and mesh, open and laparoscopic, but no randomised trials. Hernia surgery should be a last resort and the patient warned of a significant risk of failure to cure the pain.

Femoral hernia

**Basic anatomy**

The iliac artery and vein pass below the inguinal ligament to become the femoral vessels in the leg. The vein lies medially and the artery just lateral to the artery with the femoral nerve lateral to the artery. They are enclosed in a fibrous sheath. Just medial to the vein is a small space containing fat and some lymphatic tissue (node of Cloquet). It is this space which is exploited by a femoral hernia. The walls of a femoral hernia are the femoral vein laterally, the inguinal ligament anteriorly, the pelvic bone covered by the

**Femoral hernia**  
**Basic anatomy**

The iliac artery and vein pass below the inguinal ligament to become the femoral vessels in the leg. The vein lies medially and the artery just lateral to the artery with the femoral nerve lateral to the artery. They are enclosed in a fibrous sheath. Just medial to the vein is a small space containing fat and some lymphatic tissue (node of Cloquet). It is this space which is exploited by a femoral hernia. The walls of a femoral hernia are the femoral vein laterally, the inguinal ligament anteriorly, the pelvic bone covered by the
ileopsoas ligament (Astley Cooper’s) posteriorly and the lac
cunar ligament (Gimbernat’s) medially. This is a strong curved lig-
ament with a sharp unyielding edge which impedes reduction of a
femoral hernia (Figure 60.20).

The female pelvis has a different shape to the male, increas-
ing the size of the femoral canal and the risk of hernia. In old
age, the femoral defect increases and femoral hernia is com-
monly seen in low-weight, elderly females. There is a substantial
risk of developing a femoral hernia after a sutured inguinal
hernia repair (Denmark Hernia Registry) (Summary box 60.11).

Summary box 60.11

Femoral hernia
■ Less common than inguinal hernia
■ It is more common in females than in males
■ Easily missed on examination
■ Fifty per cent of cases present as an emergency with very
  high risk of strangulation

Diagnosis of femoral hernia

Diagnostic error is common and often leads to delay in diag-
nosis and treatment. The hernia appears below and lateral to
the pubic tubercle and lies in the upper leg rather than in the
lower abdomen. Inadequate exposure of this area during routine
examination leads to failure to detect the hernia. The hernia
often rapidly becomes irreducible and loses any cough impulse
due to the tightness of the neck. It may only be 1–2 cm in size
and can easily be mistaken for a lymph node. As it increases in
size, it is reflected superiorly and becomes difficult to distinguish
from a medial direct hernia which arises only a few centimetres
above the femoral canal. A direct inguinal hernia leaves the
abdominal cavity just above the inguinal ligament and a femoral
hernia just below (Figure 60.21) (Summary box 60.12).

Investigations

In routine cases, no specific investigations are required.
However, if there is uncertainty then ultrasound or CT should
be requested. In the emergency patient, bowel obstruction
usually occurs and a plain x-ray is likely to show small bowel
obstruction. All patients with unexplained small bowel obstruc-
tion should undergo careful examination for a femoral hernia.
It is now common to perform CT scanning in cases of bowel
obstruction primarily to exclude malignancy, but it can identify
an obstructing femoral hernia missed by clinicians.

Surgery for femoral hernia

There is no alternative to surgery for femoral hernia and it is
wise to treat such cases with some urgency. There are three
open approaches and appropriate cases can be managed laparo-
scopically.

Low approach (Lockwood)

This is the simplest operation for femoral hernia but only suit-
able when there is no risk of bowel resection. It can easily be
performed under local anaesthesia. A transverse incision is
made over the hernia. The sac of the hernia is opened and its
contents reduced. The sac is also reduced and non-absorbable
sutures placed between the inguinal ligament above and the fas-
cia overlying the bone below. A small incision can be made in
the medial lacunar ligament to aid reduction but there may be
an abnormal branch of the obturator artery just deep to it which
can bleed. The femoral vein, lateral to the hernia, needs to be
protected. Some surgeons place a mesh plug into the hernia
defect for further re-enforcement.

The inguinal approach (Lotheissen)

The initial incision is identical to that of a Bassini or
Lichtenstein operation into the inguinal canal. The spermatic
cord (or round ligament) is mobilised and the transversalis fas-
cia opened from deep inguinal ring to pubic tubercle. A femoral
hernia lies immediately below this incision and can be reduced
by a combination of pulling from above and pushing from

■ Femoral artery aneurysm
■ Psoas abscess
■ Rupture of adductor longus with haematoma

Charles Barrett Lockwood, 1856–1914, surgeon, St Bartholomew’s Hospital, London, UK.
below. If necessary, the peritoneum can be opened to help with reduction. Once reduced, the neck of the hernia is closed with sutures or a mesh plug, protecting the iliac vein throughout. The layers are closed as for inguinal hernia and the surgeon may place a mesh into the inguinal canal to protect against development of an inguinal hernia.

Some surgeons believe that exploration of the femoral canal to exclude a hernia should be a routine part of inguinal hernia surgery but most surgeons do not do this.

High approach (McEvedy)

This more complex operation is ideal in the emergency situation where the risk of bowel strangulation is high. It requires regional or general anaesthesia. A horizontal incision (classically vertical) is made in the lower abdomen centred at the lateral edge of the rectus muscle. The anterior rectus sheath is incised and the rectus muscle displaced medially. The surgeon proceeds deep to the muscle in the preperitoneal space. The femoral hernia is reduced and the sac opened to allow careful inspection of the bowel, and a decision made regarding the need for bowel resection. This is performed if necessary. In dubious cases, the bowel is replaced into the peritoneal cavity for 5 minutes and then re-examined. The femoral defect is then closed with sutures, mesh or plug. This approach allows a generous incision to be made in the peritoneum which aids inspection of the bowel and facilitates bowel resection.

Laparoscopic approach

Both the TEP and TAPP approaches can be used for femoral hernia and a standard mesh inserted. This is ideal for reducible femoral hernias presenting electively but not in emergency cases not for irreducible hernia.

VENTRAL HERNIA

This term refers to hernias of the anterior abdominal wall. Inguinal and femoral hernias are not included even though they are ventral. Lumbar hernia is included despite being dorsolateral. The European Hernia Society classification (2009) distinguished primary ventral from incisional hernia but did not include paraumbilical hernia. We have included paraumbilical hernia and traumatic hernia (Summary box 60.13).

Summary box 60.13

Ventral hernias

- Umbilical – paraumbilical
- Epigastric
- Incisional
- Parastomal
- Spigelian
- Lumbar
- Traumatic

Umbilical hernia

The umbilical defect is present at birth but closes as the stump of the umbilical cord heals, usually within a week of birth. This process may be delayed, leading to the development of herniation in the neonatal period. The umbilical ring may also stretch and reopen in adult life.

Umbilical hernia in children

This common condition occurs in up to 10 per cent of infants, with a higher incidence in premature babies. The hernia appears within a few weeks of birth and is often symptomless but increases in size on crying and assumes a classical conical shape. Sexes are equally affected but the incidence in black infants is up to eight times higher than in white. Obstruction and/or strangulation are extremely uncommon below the age of three years.

Treatment

Conservative treatment is indicated under the age of two years when the hernia is symptomless. Parental reassurance is all that is necessary. Ninety-five per cent of hernias will resolve spontaneously. If the hernia persists beyond the age of two years it is unlikely to resolve and surgical repair is indicated.

Operation

A small curved incision is made immediately below the umbilicus. The neck of the sac is defined, opened and any contents are returned to the peritoneal cavity. The sac is closed and redundant sac is excised. The defect in the linea alba is closed with interrupted sutures (Summary box 60.14).

Summary box 60.14

Umbilical hernia in children

- Common in infants and most resolve spontaneously
- Rarely strangulate

Umbilical hernia in adults

Conditions which cause stretching and thinning of the mid-line raphe (linea alba), such as pregnancy, obesity and liver disease with cirrhosis, predispose to reopening of the umbilical defect. In adults, the defect in the median raphe is immediately adjacent to (most often above) the true umbilicus, although at operation this is indistinguishable. The term paraumbilical hernia is commonly used (Figure 60.22). The defect is rounded with a well-defined fibrous margin. Small umbilical hernias often contain extraperitoneal fat or omentum. Larger hernias can contain small or large bowel but, even when very large, the neck of the sac is narrow compared with the volume of its contents. As a result, in adults, umbilical hernias which include
bowel are prone to become irreducible, obstructed and strangulated.

**Clinical features**

Patients are commonly overweight with a thinned and attenuated midline raphe. The bulge is typically slightly to one side of the umbilical depression, creating a crescent-shaped appearance to the umbilicus (Figure 60.23). Women are affected more than men. Most patients complain of pain due to tissue tension or symptoms of intermittent bowel obstruction. In large hernias, the overlying skin may become thinned, stretched and develop dermatitis.

**Treatment**

Because of the high risk of strangulation, operation should be advised in cases where the hernia contains bowel. Small hernias may be left alone if they are asymptomatic, but they may enlarge and require surgery at a later date. Surgery may be performed open or laparoscopically.

**Open umbilical hernia repair**

Very small defects less than 1 cm in size may be closed with a simple figure-of-eight suture, or repaired by a darn technique where a non-absorbable, monofilament suture is criss-crossed across the defect and anchored firmly to the fascia all around.

Defects up to 2 cm in diameter may be sutured primarily with minimal tension, although the larger the defect, the more tension and the more likely it is that mesh reinforcement will be beneficial. The classical repair was described by Mayo. A transverse incision is made and the hernia sac dissected, opened and its content reduced. Any non-viable tissue is removed, sometimes involving bowel resection. The peritoneum is closed. The defect in the anterior rectus sheath is extended laterally on both sides and elevated to create an upper and lower flap. The lower flap is then inserted beneath the upper flap and sutured to it, with the upper flap being brought downwards over it so that the tissue is two-layered (double breasted). Non-absorbable sutures are used. There is often a large subcutaneous space. A suction drain is placed to reduce the risk of seroma and haematoma. The skin is closed but stretched or redundant skin may need to be excised (apronectomy) to achieve a better cosmetic result. Today, with modern suture materials, surgeons simply close the anterior sheath in a single layer.

For defects larger than 2 cm in diameter, mesh repair is recommended (Figure 60.24). The mesh may be placed in one of several anatomical planes:

- Within the peritoneal cavity – a tissue separating mesh is placed through the defect and spread out on the underside of the abdominal wall and fixed to it, ideally, with an overlap of 5 cm in each direction. This is a quick repair but requires the use of expensive mesh.
- In the retromuscular space – the linea alba is opened both vertically and both left and right posterior rectus sheaths are incised 1 cm to the side of the midline exposing the rectus muscle. The posterior sheaths are sutured together and the muscles elevated away from the sheath to develop the retromuscular space into which a sheet of mesh is placed and fixed by sutures. The mesh should overlap the midline by 5 cm laterally and the umbilicus vertically. It should therefore be a minimum diameter of 10 cm. A drain may be placed deep to the linea alba. This is a very secure repair but requires extensive dissection.
- In the extraperitoneal space – it is difficult, but possible, to develop the plane below the posterior rectus sheath, just outside the peritoneum. Care must be taken to avoid ‘button-holing’ the peritoneum as it is thin and fragile. Mesh can then be tacked into this space, ensuring a good overlap as before. Ideally, the linea alba is closed over the mesh but if this is not possible, a flap of peritoneal sac can be used to cover the mesh. This is a good repair, but if the peritoneum is extensively damaged during the dissection, it will have to be abandoned in favour of an alternative technique.
- In the subcutaneous plane – this is the simplest technique, called an onlay mesh. The peritoneal sac and contents are dealt with as above. An attempt is made to close linea alba vertically with sutures and a disc of mesh is placed on the anterior rectus sheath and sutured to it. The mesh is lying in the subcutaneous space and is prone to infection.

---

**Figure 60.23** A large paraumbilical hernia.

**Figure 60.24** A massive paraumbilical hernia – operative view.
Laparoscopic umbilical hernia repair
Three ports are placed laterally on the abdominal wall, usually on the left side unless adhesions from previous surgery are likely. The contents of the hernia are reduced by traction and external pressure. A disc of non-adherent mesh, designed for intraperitoneal use, is introduced and positioned on the under surface of the abdominal wall, centred on the defect. It is then fixed to the peritoneum and posterior rectus sheaths using staples, tacks or sutures. This is a simple and secure repair which achieves generous overlap without surgical damage to umbilicus and surrounding fascia (Figure 60.25). However, it requires specialised equipment and expensive tissue-separating mesh. Intraperitoneal meshes can cause severe pain lasting for 24–48 hours after surgery which can mimic peritonitis.

Figure 60.25 Paraumbilical defect – laparoscopic view.

Emergency repair of umbilical hernia
Incarceration, bowel obstruction and strangulation are frequent because of the narrow neck and the fibrous edge of the defect in the midline raphe. Delay to surgery can lead to gangrene of omentum or bowel. Large hernias are often multiloculated and there may be strangulated bowel in one component when other areas are clinically soft and non-tender hernia.

Operation
In cases of simple incarceration without clinical evidence of strangulation, repair may be attempted laparoscopically but reduction of the contents can be very difficult if the hernia contains bowel. The majority of emergency repairs are performed by open surgery. In the presence of established strangulation it is unwise to place mesh at all because of the risk of infection, so an open sutured repair should be performed, accepting a high risk of later recurrence. Alternatively, a two-stage repair could be planned: the hernia contents being dealt with initially with little attempt made to close the defect and then subsequent definitive mesh repair once sepsis has been controlled (Summary box 60.15).

Summary box 60.15

**Umbilical hernia in adults**
- Common in overweight men or multiparous women
- Progressively increase in size and may get very large indeed
- Round defect with rigid fibrous margins
- Surgery advised because of risk of obstruction and strangulation

Epigastric hernia
These arise through the midline raphe (linea alba) anywhere between the xiphoid process and the umbilicus, usually midway. When close to the umbilicus they are called supraumbilical hernias. Epigastric hernias begin with a transverse split in the midline raphe so, in contrast to umbilical hernias, the defect is elliptical. It has been hypothesised that the defect occurs at the site where small blood vessels pierce the linea alba or, more likely, that it arises at weaknesses due to abnormal decussation of aponeurotic fibres related to heavy physical activity (Figure 60.26).

Epigastric hernia defects are usually less than 1 cm in maximum diameter and commonly contain only extraperitoneal fat which gradually enlarges, spreading in the subcutaneous plane to resemble the shape of a mushroom. When very large they may contain a peritoneal sac but rarely any bowel. More than one hernia may be present. The most common cause of ‘recurrence’ is failure to identify a second defect at the time of original repair.

Clinical features
The patients are often fit, healthy males between 25 and 40 years of age. These hernias can be very painful even when the swelling is the size of a pea due to the fatty contents becoming nipped sufficiently to produce partial strangulation. The pain may mimic that of a peptic ulcer but symptoms should not be ascribed to the hernia until gastrointestinal pathology has been excluded. A soft midline swelling can often be felt more easily than it can be seen. It may be locally tender. It is unlikely to be reducible because of the narrow neck. It may resemble a lipoma. A cough impulse may or may not be felt.

Figure 60.26 Epigastric hernia – external view.
Treatment
Very small epigastric hernias have been known to disappear spontaneously, probably due to infarction of the fat. Small to moderate-sized hernias without a peritoneal sac are not inherently dangerous and surgery should only be offered if the hernia is sufficiently symptomatic.

Operation
This may be done by open or laparoscopic surgery. At open surgery, a vertical or transverse incision is made over the swelling and down to the linea alba. Protruding extraperitoneal fat can simply be pushed back through the defect or excised. Often a small vessel is present in the hernia content which can cause troublesome bleeding. The defect in the linea alba is closed with non-absorbable sutures in adults and absorbable sutures in children. In larger hernias and when a peritoneal sac is present, the surgical approach is similar to an umbilical mesh repair.

Laparoscopic repair is very similar to that for umbilical hernia except that the defect is hidden behind the falciform ligament which must be taken down from the undersurface of the abdominal wall. The margins of the defect must be clearly exposed and the fatty contents reduced before the mesh is placed. Simply placing a mesh under the linea midline may not in fact remove the hernia when its contents are extraperitoneal fat.

Incisional hernia
These arise through a defect in the musculofascial layers of the abdominal wall in the region of a postoperative scar. Thus they may appear anywhere on the abdominal surface.

Incidence and aetiology
Incisional hernias have been reported in 10–50 per cent of laparotomy incisions and 1–5 per cent of laparoscopic port-site incisions. Factors predisposing to their development are patient factors (obesity, general poor healing due to malnutrition, immunosuppression or steroid therapy, chronic cough, cancer), wound factors (poor quality tissues, wound infection) and surgical factors (inappropriate suture material, incorrect suture placement).

An incisional hernia usually starts as disruption of the musculofascial layers of a wound in the early postoperative period. Often the event passes unnoticed if the overlying skin wound has healed securely. Many incisional hernias may be preventable with the use of good surgical technique. The classic sign of wound disruption is a serosanguinous discharge.

Clinical features
These hernias commonly appear as a localised swelling involving a small portion of the scar but may present as a diffuse bulging of the whole length of the incision (Figure 60.27). There may be several discrete hernias along the length of the incision and unsuspected defects are often found at operation (Figure 60.28). Incisional hernias tend to increase steadily in size with time. The skin overlying large hernias may become thin and atrophic so that peristalsis may be seen in the underlying intestine. Vascular damage to skin may lead to dermatitis. Attacks of partial intestinal obstruction are common as there are usually coexisting internal adhesions. Strangulation is less frequent and most likely to occur when the fibrous defect is small and the sac is large. Most incisional hernias are broad-necked and carry a low risk of strangulation (Summary box 60.16).

Summary box 60.16
Incisional hernia
- Incidence 10–50 per cent after surgery
- Caution due to patient, wound and surgeon factors
- Wide variation in size
- Often multiple defects within the same scar
- Obstruction is common but strangulation is rare
- Open and laparoscopic repairs possible

Treatment
Asymptomatic incisional hernias may not require treatment at all. The wearing of an abdominal binder or belt may prevent the hernia from increasing in size.

Principles of surgery
For the majority of incisional hernias, surgery is relatively straightforward and both open and laparoscopic options are available. A number of principles apply, irrespective of the technique used.

The repair should cover the whole length of the previous incision. Approximation of the musculofascial layers should be done with minimal tension and prosthetic mesh should be used...
to reduce the risk of recurrence. Mesh may be contraindicated in a contaminated field, e.g. bowel injury during the dissection but, in a clean-contaminated field, such as after an elective bowel resection, mesh may be used if placed in a different anatomical plane to the contamination, such as in the extraperitoneal retro-muscular space. Appropriate systemic antibiotics should be used.

Open repair

Simple suture techniques without the use of prosthetic mesh for reinforcement, even with layered closure such as in Mayo, ‘keel’ or da Silva repairs, are not recommended today because of the high risk of recurrence. However, they may be the only option in the presence of gross contamination such as peritonitis.

The previous incision is opened along its full length to reveal any clinically unsuspected defects. The hernial sac, its neck and the margins of the defect are fully exposed. The sac can be opened, contents reduced, local adhesions divided and any redundant sac excised to allow safe reclosure of the peritoneum.

Mesh can be placed in one of several planes as for umbilical hernia repair. The simplest approach is an onlay mesh but increasingly the retromuscular sublay repair is preferred by expert surgeons and is described below.

Retromuscular sublay mesh repair

Vertical incisions are made through the fascia surrounding the rectus abdominis muscles so that the muscle can be separated and elevated from the posterior rectus sheath below. If possible, the medial edges of the posterior rectus sheath edges are sutured together with a continuous suture. In very large defects this may not be possible and below the arcuate line, the posterior sheath is deficient, being peritoneum and transversalis fascia only. In the case of transverse incision, where the defect extends lateral to the rectus sheath, internal oblique and transversus abdominis muscles form the posterior layer. A sheet of lightweight, large-pore prosthetic, elastic mesh is then laid between this posterior rectus sheath and belly(s) of the rectus muscle. It is fixed to the sheath by interrupted sutures. The mesh must be large enough to ensure 5 cm overlap of the underlying fascial defect in all directions. Careful haemostasis and meticulous asepsis are essential during this operation. The anterior rectus sheaths are then sutured together over the mesh so that, ideally, the mesh is completely covered by muscle and fascia and is not lying in the subcutaneous plane. Redundant skin may need to be excised. The risk of postoperative serous fluid collections is reduced by suction drainage.

Laparoscopic repair

Incisional hernias are increasingly being repaired by laparoscopic mesh techniques. Laparoscopy and division of adhesions is initially performed. Hernia contents are reduced and the fibrous margins of the hernia defect(s) are exposed. Often the falciform ligament and median umbilical fold need to be taken down. Some surgeons prefer to suture close the muscle defects first and then reinforce with mesh. Others simply fix the mesh under the defect with adequate overlap. The use of a tissue-separating mesh is essential. Various techniques have been described to size and then position the mesh accurately. The mesh is fixed to the abdominal wall by staples or transfascial sutures which pass through all muscle layers to hold the mesh.

In the presence of dense peritoneal adhesions, the laparoscopic surgeon needs to take great care as injury to bowel is possible and may not be recognised. Diathermy is not used. If occult bowel injury does occur it can lead to postoperative peritonitis which is an extremely dangerous complication.

Management of the very large incisional hernia

Very large incisional hernias often require careful thought before treatment begins. If the volume of the sac is more than 25% of the volume of the abdominal cavity (and this can be calculated from CT scan images) then there are likely to be issues of loss of abdominal domain when the hernia is repaired. The contents of the hernia, which have been outside the abdominal cavity for a long time, will not fit back inside, or if they do, it will result in high tension. High intra-abdominal pressure can lead to visceral compression and pulmonary complications due to impaired diaphragmatic movement. A tight abdomen can lead to wound breakdown and failure of the repair.

Techniques to overcome the potential loss of abdominal domain include preoperative abdominal expansion with progressive preoperative pneumoperitoneum over several weeks, resection of the omentum and/or colon at the time of repair, the use of prosthetic mesh to span the unclosable gap in the musculofascial layer, or the use of musculofascial advancement or transposition flaps to achieve closure.

Even if loss of domain is not a concern, large defects can still be very difficult to close and the same special techniques may need to be used to avoid producing excessive tension in the repair. The Ramirez component separation technique, which incorporates relaxing incisions in the external oblique aponeurosis and/or the posterior sheath, is very useful as this enables either the anterior or posterior component of the rectus sheath to be drawn together. It may then be reinforced with a mesh.

Patients with poor quality or redundant skin may benefit from a wedge excision of skin and fat (lipectomy) to improve the abdominal contour postoperatively. Repair of these very large hernias is highly specialised surgery and is best done in specialist centres.

Reducing the risk of incisional hernia

The incidence of incisional hernia may be reduced by improving the patient’s general condition preoperatively where possible – e.g. weight loss for obesity, or improving nutritional state for malnutrition. Closing the fascial layers with non-absorbable, or very slowly absorbable, sutures of adequate gauge is important. Traditional teaching was that sutures should be 1 cm deep and 1 cm apart. Recent work has shown that lower incisional hernia rates and reduced infection rates are gained when smaller and closer bites are used with a 2/0 suture rather than traditional heavier materials.

There is no evidence that interrupted sutures are better or worse than continuous. However, if continuous suturing is used, the tissue bites must not be too near the fascial edge nor pulled too tight or they may cut out. It has also been confirmed that the optimal ratio of suture length to wound length is 4:1 (Jenkins’ rule). If less length than this is used, the suture bites are too far apart or too tight and the converse applies if more length than this is used.

Drains should be brought out through separate incisions and not through the wound itself as this leads to hernia formation.

Recent reports have suggested that placement of a prophylactic mesh in patients at high risk of hernia formation will substantially reduce that risk. This has been reported in obese
patients undergoing bariatric surgery and also to prevent parastomal herniation which occurs in up to 50 per cent of patients.

**Spigelian hernia**

These hernias are uncommon although are probably underdiagnosed. They affect men and women equally and can occur at any age, but are most common in the elderly. They arise through a defect in the Spigelian fascia which is the aponeurosis of the transversus abdominis muscle. Often these hernias advance through the internal oblique as well and spread out deep to the external oblique aponeurosis. The Spigelian fascia extends between the transversus muscle and the lateral border of the rectus sheath from the costal margin to the groin where it blends into the conjoint tendon. Most Spigelian hernias appear below the level of the umbilicus near the edge of the rectus sheath but they can be found anywhere along the 'Spigelian line' (Figure 60.29). There is a common misconception that they protrude below the arcuate line owing to deficiency of the posterior rectus sheath at that level, but in fact the defect is almost always above the arcuate line. In young patients they usually contain extraperitoneal fat only but in older patients there is often a peritoneal sac and they can become very large indeed.

They have also been described in infants and may be congenital, reflecting incomplete differentiation of the mesenchymal layers within the abdominal wall.

**Clinical features**

Young patients usually present with intermittent pain, due to pinching of the fat, similar to an epigastric hernia. A lump may or may not be palpable as the fatty hernia is small and the overlying external oblique is intact. Older patients generally present with a reducible swelling at the edge of the rectus sheath and pinching of the fat, similar to an epigastric hernia. A lump may be visible with the patient lying down.

**Treatment**

Surgery is recommended as the narrow and fibrous neck predisposes to strangulation. Surgery can be open or laparoscopic. At open surgery a skin crease is made over the hernia, but no abnormality will be seen until the external oblique is opened. The sac and contents are dealt with and the small defect in the Spigelian fascia is repaired by suture or mesh laid deep to external oblique aponeurosis. The plane of the mesh can be extended medially into the posterior rectus sheath if required. The external oblique aponeurosis is closed over the mesh.

Laparoscopy is useful if no sac is palpable, but in young patients with a hernia only containing extraperitoneal fat, no hernia will be seen from within the peritoneum. In such cases, the peritoneum can be incised and the extraperitoneal plane explored for the small defect, which can then be closed either by suture or mesh. When an intraperitoneal sac is present, laparoscopic repair can be performed using either the intraperitoneal onlay of mesh (IPOM) or TAPP technique (Summary box 60.17).

**Summary box 60.17**

- Spigelian hernia
  - Rare
  - Often misdiagnosed
  - High risk of complications

**Lumbar hernia**

Most primary lumbar hernias occur through the inferior lumbar triangle of Petit bounded below by the crest of the ilium, laterally by the external oblique muscle and medially by the latissimus dorsi (Figure 60.30). Less commonly, the sac comes through the superior lumbar triangle, which is bounded by the 12th rib above, medially by the sacrospinalis and laterally by the posterior border of the internal oblique muscle. Primary lumbar hernias are rare, but may be mimicked by incisional hernias arising through flank incisions for renal operations or through incisions for bone grafts harvested from the iliac crest.

**Differential diagnosis**

A lumbar hernia must be distinguished from:

- a lipoma;
- a cold (tuberculous) abscess pointing to this position;
- pseudo-hernia due to local muscular paralysis. Lumbar pseudo-hernia can result from any interference with the nerve supply of the affected muscles, the most common cause being injury to the subcostal nerve during a renal operation.

**Treatment**

The natural history is for these hernias to increase in size and surgery is recommended. Lumbar hernias can be approached by open or laparoscopic surgery. The defects can be difficult to close with sutures and mesh is recommended. The TAPP laparoscopic approach is gaining popularity. With the patient in a semilateral position ports are inserted well away from the defect. The peritoneum is incised above the hernia and dissected back to expose the muscle defect. The content, often extraperitoneal fat, is reduced and a mesh fixed with ample overlap. The peritoneum can then be resutured or tucked back to cover the mesh.

Lumbar incisional hernias can be approached in the same way but large ones, especially if there is a component of neuropathic...
muscle atrophy causing a diffuse bulge (pseudo-hernia), can be very difficult and muscle-flap double-breasting with mesh reinforcement may be required.

**Parastomal hernia**

When surgeons create a stoma, such as a colostomy or ileostomy, they are effectively creating a hernia by bringing bowel out through the abdominal wall. The muscle defect created tends to increase in size over time and can ultimately lead to massive herniation around the stoma. The rate of parastomal hernia is over 50 per cent. For patients, it is very difficult to manage a stoma which is lying adjacent to or atop of a large hernia. Stoma appliance bags fit poorly leading to leakage.

The ideal surgical solution for the patient is to rejoin the bowel and remove the stoma altogether but this is not always possible. The stoma may be resited but further recurrence is likely. Various open suture and mesh techniques have been described to repair parastomal hernia but failure rates are high. Meshes are best placed in the retromuscular space. Laparoscopic repair is also possible using a large mesh with a central hole. It can be positioned around the bowel onto the parietal peritoneum.

Recent reports (Israelson) have described the use of prophylactic mesh insertion at the time of formation of the stoma. A lightweight, polypropylene mesh is inserted in the retromuscular space so that the bowel passes through a hole in the mesh centre. Using this technique, parastomal hernia rates have been reduced significantly.

**Traumatic hernia**

These hernias arise through non-anatomic defects caused by injury. They can be classified into three types:

1. Hernias through abdominal stab wound sites. These are effectively incisional hernias.
2. Hernias protruding through splits or tears in the abdominal muscles following blunt trauma.
3. Abdominal bulging secondary to muscle atrophy which occurs as a result of nerve injury or other traumatic denervation. Akin to the lumbar pseudo-hernia seen after open nephrectomy, these can arise following chest injury with damage to the intercostal nerves.

**Clinical features**

Traumatic hernias present as any other hernia. The key to the aetiology is in the history and the non-anatomic location of the hernia.

**Treatment**

Surgery may be justified if the hernia is sufficiently symptomatic, or if investigations suggest a narrow neck and hence a risk of obstruction or strangulation. Stab wound traumatic hernias are straightforward to repair using open or laparoscopic techniques as for other ventral hernias. Diffuse abdominal bulges are more difficult to correct and require some form of plication of the stretched musculofascial layer with mesh reinforcement to prevent further bulging in the future. Some bulging may persist however.

**Rare external hernias**

**Perineal hernia**

This type of hernia is very rare and includes:

- postoperative hernia through a perineal scar, which may occur after excision of the rectum;
- median sliding perineal hernia, which is a complete prolapse of the rectum;
- anterolateral perineal hernia, which occurs in women and presents as a swelling of the labium majus;
- posterolateral perineal hernia, which passes through the levator ani to enter the ischiorectal fossa.

**Treatment**

A combined abdominoperineal operation is generally the most satisfactory for the last two types of hernia. The hernia is exposed by an incision directly over it. The sac is opened and its contents are reduced. The sac is cleared from surrounding structures and the wound closed. With the patient in semi-Trendelenburg position, either laparoscopically or at open surgery, the abdomen is opened and the mouth of the sac is exposed. The sac is inverted, ligated and excised and the pelvic floor repaired by muscle apposition and, if indicated, buttressing of the repair with prosthetic mesh.

**Obturator hernia**

Obturator hernia, which passes through the obturator canal, occurs six times more frequently in women than in men. Most patients are over 60 years of age. The swelling is liable to be overlooked because it is covered by the pectineus. It seldom causes a definite swelling in Scarpa’s triangle, but if the limb is flexed, abducted and rotated outwards, the hernia sometimes becomes apparent. The leg is usually kept in a semiflexed position and movement increases the pain. In more than 50 per cent of cases of strangulated obturator hernia, pain is referred along the obturator nerve by its geniculate branch to the knee. On vaginal or rectal examination the hernia can sometimes be
felt as a tender swelling in the region of the obturator foramen. These hernias have often undergone strangulation, frequently of the Richter type, by the time of presentation.

Treatment
Operation is indicated. The diagnosis is rarely made preoperatively and so it is often approached through a laparotomy incision. Full Trendelenburg position is adopted. The constricting agent is the obturator fascia which can be stretched by inserting the operator’s index finger, or suitable forceps, through the gap in the fascia. Content is reduced. If incision of the fascia is required, it is made parallel to the obturator vessels and nerve. The contents of the sac are dealt with in standard manner. The defect cannot be simply closed as one margin is bone and the obturator nerve and vessels run through it. It is best closed using a mesh plug. In the absence of mesh or in an infected field, the broad ligament can be used as a plug.

Laparoscopic TAPP repair may also be performed again using a mesh. To avoid nerve injury, glue can be used to fix a mesh over the defect.

Gluteal and sciatic hernias
Both of these hernias are very rare. A gluteal hernia passes through the greater sciatic foramen, either above or below the piriformis. A sciatic hernia passes through the lesser sciatic foramen. Differential diagnosis must be made between these conditions and:

- a lipoma or other soft tissue tumour beneath the gluteus maximus;
- a tuberculous abscess;
- a gluteal aneurysm.

All doubtful swellings in this situation can be characterised with CT scanning but, if in doubt, they should be explored by operation.

UMBILICAL CONDITIONS IN THE ADULT

Chronic infection
Chronic infection occurs in the umbilical area, particularly in patients with poor hygiene. It may also occur in the obese and when a paraumbilical hernia is present. It can be due to a plug of keratin causing chronic irritation. It is often encountered during elective surgery and may complicate the insertion of a laparoscope port at the umbilicus. A range of bacteria and fungi can be involved. Occasionally, a rapid onset, superficial cellulitis occurs even after minor surgery in this region. It is normally a streptococcus and treated with penicillin or other appropriate antibiotic. Pre-existing infection should be treated prior to surgery where possible.

Chronic fistula
Patients may present with a persistent discharge from the umbilical area. This may be due to simple, superficial infection or possibly an infected epidermoid cyst within the umbilicus. However, it may also be due to a fistulous connection to deeper structures.

In normal patients, the umbilicus is connected to the liver, bladder and gynaecological organs by various ligaments. Diseases of these organs, such as infection or malignancy, can extend along these ligaments to appear at the umbilicus as a mass or fistulous discharge.

Chronic fistula may be a complication of umbilical hernia repair due to chronic infection of a mesh or around non-absorbable suture material. In most cases this problem arises soon after surgery but occasionally a chronic infection can occur months or even years after an operation. Antibiotics may help but most commonly the synthetic suture or mesh will need to be removed with a risk of recurrence of the hernia.

In fetal life the umbilicus was also connected to the gut by the vitellointestinal duct. In most patients this duct becomes obliterated and vanishes. The bowel end of the duct may persist as a Meckel's diverticulum. More rarely, the umbilical end persists leading to chronic discharge. If an abnormal connection between bowel and umbilicus persists then this band can act as a cause of adhesional intestinal obstruction.

Patent urachus
A connection between the urinary bladder and umbilicus usually presents in later life. This is due to increased pressure in the bladder as a result of obstruction from conditions such as prostatic hypertrophy. The cause of obstruction should be dealt with initially but if the problem persists then surgical excision of the patent urachus might be considered.

Malignancy at the umbilicus
Primary squamous carcinoma may occur. If tumour presents at the umbilicus it is most likely due to spread from internal organs along internal ligaments, for example from the liver along the falciform ligament. A malignant mass at the umbilicus is called a Sister Joseph's nodule. It usually indicates very advanced malignant disease and surgery probably has little to offer (Figure 60.31).

GENERAL INFECTION OF THE ABDOMINAL WALL

The skin of the abdominal wall, like all skin, is prone to develop superficial infection which may be spontaneous, due to minor trauma or to infection of skin lesions such as an epidermoid cyst. While antibiotics will suffice in most patients, if an abscess develops then surgical drainage may be required.

The close proximity of bowel and bowel organisms opens the abdominal wall to attack from a wide range of highly virulent bacteria. Most commonly, these are released during abdominal surgery such as appendicectomy and hence the need for appropriate antibiotic prophylactic cover.

Synergistic gangrene
This rare condition is due to the synergistic action of non-haemolytic streptococcus and staphylococcus causing rapid tissue necrosis and overwhelming systemic infection (Figure 60.32). It requires immediate administration of high-dose,

---

Antonio Scarpa, 1747–1832, Professor of Anatomy, Pavia, Italy.
Johann Frederick Meckel (the Younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany, described his diverticulum in 1809.
Alexis Littre, 1658–1726, surgeon and lecturer in Anatomy, Paris, France, described Meckel’s diverticulum in a hernial sac in 1700, 81 years before Meckel was born.

The neoplastic nodule sited at the umbilicus is known as Sister Joseph's nodule. Sister Mary Joseph made the observation that her patients with terminal cancer sometimes developed a red papular lesion in the umbilicus. She and William Mayo published this observation in 1928. However, it was Hamilton Bailey who coined the term “Sister Mary Joseph’s nodule” in 1949. Sister Mary Joseph (nee Julia Dempsey), Nursing Superintendent, St Mary’s Hospital, which became the Mayo Clinic, Rochester, MN, USA. The Mayo Clinic in Rochester, MN, USA, was founded in 1889 as the St Mary’s Hospital by William Worrall Mayo and his two sons, William James Mayo and Charles Horace Mayo, both of whom became surgeons to the hospital.
broad-spectrum, powerful antibiotics in combination with early debridement of any non-viable tissue. Hyperbaric oxygen therapy has been advocated.

Other forms of severe abdominal wall infections occur, generally known as necrotising fasciitis (e.g. Fournier’s gangrene). All of these conditions have a high associated morbidity and mortality. They occur in debilitated and immune-compromised patients but can occasionally occur in healthy patients. Rapid diagnosis and aggressive surgical debridement treatment is the key to success.

Cutaneous fistula

Due to the thickness of the abdominal wall, it is rare for abdominal inflammatory conditions to discharge spontaneously through the wall to the skin. Chronic intraperitoneal abscesses arising after occult bowel perforation, appendicitis, diverticulitis and cholecystitis are the most likely sources. CT scanning will locate the internal abscess and suggest the likely origin. Treatment today is usually by CT or ultrasound-guided drainage but the surgeon may be called on to remove the source organ, e.g. gall bladder.

Malignancy in its later stages can occasionally erode through the abdominal wall.

Figure 60.31 Secondary nodule at the umbilicus – Sister Joseph’s nodule.

Figure 60.32 Bacterial synergistic gangrene of the chest and abdominal wall. The area has become gangrenous and looks like suede leather. Beware of amoebiasis cutis.

Crohn’s disease also has a tendency to fistulate into adjacent organs and may develop an enterocutaneous fistula.

Abdominal compartment syndrome

Surgeons are increasingly aware of the harmful effect of high intra-abdominal pressures which can occur in severe intra-abdominal sepsis, such as pancreatitis and also aortic aneurysm rupture. High pressure leads to reduced blood flow and tissue ischaemia which contributes to multiorgan failure. While the abdominal wall has elasticity, if intra-abdominal volume increases due to fluid, gas, pus, tissue oedema, etc., then maximal capacity may be reached and pressure rises to a critical level. Tension releasing incisions, equivalent to a fasciotomy, have been suggested although this is not widely practised.

In some cases, after surgery for severe intraperitoneal sepsis, the surgeon cannot close the abdomen and may leave the incision wide open, covering abdominal contents with mesh or a saline-soaked dressing, planning to return at a future date to close the defect. This is called a laparostomy.

Neoplasms of the abdominal wall

As the abdominal wall is composed of muscle, fascia and bone, benign and malignant tumours can arise from each although these are rare.

Desmoid tumour

This is usually considered by pathologists to be a hamartoma and is more common in women. Some however believe it to be a fibroma and possibly the result of repeated trauma. Desmoids have been reported in familial adenomatous polyposis (FAP). Histologically they contain plasmoidal cell masses resembling giant cells. They undergo central myxomatous change. Surgical excision with a wide margin is required to prevent recurrence which is a frequent problem.

Fibrosarcoma

These tumours can occur anywhere in the body. They are generally highly malignant and respond poorly to both radio- and chemotherapy. Wide excision will often require plastic surgical reconstruction.

ANATOMY AND PHYSIOLOGY

Embryology

The peritoneal cavity, mesenters and omentum have an anatomical complexity which can perhaps only be truly understood with surgical experience. Nevertheless, an understanding of the geometric alterations occurring during early gastrointestinal (GI) morphogenesis (regionalisation, elongation and coiling) of the derivatives of the endoderm (E = epithelium) and the visceral mesoderm (M = muscle and most of the rest) along with the later fusion of adjacent layers of peritoneum will give an appreciation of how the adult disposition is as it is.

Adult arrangement and functions

The peritoneal cavity is the largest cavity in the body, the surface area of its lining membrane (2 m² in an adult) being nearly equal to that of the skin. The peritoneal membrane is composed of flattened polyhedral cells (mesothelium), one layer thick, resting upon a thin layer of fibroelastic tissue. This membrane is conveniently divided into two parts – the visceral peritoneum surrounding the viscera and the parietal peritoneum lining the other surfaces of the cavity. Beneath the peritoneum, supported by a small amount of areolar tissue, lies a network of lymphatic vessels and richplexuses of capillary blood vessels from which all absorption and exudation must occur. In health, only a few millilitres of peritoneal fluid is found in the peritoneal cavity. The fluid is pale yellow, somewhat viscid and contains lymphocytes and other leukocytes; it lubricates the viscera, allowing easy movement and peristalsis. The parietal portion is richly supplied with nerves and, when irritated, causes severe pain that is accurately localised to the affected area. The visceral peritoneum, in contrast, is poorly supplied with nerves (these being situated around blood vessels) and its irritation causes pain that is usually poorly localised to the midline.

The peritoneum has a number of functions (Summary box 61.1).

The peritoneum has the capacity to absorb large volumes of fluid: this ability is used during peritoneal dialysis in the treatment of renal failure. However, the peritoneum can also produce large volumes of fluid (ascites) and an inflammatory exudate when injured (peritonitis). During expiration, intra-abdominal pressure is reduced and peritoneal fluid, aided by capillary attraction, travels in an upward direction towards the diaphragm. Experimental evidence shows that particulate matter and bacteria are absorbed within a few minutes into the lymphatic network through a number of ‘pores’ within the diaphragmatic peritoneum. The circulation of peritoneal fluids may be responsible for the occurrence of abscesses distant from primary disease. When parietal peritoneal defects are created, healing occurs not from the edges but by the development of new mesothelial cells throughout the surface of the defect. In this way, large defects heal as rapidly as small defects.

Summary box 61.1

Functions of the peritoneum

- In health
  - Visceral lubrication
  - Fluid and particulate absorption
- In disease
  - Pain perception (mainly parietal)
  - Inflammatory and immune responses
  - Fibrinolytic activity

To recognise and understand:

- The clinical features of peritonitis and intraperitoneal abscess
- The principles of surgical management in patients with peritonitis and intraperitoneal abscess
- The causes and pathophysiology of ascites
- The pathophysiology and complications of adhesion formation
- The spectrum of mesenteric and retroperitoneal conditions
SCOPE OF DISEASE

The peritoneum, mesentery and omentum may be the site of a variety of conditions that reflect their relationship to other anatomical structures or in some instances their primary functions (Summary box 61.2).

Summary box 61.2

Scope of disease

Intraperitoneal disease
- Peritonitis
  - Primary
  - Secondary
- Abscess
- Ascites
- Transudate
- Exudate
- Tumours
  - Primary
  - Secondary
- Adhesions

Omental disease
- Hernia
- Adhesions
- Torsion
- Neoplasia

Mesenteric disease
- Trauma
- Ischaemia
- Inflammation
- Cysts
- Neoplasia

Retropertitoneal disease
- Chronic inflammation/fibrosis
- Abscess
- Tumours

PERITONITIS

Peritonitis is simply defined as inflammation of the peritoneum and may be localized or generalized. Most cases of peritonitis are caused by an invasion of the peritoneal cavity by bacteria, so that when the term ‘peritonitis’ is used without qualification, acute bacterial peritonitis is often implied. In this instance, free fluid spills into the peritoneal cavity and circulates largely directed by the normal peritoneal attachments and gravity. For example, spillage from a perforated peptic ulcer may run down the right paracolic gutter leading to presentation with pain in the right iliac fossa (Valentino’s syndrome). Even in patients with non-bacterial peritonitis (e.g. acute pancreatitis, intraperitoneal rupture of the bladder or haemoperitoneum), the peritoneum often becomes infected by transmural spread of organisms from the bowel. Such translocation is a feature of the systemic inflammatory response on the bowel and it is not long (often a matter of hours) before a bacterial peritonitis develops. Most duodenal and gastric perforations are initially sterile for up to several hours before becoming secondarily infected. Other causes of peritoneal inflammation are shown in Summary box 61.3.

Although acute bacterial peritonitis most commonly arises from a perforation of a viscus of the alimentary tract, other routes of infection can include the female genital tract and exogenous contamination. There are also less common forms in which the aetiology is a primary ‘spontaneous’ peritonitis, in which a pure infection with streptococcal, pneumococcal or haemophilus bacteria occurs. Summary box 61.4 outlines the main causes of bacterial peritonitis.

Summary box 61.3

Causes of peritoneal inflammation
- Bacterial, gastrointestinal and non-gastrointestinal
- Chemical, e.g. bile, barium
- Allergic, e.g. starch peritonitis
- Traumatic, e.g. operative handling
- Ischaemia, e.g. strangulated bowel, vascular occlusion
- Miscellaneous, e.g. familial Mediterranean fever

Summary box 61.4

Paths to peritoneal infection
- Gastrointestinal perforation, e.g. perforated ulcer, appendix, diverticulum
- Transmural translocation (no perforation), e.g. pancreatitis, ischaemic bowel
- Exogenous contamination, e.g. drains, open surgery, trauma
- Female genital tract infection, e.g. pelvic inflammatory disease
- Haematogenous spread (rare), e.g. septicaemia

Microbiology

Bacteria from the gastrointestinal tract

The number of bacteria within the lumen of the gastrointestinal tract is normally low until the distal small bowel is reached. However, disease leading to stasis and overgrowth (e.g. obstruction, chronic and acute motility disturbances) may increase proximal colonisation. The biliary and pancreatic tracts are also normally free from bacteria, although they may be infected in disease, e.g. gallstones. Peritoneal infection is usually caused by two or more bacterial strains. Gram-negative bacteria contain endotoxins (lipopolysaccharides) in their cell walls that have multiple toxic effects on the host, primarily by causing the release of tumour necrosis factor (TNF) from host leukocytes. Systemic absorption of endotoxin may produce endotoxic shock with hypotension and impaired tissue perfusion. Other bacteria such as Clostridium welchii produce harmful exotoxins. Bacteroides are commonly found in peritonitis. These Gram-negative, non-sporing organisms, although predominant in the lower intestine, often escape detection because they are strictly anaerobic and slow to grow on culture media unless there is an adequate carbon dioxide tension in the anaerobic apparatus. In many laboratories, the culture is discarded if there is no growth in 48 hours. These organisms are resistant to penicillin and streptomycin but sensitive to metronidazole, clindamycin,
lincomycin and cephalosporin compounds. Since the widespread use of metronidazole (Flagyl), Bacteroides infections have greatly diminished.

Non-gastrointestinal causes of peritonitis
Pelvic infection via the Fallopian tubes is responsible for a high proportion of ‘non-gastrointestinal’ infections. The most common offending organisms are chlamydia and gonococcus. These organisms lead to a thinning of cervical mucus and allow bacteria from the vagina into the uterus and oviducts, causing infection and inflammation. A variant of transperitoneal spread of such organisms is peritubalitis which can cause scar tissue to form on Glisson’s capsule, a thin layer of connective tissue surrounding the liver (Fitz-Hugh–Curtis syndrome). Other bacterial variants that are discussed separately include tuberculosis and other mycobacterial strains and those causing primary peritonitis (pneumococcus, staphylococcus and streptococcus spp). Fungal peritonitis is uncommon but may complicate severely ill patients (Summary box 61.5).

Localised peritonitis
Anatomical and pathological factors may favour the localisation of peritonitis.

**Anatomical**
The greater sac of the peritoneum is divided into (1) the subphrenic spaces, (2) the pelvis and (3) the peritoneal cavity proper. The last is divided into a supracolic and an infracolic compartment by the transverse colon and transverse mesocolon, which deters the spread of infection from one to the other. When the supracolic compartment overflows, as is often the case when a peptic ulcer perforates, it does so over the colon into the infracolic compartment or by way of the right paracolic gutter to the right iliac fossa and hence to the pelvis.

**Pathological**
The clinical course is determined in part by the manner in which adhesions form around the affected organ. Inflamed peritoneum loses its glistening appearance and becomes reddened and velvety. Flakes of fibrin appear and cause loops of intestine to become adherent to one another and to the parietes. There is an outpouring of serous inflammatory exudate rich in leukocytes and plasma proteins that soon becomes turbid; if localisation occurs, the turbid fluid becomes frank pus. Peristalsis is retarded in affected bowel and this helps to prevent distribution of the infection. The greater omentum, by enveloping and becoming adherent to inflamed structures, often forms a substantial barrier to the spread of infection (see below).

**Diffuse (generalised) peritonitis**
A number of factors may favour the development of diffuse peritonitis:

- Speed of peritoneal contamination is a prime factor. If an inflamed appendix or other hollow viscus perforates before localisation has taken place, there will be an efflux of contents into the peritoneal cavity, which may spread over a large area almost instantaneously. Perforation proximal to an obstruction or from sudden anastomotic separation is associated with severe generalised peritonitis and a high mortality rate.
- Stimulation of peristalsis by the ingestion of food or even water hinders localisation. Violent peristalsis occasioned by the administration of a purgative or an enema may cause the widespread distribution of an infection that would otherwise have remained localised.
- The virulence of the infecting organism may be so great as to render the localisation of infection difficult or impossible.
- Young children have a small omentum, which is less effective in localising infection.
- Disruption of localised collections may occur with injudicious handling, e.g. appendix mass or pericolic abscess.
- Deficient natural resistance (‘immune deficiency’) may result in localising infection.
- Young children have a small omentum, which is less effective in localising infection.
- Disruption of localised collections may occur with injudicious handling, e.g. appendix mass or pericolic abscess.
- Deficient natural resistance (‘immune deficiency’) may result in localising infection.
- Young children have a small omentum, which is less effective in localising infection.
- Disruption of localised collections may occur with injudicious handling, e.g. appendix mass or pericolic abscess.
- Deficient natural resistance (‘immune deficiency’) may result in localising infection.
- Young children have a small omentum, which is less effective in localising infection.
- Disruption of localised collections may occur with injudicious handling, e.g. appendix mass or pericolic abscess.
- Deficient natural resistance (‘immune deficiency’) may result in localising infection.
- Young children have a small omentum, which is less effective in localising infection.
- Disruption of localised collections may occur with injudicious handling, e.g. appendix mass or pericolic abscess.
- Deficient natural resistance (‘immune deficiency’) may result in localising infection.
- Young children have a small omentum, which is less effective in localising infection.
- Disruption of localised collections may occur with injudicious handling, e.g. appendix mass or pericolic abscess.
- Deficient natural resistance (‘immune deficiency’) may result in localising infection.

With appropriate treatment, localised peritonitis usually resolves; in about 20 per cent of cases, an abscess follows. Infrequently, localised peritonitis becomes diffuse. Conversely, in favourable circumstances, diffuse peritonitis can become localised, most frequently in the pelvis or at multiple sites within the abdominal cavity.

**Clinical features**

**Localised peritonitis**
The initial symptoms and signs of localised peritonitis are those of the underlying condition - usually visceral inflammation (hence abdominal pain, specific GI symptoms + malaise, anorexia and nausea). When the peritoneum becomes inflamed, abdominal pain will worsen and, in general, temperature and pulse rate will rise. The pathognomonic signs are localised guarding (involuntary abdominal wall contraction to protect the viscus from the examining hand), a positive ‘release’ sign (rebound tenderness) and, sometimes, rigidity (involuntary constant contraction of the abdominal wall over the inflamed parietes). If inflammation arises under the diaphragm, shoulder tip (‘phrenic’) pain may be felt as the pain is referred to the C5 dermatome. In cases of pelvic peritonitis arising from an inflamed
appendix in the pelvic position or from salpingitis, the abdominal signs are often slight; there may be deep tenderness of one or both lower quadrants alone, but a rectal or vaginal examination reveals marked tenderness of the pelvic peritoneum.

**Diffuse (generalised) peritonitis**

**Early**

Abdominal pain is severe and made worse by moving or breathing. It is first experienced at the site of the original lesion and spreads outwards from this point. The patient usually lies still. Tenderness and generalised guarding are found on palpation when the peritonitis affects the anterior abdominal wall. Infrequent bowel sounds may still be heard for a few hours but they cease with the onset of paralytic ileus. Pulse and temperature rise in accord with degree of inflammation and infection.

**Late**

If resolution or localisation of generalised peritonitis does not occur, the abdomen will become rigid (generalised rigidity). Distension is common and bowel sounds are absent. Circulatory failure ensues, with cold, clammy extremities, sunken eyes, dry tongue, thready (irregular) pulse and drawn and anxious face (Hippocratic facies; Figure 61.1). The patient finally lapses into unconsciousness. With early diagnosis and adequate treatment, this condition is rarely seen in modern surgical practice (Summary box 61.6).

---

**Summary box 61.6**

**Clinical features of peritonitis**

- Abdominal pain, worse on movement, coughing and deep respiration
- Constitutional upset: anorexia, malaise, fever, lassitude
- GI upset: nausea ± vomiting
- Pyrexia (may be absent)
- Raised pulse rate
- Tenderness ± guarding/rigidity/rebound of abdominal wall
- Pain/tenderness on rectal/vaginal examination (pelvic peritonitis)
- Absent or reduced bowel sounds
- ‘Septic shock’ (systemic inflammatory response syndrome (SIRS) and multiorgan dysfunction syndrome (MODS)) in later stages

---

**Diagnostic aids**

Investigations may elucidate a doubtful diagnosis, but the importance of a careful history and repeated examination must not be forgotten.

**Bedside**

- Urine dipstick for urinary tract infection
- ECG if diagnostic doubt (as to cause of abdominal pain) or cardiac history.

**Bloods**

- Baseline U&E for treatment
- Full blood count for white cell count (WCC)
- Serum amylase estimation may establish the diagnosis of acute pancreatitis provided that it is remembered that moderately raised values are frequently found following other abdominal catastrophes and operations, e.g. perforated duodenal ulcer

---

**Imaging**

- Erect chest radiograph to demonstrate free subdiaphragmatic gas (Figure 61.2a).
- A supine radiograph of the abdomen may confirm the presence of dilated gas-filled loops of bowel (consistent with a paralytic ileus), occasionally show other gas-filled structures that may aid diagnosis, e.g. bile duct; the faecal pattern may act as a guide to colonic disease (absent in sites of significant inflammation, e.g. diverticulitis). In the patient who is too ill for an ‘erect’ film, a lateral decubitus film can show gas beneath the abdominal wall (if CT unavailable).
- Multiplanar computed tomography (CT) is increasingly used to identify the cause of peritonitis (Figures 61.2b and 61.3) and may also influence management decisions, e.g. surgical strategy. There is an abundance of recent published evidence to support its use in managing acute abdominal pain.
- Ultrasound scanning has undoubted value in certain situations such as pelvic peritonitis in females and localised right upper quadrant peritonism.

---

**Management**

**General care of the patient**

The care of critically ill surgical patients is described in detail in Chapters 14, 17 and 21. Nutritional support is covered in Chapter 18 and anaesthesia and pain relief in Chapter 15. Depending on degree (localised/generalised), duration and severity, patients will require some or all of the following.
Correction of fluid loss and circulating volume
Patients are frequently hypovolaemic with electrolyte disturbances. The plasma volume must be restored and electrolyte concentrations corrected. Fluid balance should be monitored and pre-existent and ongoing losses corrected. Special measures may be needed for cardiac, pulmonary and renal support, especially if septic shock is present (see Chapter 2), including central venous pressure monitoring in patients with concurrent disease.

Urinary catheterisation ± gastrointestinal decompression
A urinary catheter will give a guide to central perfusion and will be required if abdominal surgery is to proceed. A nasogastric tube is commonly passed to allow drainage ± aspiration until paralytic ileus has resolved.

Antibiotic therapy
Administration of parenteral broad-spectrum (aerobic and anaerobic) antibiotics prevents the multiplication of bacteria and the release of endotoxins.

Analgesia
The patient should be nursed in the sitting-up position and must be relieved of pain before and after operation. If appropriate expertise is available, epidural infusion may provide excellent analgesia. Freedom from pain allows early mobilisation and adequate physiotherapy in the postoperative period, which helps to prevent basal pulmonary collapse, deep-vein thrombosis and pulmonary embolism.

Specific treatment of the cause
While difficult to generalise, in patients where specific treatment has not been guided by CT scanning, early surgical intervention is to be preferred to a ‘wait and see’ policy assuming that the patient is fit for anaesthesia and that resuscitation has resulted in a satisfactory restitution of normal body physiology. This rule is particularly true for previously healthy patients and those with postoperative peritonitis. More caution is, of course, required in patients at high operative risk because of comorbidity or advanced age.

In those patients with a preoperative diagnosis, if the cause of peritonitis is amenable to surgery, operation must be carried out as soon as the patient is fit. This is usually within a few hours. In peritonitis caused by pancreatitis or salpingitis, or in cases of primary peritonitis of streptococcal or pneumococcal origin, non-operative treatment is preferred provided the diagnosis can be made with confidence. It is beyond the remit of this chapter to cover specific causes of peritonitis and their treatment, be it by open or laparoscopic approach. However, in general, surgery is directed to removing (or diverting) the cause and subsequent adequate peritoneal lavage ± drainage. In operations for generalised peritonitis it is essential that, after the cause has been dealt with, the whole peritoneal cavity is explored with the sucker and, if necessary, mopped dry until all seropulent exudate is removed. The use of a large volume of saline (typically 3 litres) containing dissolved antiseptic or antibiotic has been shown to be effective (Summary box 61.7).

Prognosis and complications
With modern treatment, diffuse peritonitis carries a mortality rate of about 10% per cent reflecting the degree and duration of peritoneal contamination, age and fitness of the patient and the
nature of the underlying cause. The systemic and local complications are shown in Summary box 61.8. Paralytic ileus is covered in detail in Chapter 69; abscess formation and adhesions are covered below.

**Summary box 61.7**

**Management of peritonitis**

- General care of patient
  - Correction of fluid and electrolyte imbalance
  - Insertion of nasogastric drainage tube and urinary catheter
  - Broad-spectrum antibiotic therapy
  - Analgesia
  - Vital system support

- Operative treatment of cause when appropriate
  - Remove or divert cause
  - Peritoneal lavage ± drainage

**Summary box 61.8**

**Complications of peritonitis**

- Systemic complications
  - Bacteraemic/endotoxin shock
  - Systemic inflammatory response syndrome
  - Multigorgan dysfunction syndrome
  - Death

- Abdominal complications
  - Paralytic ileus
  - Residual or recurrent abscess/inflammatory mass
  - Portal pyaemia/liver abscess
  - Adhesional small bowel obstruction

**SPECIAL FORMS OF PERITONITIS**

**Bile peritonitis**

Unless there is reason to suspect that the biliary tract was damaged during operation or the patient has proven acute cholecystitis, it is improbable that bile as a cause of peritonitis will be thought of until the abdomen has been opened. The common causes of bile peritonitis are shown in Summary box 61.9.

Unless the bile has extravasated slowly and the collection becomes shut off from the general peritoneal cavity, there are symptoms (often severe pain) and signs of diffuse peritonitis. After a few hours a tinge of jaundice is not unusual. Laparotomy (or laparoscopy) should be undertaken with evacuation of the bile and peritoneal lavage. The source of bile leakage should be identified and treated accordingly. Infected bile is more lethal than sterile bile. A ‘blown’ duodenal stump should be drained as it is too oedematous to repair, but sometimes it can be covered by a jejunal patch. The patient is often jaundiced from absorption of peritoneal bile, but the surgeon must ensure that the abdomen is not closed until any obstruction to a major bile duct has been either excluded or relieved. Bile leaks after cholecystectomy or liver trauma may be dealt with by percutaneous (ultrasound-guided) drainage and endoscopic biliary stenting to reduce bile duct pressure. The drain is removed when dry and the stent at 4–6 weeks.

**Summary box 61.9**

**Causes of bile peritonitis**

- Perforated cholecystitis
- Postcholecystectomy
  - Cystic duct stump leakage
  - Leakage from an accessory duct in the gall bladder bed
  - Bile duct injury
  - T-tube drain dislodgement (or tract rupture on removal)
- Following other operations/procedures
  - Leaking duodenal stump postgastrectomy
  - Leaking biliary-enteric anastomosis
  - Leakage around percutaneous placed biliary drains
- Following liver trauma

**Primary peritonitis**

Primary pneumococcal peritonitis may complicate nephrotic syndrome or cirrhosis in children. Otherwise healthy children, particularly girls between three and nine years of age, may also be affected, and it is likely that the route of infection is sometimes via the vagina and Fallopian tubes. At other times, and always in males, the infection is blood-borne and secondary to respiratory tract or middle ear disease. The prevalence of pneumococcal peritonitis has declined greatly and the condition is now rare.

**Clinical features**

The onset is sudden and the earliest symptom is pain localised to the lower half of the abdomen. The temperature is raised to 39°C or more and there is usually frequent vomiting. After 24–48 hours, profuse diarrhoea is characteristic. There is usually increased frequency of micturition. The last two symptoms are caused by severe pelvic peritonitis. On examination, peritonism is usually diffuse but less prominent than in most cases of a perforated viscus leading to peritonitis.

**Investigation and treatment**

A leucocytosis ≥30 000 µL with approximately 90 per cent polymorphs suggests pneumococcal peritonitis rather than another cause, e.g. appendicitis. After starting antibiotic therapy and correcting dehydration and electrolyte imbalance, early surgery is required unless spontaneous infection of pre-existing ascites is strongly suspected, in which case a diagnostic peritoneal tap is useful. Laparotomy or laparoscopy may be used. Should the exudate be odourless and sticky, the diagnosis of pneumococcal peritonitis is practically certain, but it is essential to perform a careful exploration to exclude other pathology. Assuming that no other cause for the peritonitis is discovered, some of the exudate is aspirated and sent to the laboratory for microscopy, culture and sensitivity tests. Thorough peritoneal lavage is carried out and the incision closed. Antibiotic and fluid replacement therapy are continued and recovery is usual.

Other organisms are now known to cause some cases of primary peritonitis in children, including Flavobacterium, other streptococci and a few Gram-negative bacteria. Underlying pathology (including an intravaginal foreign body in girls) must always be excluded before primary peritonitis can be diagnosed with certainty. Idiopathic streptococcal and staphylococcal peritonitis can also occur in adults.
Tuberculous peritonitis

Intra-abdominal tuberculosis is very common in the developing world where all general surgeons are familiar with its presentation and management. The incidence is however also rising in areas of the developed world as a consequence of migration and immunosuppression where *Mycobacterium avium-intracellulare* is becoming increasingly prevalent with the widespread increase in human immunodeficiency virus (HIV) coinfection. Abdominal tuberculosis (TB) includes intraperitoneal, GI tract and solid organ disease forms with TB peritonitis being a common site-specific variant. Although still uncommon, TB peritonitis requires some specific mention since it is often diagnosed late in the course of the disease, resulting in undue patient morbidity and mortality.

Tuberculosis can spread to the peritoneum through the GI tract (typically ileocaecal region) via mesenteric lymph nodes or directly from the blood, usually from the ‘miliary’ (Figure 61.4a) but occasionally the ‘cavitating’ form of pulmonary TB, lymph and the Fallopian tubes; 50–83 per cent of patients with abdominal TB can be expected to have peritoneal involvement. Clinical or subclinical ascites is reported in virtually all patients with TB peritonitis and is frequently a presenting feature. In the most common form of the disease, wet-type peritonitis, ascites may be localised or generalised throughout the peritoneal cavity. Multiple tubercle deposits appear on both layers of the peritoneum. Diagnosis is via abdominal ultrasound or CT to detect ascites and lymphadenopathy ± diffuse thickening of the peritoneum, mesentery and/or omentum (Figure 61.4b). Ascitic fluid is typically a straw-coloured exudate (protein >25–30 g/L) with white cells >500 mm<sup>3</sup> and lymphocytes >40 per cent. Unfortunately, diagnostic smears for acid-fast bacilli are diagnostic in <3 per cent of patients and culture may take up to 4–8 weeks with no guarantee of a positive result. Laparoscopy and peritoneal biopsy may thus be helpful to couple typical appearances with histology. Management is principally supportive (nutrition and hydration) and medical (systemic antituberculous therapy) although surgery may be required for specific complications such as intestinal obstruction.

The main features are summarized in Summary box 61.10.

**Summary box 61.10**

**Tuberculous peritonitis**
- Acute (may be clinically indistinguishable from acute bacterial peritonitis) and chronic forms
- Abdominal pain, sweats, malaise and weight loss are frequent
- Ascites common, may be loculated
- Caseating peritoneal nodules are common – distinguish from metastatic carcinoma and fat necrosis of pancreatitis
- Intestinal obstruction may respond to antituberculous treatment without surgery

**Familial Mediterranean fever (periodic peritonitis)**

Familial Mediterranean fever (periodic peritonitis) is characterised by abdominal pain and tenderness, mild pyrexia, polymorphonuclear leukocytosis and, occasionally, pain in the...
thorax and joints. The duration of an attack is 24–72 hours, when it is followed by complete remission, but exacerbations recur at regular intervals. Most of the patients have undergone appendicectomy in childhood. This disease, often familial, is limited principally to Arab, Armenian and Jewish populations; other races are occasionally affected. Mutations in the MEFV (Mediterranean fever) gene appear to cause the disease. This gene produces a protein called pyrin, which is expressed mostly in neutrophils but whose exact function is not known.

Usually, children are affected but it is not rare for the disease to make its first appearance in early adult life, with cases in women outnumbering those in men by two to one. Exceptionally, the disease becomes manifest in patients over 40 years of age. At operation, which may be necessary to exclude other causes (but should be avoided if possible), the peritoneum is inflamed, particularly in the vicinity of the spleen and the gall bladder. There is no evidence that the interior of these organs is abnormal. Colchicine therapy is used during attacks and to prevent recurrent attacks.

**INTRAPERITONEAL ABSCESS**

Following intraperitoneal sepsis (usually manifest first as local or diffuse peritonitis), the anatomy of the peritoneal cavity is such that with the influence of gravity (depending on patient position – sitting or supine), abscess development usually occupies one of a number of specific abdominal or pelvic sites (Figure 61.5).

In general, the symptoms and signs of a purulent collection may be vague and consist of nothing more than lassitude, anorexia and malaise; pyrexia (often low-grade), mild tachycardia and localised tenderness. Certain sites have more specific clinical features (Summary box 61.11). Larger abscesses will give rise to the picture of swinging pyrexia and pulse and a palpable mass. Blood tests will reveal elevated inflammatory markers.

**Summary box 61.11**

**Clinical features of an abdominal/pelvic abscess**

**Symptoms**
- Malaise, lethargy – failure to recover from surgery as expected
- Anorexia and weight loss
- Sweats ± rigors
- Abdominal/pelvic pain
- Symptoms from local irritation, e.g. shoulder tip/hiccoughs (subphrenic), diarrhoea and mucus (pelvic), nausea and vomiting (any upper abdominal)

**Signs**
- Increased temperature and pulse ± swinging pyrexia
- Localised abdominal tenderness ± mass (including on pelvic exam)

**Pelvic abscess**

The pelvis is the most common site of abscess formation because the vermiform appendix is often pelvic in position and the Fallopian tubes are also frequent sites of infection. A pelvic abscess can also occur as a sequel to any case of diffuse peritonitis and is common after anastomotic leakage following colorectal surgery.

**Clinical features**

The most characteristic symptoms are of pelvic pain, diarrhoea and the passage of mucus in the stools. Rectal examination reveals a bulging of the anterior rectal wall, which, when the abscess is ripe, becomes softly cystic.

**Investigation and management**

Left to nature, a proportion of these abscesses burst into the rectum, after which the patient nearly always recovers rapidly. If this does not occur, the abscess should be drained deliberately. In women, vaginal drainage through the posterior fornix is often chosen. In other cases, when the abscess is definitely pointing into the rectum, rectal drainage (Figure 61.6) is employed. If any uncertainty exists, the presence of pus should be confirmed by ultrasound or CT scanning (Figure 61.7). Laparotomy is almost never necessary and rectal drainage of a pelvic abscess is far preferable to suprapubic drainage, which risks exposing the general peritoneal cavity to infection. Drainage tubes can also be inserted percutaneously or via the vagina or rectum under ultrasound or CT guidance.

**Figure 61.5** Common situations for residual abscesses: (1) subphrenic; (2) paracolic; (3) right iliac fossa; (4) pelvic.

**Figure 61.6** Opening a pelvic abscess into the rectum.
Intraperitoneal abscess

Anatomy
The complicated arrangement of the peritoneum results in the formation of four intraperitoneal spaces in which pus may commonly collect (Figure 61.8).

Left subphrenic space
This is bounded above by the diaphragm and behind by the left triangular ligament and the left lobe of the liver, the gastrohepatic omentum and the anterior surface of the stomach. To the right is the falciform ligament and to the left the spleen, gastroplenic omentum and diaphragm. The common cause of an abscess here is an operation on the stomach, the tail of the pancreas, the spleen or the splenic flexure of the colon.

Left subhepatic space/lesser sac
The most common cause of infection here is complicated acute pancreatitis. In practice, a perforated gastric ulcer rarely causes a collection here because the potential space is obliterated by adhesions.

Right subphrenic space
This space lies between the right lobe of the liver and the diaphragm. It is limited posteriorly by the anterior layer of the coronary and the right triangular ligaments and to the left by the falciform ligament. Common causes of abscess here are perforating cholecystitis, a perforated duodenal ulcer, a duodenal cap 'blow-out' following gastrectomy and appendicitis.

Investigation and management
Examination of the chest and plain radiograph are important, as in the majority of cases, collapse of the lung or evidence of basal effusion or even an empyema are evident. The modern management of an abscess is by radiological diagnosis using ultrasound or CT guidance (Figure 61.9) followed by drainage. The same tube can be used to instill antibiotic solutions or irrigate the

nutritional intake, diminished intestinal absorption, abnormal protein losses or defective protein synthesis such as occurs in cirrhosis. Peritoneal lymphatic drainage may be impaired, resulting in the accumulation of protein-rich fluid. A list of causes of ascites is given in Summary box 61.12.

**Summary box 61.12**

### Causes of ascites

**Transudates (protein <25 g/L)**
- Low plasma protein concentrations
  - Malnutrition
  - Nephrotic syndrome
- High central venous pressure
- Congestive cardiac failure
- Portal hypertension
- Portal vein thrombosis
- Cirrhosis

**Exudates (protein >25 g/L)**
- Tuberculous peritonitis
- Peritoneal malignancy
- Budd–Chiari syndrome (hepatic vein occlusion or thrombosis)
- Pancreatic ascites
- Chylous ascites
- Meigs’ syndrome

### Clinical features

Ascites can usually only be recognised clinically when the amount of fluid present exceeds 1.5 L, depending on body habitus: in the obese, a greater quantity than this is necessary before there is clear evidence. The abdomen is distended evenly with fullness of the flanks, which are dull to percussion. Usually, shifting dullness is present but when there is a very large accumulation of fluid this sign is absent. In such cases, on flicking the abdominal wall, a characteristic fluid thrill is transmitted from one side to the other. In women, ascites must be differentiated from an enormous ovarian cyst.

Congestive heart failure, the most common cause of ascites, results in increased venous pressure in the vena cava and consequent obstruction to the venous outflow from the liver. The ascitic fluid is light yellow and of low specific gravity, about 1.010, with a low protein concentration (<25 g/L). Patients with constrictive pericarditis (Pick’s disease) have both peritoneal and pleural effusions because of engorgement of the vena cavae consequent upon the diminished capacity of the right side of the heart. Ascites occurs with low plasma albumin concentrations, for example in patients with albuminuria or starvation. The ascites in this instance is caused by alterations in the osmotic pressure of the capillary blood and has a low specific gravity.

In cirrhosis, there is obstruction to the portal venous system, which is caused by oblitative fibrosis of the intrahepatic venous bed. In the Budd–Chiari syndrome (see Chapter 65), thrombosis or obstruction of the hepatic veins is responsible for obstruction to venous outflow from the liver. The ascites seen in patients with peritoneal metastases is caused by excessive exudation of fluid and lymphatic blockage. The fluid is dark yellow and frequently blood-stained. The specific gravity, 1.020 or over, and the protein content (>25 g/L) are high. Microscopic

George Budd, 1808–1882, Professor of Medicine, King’s College Hospital, London, UK, described this syndrome in 1845.
examination often reveals cancer cells, especially if large quantities of fluid are ‘spun down’ to produce a concentrated deposit for sampling. Rarely, ascites and pleural effusion are associated with solid fibromas of the ovary (Meigs’ syndrome). The effusions disappear when the tumour is excised.

Investigation

In addition to relevant investigations that may determine the underlying cause, e.g. liver and cardiac function tests, ultrasound and/or CT imaging (Figure 61.10) will determine much smaller quantities of ascites than possible clinically. These will often also diagnose aetiology, e.g. carcinomatosis, liver disease. Ascitic aspiration or tap (below) is now most commonly performed under imaging guidance to minimize the risk of visceral injury. The bladder having been emptied, puncture of the peritoneum is carried out under local anaesthetic using a moderately sized trocar and cannula. Alternatively, a peritoneal drain may be inserted. In cases where the effusion is caused by cardiac failure, the fluid must be evacuated slowly. Fluid is sent for microscopy/cytology, culture, including mycobacteria, and analysis of protein content and amylase. Unless other measures are taken the fluid soon reaccumulates, and repeated tapings remove valuable protein.

Treatment

Treatment of the specific cause is undertaken whenever possible; for example, if portal venous pressure is raised, it may be possible to lower it by treatment of the primary condition. Dietary sodium restriction to 200 mg/day may be helpful, but diuretics are usually required. In rare cases in which ascites accumulates rapidly after paracentesis and the patient is otherwise fit, permanent drainage of the ascitic fluid via a peritoneovenous shunt (e.g. LeVeen, Denver) may render the patient more comfortable. Similar in concept to shunts for hydrocephalus (see Chapter 43), a catheter (e.g. of silicone) is constructed with a valve so as to allow one-way flow from the peritoneum to a central vein (e.g. internal jugular). A chamber placed subcutaneously over the chest wall may be included for manual compression. Insertion is relatively simple. The complications include overloading the venous system, cardiac failure and disseminated intravascular coagulopathy. The frequency of these complications may be reduced by evacuating ascitic fluid and partially replacing it with normal saline at the time of shunt insertion.

The procedure may also be used for patients with terminal malignant ascites, giving improved quality of life despite the risk of further dissemination of malignant cells.

Special cases

Chylous ascites

In some patients the ascitic fluid appears milky because of an excess of chylomicrons (triglycerides). Most cases are associated with malignancy, usually lymphomas; other causes are cirrhosis, tuberculosis, filariasis, nephrotic syndrome, abdominal trauma (including surgery), constrictive pericarditis, sarcoidosis and congenital lymphatic abnormality. The diagnosis is poor unless the underlying condition can be cured. In addition to other measures used to treat ascites, patients should be placed on a fat-free diet with medium-chain triglyceride supplements.

TUMOURS OF THE PERITONEUM

Primary tumours

Primary tumours of the peritoneum are rare and in most cases take their origin not from the serous layer but from some adjacent structure, e.g. lipoma from appendices epiploicae, fibroma from connective tissue. Mesothelioma of the peritoneum is less frequent than in the pleural cavity but equally lethal. Asbestos is a recognised cause. It has a predilection for the pelvic peritoneum. Chemocytotoxic agents are the mainstay of treatment. Desmoid tumours which have a relationship to the peritoneum are considered under familial adenomatous polyposis (Chapter 69).

Secondary tumours

Carcinomatosis peritonei

This is a common terminal event in many cases of carcinoma of the stomach, colon, ovary or other abdominal organs and also of the breast and bronchus. The peritoneum, both parietal and visceral, is studded with secondary growths and the peritoneal cavity becomes filled with clear, straw-coloured or blood-stained ascitic fluid.

The main forms of peritoneal metastases are:

- discrete nodules – by far the most common variety;
- plaques varying in size and colour;
- diffuse adhesions – this form occurs at a late stage of the disease and gives rise, sometimes, to a ‘frozen pelvis’.

Gravity probably determines the distribution of free malignant cells within the peritoneal cavity. Cells not caught in peritoneal folds gravitate into the pelvic pouches or into a hernial sac, the enlargement of which is occasionally the first indication of the condition. Implantation occurs also on the greater omentum, the appendices epiploicae and the inferior surface of the diaphragm. The main differential diagnosis is from tuberculous peritonitis (tubercles are greyish and translucent and closely resemble the discrete nodules of peritoneal carcinomatosis). Investigation and treatment are as for underlying malignancy.

Pseudomyxoma peritonei

This rare condition occurs more frequently in women. The abdomen is filled with a yellow jelly, large quantities of which are often encysted. The condition is associated with mucinous

Figure 61.10 Computed tomography scan showing gross ascites.

Friedel Pick, 1867–1926, physician, Prague, The Czech Republic, described this disease in 1896.

Harry LeVeen, Professor of Surgery, the University of South Carolina, SC, USA.
Adhesions (peritoneal mice)
Peritoneal loose bodies (peritoneal mice) may be confused with a small tumour but almost never cause symptoms. One or more may be found in a hernial sac or in the pouch of Douglas. The loose body may come from an appendix epiploica that has undergone axial rotation followed by necrosis of its pedicle and detachment but they are also found in those who suffer from subacute attacks of pancreatitis. These hyaline bodies attain the size of a pea or bean and contain saponified fat surrounded by fibrin.

ADHESIONS
Pathophysiology
Adhesions are strands of fibrous tissue that form, usually as a result of surgery, between surgically injured tissues. After injury, there is bleeding and an increase in vascular permeability with extravasation of fibrinogen-rich fluid from the injured surfaces forming a temporary fibrin matrix. An inflammatory response ensues with cell migration, release of cytokines, and activation of the coagulation cascade. The activation of the coagulation system results in thrombin formation, which is necessary for the conversion of fibrinogen to fibrin. In the absence of fibrinolysis, adhesions will form within 5–7 days as the matrix gradually becomes more organised with collagen secretion by fibroblasts. Fibrinolysis is therefore the key factor in determining whether an adhesion persists. This is governed by several cascades and activators that may account for interindividual differences (Chapter 59). Of great importance however to the surgeon is the fact that ischaemic tissue loses its ability to break down fibrin and inhibits fibrinolysis in adjacent tissues.

Complications
The most common adhesion-related problem is small bowel obstruction (SBO). Adhesions are the most frequent cause of SBO in the developed world and are responsible for 60–70 per cent of SBO (see Chapter 69). Adhesions are implicated as a major cause of secondary infertility (beyond the remit of this text). The relationship of adhesions to chronic abdominal and pelvic pain is contentious. Unguided division of adhesions has not been shown to reduce chronic abdominal pain in definitive randomised controlled trials although conscious pain mapping (laparoscopy under local anaesthesia) to direct lysis may improve success rates.

Prevention
Because of the scale of the problem there has been significant research into ways of preventing postoperative adhesion formation. Minimising the production of ischaemic tissue by careful operative technique, including meticulous control of bleeding, remains however the most critical concepts. The evolution of laparoscopic bowel surgery has been shown by collective review data to result in reduced adhesion-related readmissions for a number of abdominal and pelvic procedures, e.g. cholecystectomy, hysterectomy and colectomy. It should be noted however that only one randomised controlled trial (after Crohn’s resection) has ever shown a definitive effect and this was not confirmed by evidence synthesis at Cochrane review.

The effect of a number of drugs including anti-inflammatory drugs like aspirin and steroids, some hormones, anticoagulating agents, antibiotics, vitamin E and even methylene blue have been investigated in adhesion prevention but have not achieved widespread use either because of side effects or lack of consistent evidence of effectiveness. Many barrier methods of reducing adhesions have also been trialled. Adept® (4 per cent icodextrin solution) is a solution applied inside the abdomen at the time of surgery and has been shown to reduce the extent and severity of adhesion formation in animal models. It has also been used widely as a peritoneal dialysis solution for many years. Interceed® is a mesh-like product (oxidised regenerated cellulose) which quickly forms a soft gelatinous mass around healing tissues and is absorbed within 2 weeks. It has been shown to significantly reduce the number of adhesions at the site where it is used. However, it is worth noting that a reduction in the number of adhesions in such studies does not necessarily equate to a reduction in adhesion-related problems in the future. In a review of seven randomised trials looking at a similar barrier-type product (hyaluronic acid/carboxymethyl membrane), there was a significant reduction in the incidence, extent and severity of adhesions but no reduction in the incidence of intestinal obstruction or operative intervention. Such barriers when placed around bowel anastomosis also led to a significant increase in the anastomotic leaks. For these reasons barrier approaches have not gained popularity.

Special forms of intraperitoneal fibrosis
Sclerosing encapsulating peritonitis
Also known as abdominal cocoon syndrome, sclerosing encapsulating peritonitis (SEP) is described in patients as a complication of long-term peritoneal dialysis or portovenous shunting. The peritoneal cavity becomes obliterated as a result of gross subserosal thickening by fibrosis leading to bowel obstruction and other sequelae. Surgery should be undertaken with trepidation and avoided if possible.

Diffuse fibromatosis
This is a variant of intra-abdominal fibromatosis (IAF) and is actually a rare tumour characterised by an abnormal proliferation of myofibroblasts. Although non-metastasising, and said to be benign, it can nevertheless prove widely invasive, compressing and infiltrating surrounding tissues such as the bowel and mesentery with complications thereof. IAF is very rare within the general population but has a recognised association with familial adenomatous polyposis (FAP).
THE OMENTUM

Rutherford Morison called the greater omentum 'the abdominal policeman'. The greater omentum attempts, often successfully, to limit intraperitoneal infective and other noxious processes (Figure 61.11). For instance, an acutely inflamed appendix is often found wrapped in omentum, and this saves many patients from developing diffuse peritonitis. Some sufferers of herniae are also greatly indebted to this structure, for it often plugs the neck of a hernial sac and prevents a coil of intestine from entering and becoming strangulated. It can, of course, also be a cause of obstruction (acting as a large adhesion). The omentum is usually involved in tuberculous peritonitis and carcinomatosis of the peritoneum.

Torsion of the omentum

Torsion of the omentum is a rare emergency and consequently is seldom diagnosed correctly. It is usually mistaken for appendicitis with somewhat abnormal signs. It may be primary, or secondary to adhesion of the omentum to an old focus of infection or hernia. The patient is most frequently a middle-aged, obese man. A tender lump may be present in the abdomen. The blood supply having been jeopardised, the twisted mass sometimes becomes gangrenous, in which case bacterial peritonitis may follow. Treatment is surgical; the pedicle above the twist is ligated securely and the mass removed.

THE MESENTERY

Mesenteric injury

A wound of the mesentery can follow severe abdominal contusion and is a cause of haemoperitoneum. More commonly, it is injured by a torsional force, so-called seatbelt syndrome. This occurs during a vehicular collision when a seatbelt is being worn with sudden deceleration resulting in a torn mesentery. This possibility should be borne in mind, particularly as multiple injuries may distract attention from this injury (the management of abdominal trauma is covered in Chapter 23). Aside from control of any ongoing haemorrhage, associated ischaemic or ruptured gut will require resection.

Ischaemia

Torsion of the mesentery is covered under midgut volvulus and volvulus of the small intestine (see Chapter 70). Embolism and thrombosis of mesenteric vessels leading to intestinal ischaemia are also covered in Chapter 70.

Inflammation

A number of somewhat miscellaneous conditions are best described under this umbrella term.

Acute non-specific ileocaecal mesenteric adenitis

Non-specific mesenteric adenitis was so named to distinguish it from specific (tuberculous) mesenteritis. It is now much more common than the tuberculous variety. The aetiology often remains unknown, although some cases are associated with Yersinia infection of the ileum. In other cases, an unidentified virus is blamed. In about 25 per cent of cases, a respiratory infection precedes an attack of non-specific mesenteric adenitis.

This self-limiting disease is never fatal but may be recurrent. Its significance thus mainly lies in its differential diagnosis with appendicitis in children.

Diagnosis

During childhood, acute non-specific mesenteric adenitis is a common condition. The typical history is one of short attacks of central abdominal pain lasting from 10 to 30 minutes, commonly associated with vomiting. The patient seldom looks ill. In more than half of the cases the temperature is elevated. Abdominal tenderness is poorly localised, and when present, shifting tenderness is a valuable sign for differentiating the condition from appendicitis. The neck, axillae and groins should be palpated for enlarged lymph nodes. There is often a leukocytosis of 10,000–12,000 µL (10–12 × 10^9 L) or more on the first day of the attack, but this falls on the second day.

Treatment

When the diagnosis can be made with assurance, bed rest and simple analgesia is the only treatment necessary. If at a second examination a few hours later, acute appendicitis cannot be excluded, it is safer to perform either appendicectomy or diagnostic laparoscopy. If surgery is mistakenly undertaken, there is a small increase in the amount of peritoneal fluid. The ileocaecal mesenteric lymph nodes are enlarged and can be seen and felt between the leaves of the mesentery. In very acute cases they are distinctly red, and many of them are the size of a walnut. The nodes nearest the attachment of the mesentery are the largest. They are not adherent to their peritoneal coats and, if a small incision is made through the overlying peritoneum, a node is extruded easily.

**Tuberculosis of the mesenteric lymph nodes**

Tuberculous mesenteric lymphadenitis is considerably less common than acute non-specific lymphadenitis. Tubercle bacilli, usually, but not necessarily, bovine, are ingested and enter the mesenteric lymph nodes by way of Peyer’s patches. Sometimes only one lymph node is infected; usually there are several; occasionally massive involvement occurs. The presentation may be with abdominal pain (a rare differential for appendicitis) or with general constitutional symptoms (pyrexia, weight loss, etc.). Calcified lymph nodes may be demonstrated on a plain radiograph of the abdomen where they must be distinguished from other calcified lesions, e.g. renal or ureteric stones.

**Misty mesentery**

The term ‘misty mesentery’ indicates a pathological increase in mesenteric fat attenuation on CT (Figure 61.12). It is frequently observed on multidetector CT (MDCT) scans performed during daily clinical practice and may be caused by various pathological conditions, including oedema, inflammation (especially in association with pancreatitis), haemorrhage, neoplastic infiltration (especially otherwise occult lymphoma) or sclerosing mesentery. In patients suffering from acute abdominal disease, misty mesentery may be considered a feature of the underlying disease. Otherwise, it may represent an incidental finding on MDCT performed for other reasons. Follow-up scans may be required to dictate whether further investigation is required depending on progression or resolution. It should be noted that the term ‘mesenteric panniculitis’ is frequently used synonymously with ‘misty mesentery’. Correctly this term should be reserved for ‘mesenteric panniculitis’ is frequently used synonymously with ‘mesenteric panniculitis’.

**Mesenteric cysts**

Cysts may occur in the mesentery of either the small intestine (60 per cent) or the colon (40 per cent) and can be classified as:

- chylolymphatic;
- enterogenous;
- urogenital remnant (actually retroperitoneal but project into peritoneum);
- dermoid.

**Pathology**

**Chylolymphatic cyst**

This is the most common variety, probably arising in congenitally misplaced lymphatic tissue that has no efferent communication with the lymphatic system (most frequently in the mesentery of the ileum). The thin wall of the cyst, which is composed of connective tissue lined by flat endothelium, is filled with clear lymph or, less frequently, with chyle varying in consistency from watered milk to cream. Occasionally, the cyst attains a great size. More often unilocular than multilocular, a chylolymphatic cyst is almost invariably solitary, although there is an extremely rare variety in which myriads of cysts are found in the various mesenteries of the abdomen. A chylolymphatic cyst has a blood supply that is independent from that of the adjacent intestine and, thus, enucleation is possible without the need for resection of gut.

**Enterogenous cysts**

These are believed to be derived either from a diverticulum of the mesenteric border of the intestine that has become sequestered from the intestinal canal during embryonic life or from a duplication of the intestine (see Chapter 8). An enterogenous cyst has a thicker wall than a chylolymphatic cyst and it is lined by mucous membrane, sometimes ciliated. The content is mucinous and is either colourless or yellowish brown as a result of past haemorrhage. The muscle in the wall of an enteric duplication cyst and the bowel with which it is in contact have a common blood supply; consequently, removal of the cyst always entails resection of the related portion of intestine.

**Urogenital remnant**

A cyst developing in the retroperitoneal space (see below) often attains very large dimensions and has first to be distinguished from a large hydronephrosis. Even after the latter condition has been eliminated by scanning or urography, a retroperitoneal cyst can seldom be distinguished with certainty from a retroperitoneal tumour until displayed at operation. The cyst may be unilocular or multilocular. Many of these cysts are believed to be derived from a remnant of the Wolffian duct, in which case they are filled with clear fluid.

**Clinical features**

These are shown for mesenteric cysts in general in Summary box 61.13.

**Investigation and treatment**

Ultrasound and CT scanning will demonstrate the lesion and may allow diagnosis of cyst type (Figure 61.14a,b). There are no suitable medical therapies. The goal of surgical therapy is complete excision of the mass. The preferred treatment of

Figure 61.12 Computed tomography scan showing ‘misty mesentery’ in a patient with probable peritoneal inflammation secondary to acute pancreatitis (courtesy of Dr K Patel, Homerton University Foundation Trust, London, UK).
enterogenous mesenteric cyst, i.e. with resection of the adjacent intestine. A malignant tumour of the mesentery requires biopsy confirmation and specific, usually non-surgical, treatment, e.g. chemotherapy for lymphoma.

Summary box 61.13

Mesenteric cysts: clinical features
- Cysts occur most commonly in adults with a mean age of 45 years
- Twice as common in women as in men
- Rare – incidence around 1 per 140 000
- Approximately one-third of cases occur in children younger than 15 years
- The mean age of children affected is 4.9 years
- The most common presentation is of a painless abdominal swelling with characteristic physical signs
  - there is a fluctuant swelling near the umbilicus
  - the swelling moves freely in a plane at right angles to the attachment of the mesentery [Tillaux’s sign] (Figure 61.13)
  - there is a zone of resonance around the cyst
- Other presentations are with recurrent attacks of abdominal pain with or without vomiting (pain resulting from recurring temporary impaction of a food bolus in a segment of bowel narrowed by the cyst or possibly from torsion of the mesentery) and acute abdominal catastrophe, due to torsion of that portion of the mesentery containing the cyst
- rupture of the cyst, often as a result of a comparatively trivial accident
- haemorrhage into the cyst

THE RETROPERITONEAL SPACE

Retroperitoneal chronic inflammation/fibrosis
This is a relatively rare diagnosis characterised by the development of a flat grey/white plaque of tissue which is found first in the low lumbar region but then spreads laterally and upwards to encase the common iliac vessels, ureters and aorta. Histological appearances vary from active inflammation with a high cellular content interspersed with bundles of collagen through to one of acellularity and mature fibrosis/calcification. Its aetiology is obscure in most cases (idiopathic) being allied to other fibromatoses (others being Dupuytren’s contracture and Peyronie’s disease). In other patients the cause is known (Summary box 61.15).

Summary box 61.14

Mesenteric tumours
Benign
- Lipoma
- Fibroma
- Fibromyxoma
Malignant
- Lymphoma
- Secondary carcinoma

Neoplasms of the mesentery
The mesentery is necessarily affected by local lymphatic spread of carcinoma arising from the peritoneal viscera. Other benign and malignant tumours are less common (Summary box 61.14).

Tumours situated in the mesentery give rise to physical signs that are similar to those of a mesenteric cyst, the sole exception being that they sometimes feel solid. If indicated, a benign tumour of the mesentery is excised in the same way as an enterogenous mesenteric cyst, i.e. with resection of the adjacent intestine. A malignant tumour of the mesentery requires biopsy confirmation and specific, usually non-surgical, treatment, e.g. chemotherapy for lymphoma.
The clinical presentation may be one of ill-defined chronic backache or may occur as a result of compromise to involved structures, e.g. lower limb or scrotal oedema secondary to venous occlusion, or chronic renal failure secondary to ureteric obstruction. Treatment will be directed to the cause, to the modification of disease activity when appropriate, e.g. immune suppression with steroids and restoration of flow in affected structures, e.g. ureteric stenting.

**Retroperitoneal (psoas) abscess**

The retroperitoneal space can also be a site for abscess formation which for practical purposes is almost synonymous with psoas abscess. Psoas abscess is a relatively uncommon diagnosis whose true incidence is not well described. At the beginning of the twentieth century, psoas abscess was mainly caused by tuberculosis of the spine (Pott’s disease). With the decline of *Mycobacterium tuberculosis* as a major pathogen in developed countries a psoas abscess was mostly found secondary to direct spread of infection from the inflamed ± perforated digestive or urinary tract. In recent years, a primary psoas abscess due to haematogenous spread from an occult source is more common, especially in immunocompromised and older patients as well as in association with intravenous drug misuse.

Clinical presentation is with back pain, lassitude and fever. A swelling may point to the groin as it tracks along ileopsoas (see Chapter 73). Pain may be elicited by passive extension of the hip or a fixed flexion of the hip evident on inspection.

Radiological investigation is via CT scanning (Figure 61.15) and treatment usually by percutaneous CT-guided drainage and appropriate antibiotic therapy.

**Retroperitoneal tumours**

Although swellings in the retroperitoneum may include abscess, haematoma, cysts (see above) and spread of malignancy from retroperitoneal organs (kidney, ureter, adrenal), the term retroperitoneal tumour is usually confined to primary tumours arising in other tissues in this region, e.g. muscles, fat, lymph nodes and nerves. The management of such tumours is now frequently by referral to a specialist centre and this should be done before biopsy which may compromise subsequent surgical cure. The two most common are briefly described.

**Retroperitoneal lipoma**

The patient may seek advice on account of a swelling or because of indefinite abdominal pain. Women are more often affected. These swellings sometimes reach an immense size. Diagnosis is usually by ultrasound and CT scanning. A retroperitoneal lipoma sometimes undergoes myxomatous degeneration, a complication that does not occur in a lipoma in any other part of the body. Moreover, a retroperitoneal lipoma is often malignant (liposarcoma) (see below) and may increase rapidly in size.

**Retroperitoneal sarcoma**

Retroperitoneal sarcomas are rare tumours accounting for only 1–2 per cent of all solid malignancies (10–20 per cent of all sarcomas are retroperitoneal). The peak incidence is in the fifth decade of life, although they can occur at almost any age. The most common types of retroperitoneal soft tissue sarcomas in adults vary from study to study. However, in most studies, the most frequently encountered cell types are:

---

Baron Guillaume Dupuytren, 1777–1835, Surgeon in Chief, Hôtel Dieu, Paris, France, described this condition in 1831.

François de la Peyronie, 1678–1747, surgeon to King Louis XIV of France and founder of the Royal Academy of Surgery, Paris, France.

JK Ormond, an American urologist.
Clinical features
Patients with sarcomas present late, because these tumours arise in the large potential spaces of the retroperitoneum and can grow very large without producing symptoms. Moreover, when symptoms do occur, they are non-specific, such as abdominal pain and fullness, and are easily dismissed as being caused by other less serious processes. Retroperitoneal sarcomas, therefore, are usually very large at the time of presentation.

Investigation
Detailed multiplanar imaging (CT + magnetic resonance imaging) with reconstructions are required not only for tumour detection, staging and operative planning, but also for guiding percutaneous or surgical biopsy of these tumours. Such biopsies have a greater role than for other sarcomas.

Treatment
The definitive treatment of primary retroperitoneal sarcomas is surgical resection. Chemotherapy and radiotherapy without surgical debulking have rarely been beneficial, when used alone or in combination. A multidisciplinary team approach with imaging review will be required when assessing operability (based on adjacency or involvement of vital structures) and approach. Up to 75 per cent of retroperitoneal sarcoma resections involve resection of at least one adjoining intra-abdominal visceral organ (commonly large or small bowel or kidney). The most common types of vascular involvement precluding resection are involvement of the proximal superior mesenteric vessels or involvement of bilateral renal vessels.

Prognosis
In the vast majority of sarcomas, cell type has no impact on treatment and long-term survival. Survival rates are, in general, poor, even after complete resection, these being in the order of 35–50 per cent (excluding low grade liposarcomas, which may frequently be cured by resection).

Chapter 62
The oesophagus

Learning Objectives

To understand:
- The anatomy and physiology of the oesophagus and their relationship to disease
- The clinical features, investigations and treatment of benign and malignant disease with particular reference to the common adult disorders

Background

Surgical anatomy
The oesophagus is a muscular tube, approximately 25 cm long, mainly occupying the posterior mediastinum and extending from the upper oesophageal sphincter (the cricopharyngeus muscle) in the neck to the junction with the cardia of the stomach. The musculature of the upper oesophagus, including the upper sphincter, is striated. This is followed by a transitional zone of both striated and smooth muscle with the proportion of the latter progressively increasing so that, in the lower half of the oesophagus, there is only smooth muscle. It is lined throughout with squamous epithelium. The parasympathetic nerve supply is mediated by branches of the vagus nerve that has synaptic connections to the myenteric (Auerbach’s) plexus. Meissner’s submucosal plexus is sparse in the oesophagus.

The upper sphincter consists of powerful striated muscle. The lower sphincter is more subtle, and is created by the asymmetrical arrangement of muscle fibres in the distal oesophageal wall just above the oesophago gastric junction. It is helpful to remember the distances 15, 25 and 40 cm for anatomical location during endoscopy (Figure 62.1).

Physiology
The main function of the oesophagus is to transfer food from the mouth to the stomach in a coordinated fashion. The initial movement from the mouth is voluntary. The pharyngeal phase of swallowing involves sequential contraction of the oropharyngeal musculature, closure of the nasal and respiratory passages, cessation of breathing and opening of the upper oesophageal sphincter. Beyond this level, swallowing is involuntary. The body of the oesophagus propels the bolus through a relaxed lower oesophageal sphincter (LOS) into the stomach, taking air with it (Figure 62.2). This coordinated oesophageal wave that follows a conscious swallow is called primary peristalsis. It is under vagal control, although there are specific neurotransmitters that control the LOS.

The upper oesophageal sphincter is normally closed at rest and serves as a protective mechanism against regurgitation of oesophageal contents into the respiratory passages. It also serves to stop air entering the oesophagus other than the small amount that enters during swallowing.

The LOS is a zone of relatively high pressure that prevents gastric contents from refluxing into the lower oesophagus (Figure 62.3). In addition to opening in response to a primary peristaltic wave, the sphincter also relaxes to allow air to escape from the stomach and at the time of vomiting. A variety of factors influence sphincter tone, notably food, gastric distension, gastrointestinal hormones, drugs and smoking. The arrangement of muscle fibres, their differential responses to specific neurotransmitters and the relationship to diaphragmatic contraction all contribute to the action of the LOS. The presence of the physiological sphincter was first demonstrated by Code using manometry with small balloons. Nowadays, LOS pressure is measured by perfused tubes or microtransducers. The normal LOS is 3–4 cm long.

Leopold Auerbach, 1828–1897, Professor of Neuropathology, Breslau, Germany (now Wroclaw, Poland), described the myenteric plexus in 1862.
George Meissner, 1829–1905, Professor of Physiology, Göttingen, Germany, described the submucosal plexus in 1852.
and has a pressure of 10–25 mmHg. Accurate measurement of sphincter relaxation is achieved using a device (Dent sleeve) that straddles the high-pressure zone.

Manometry is also used to assess the speed and amplitude of oesophageal body contractions and ensure that peristalsis is propagated down the entire length of the oesophagus (Figure 62.4). Secondary peristalsis is the normal reflex response to a stubborn food bolus or refluxed material designed to clear the oesophagus by a contraction that is not preceded by a conscious swallow. It is worth remembering that the majority of clearance swallows to neutralise refluxed gastric acid are, however, achieved by primary peristalsis, which carries saliva with its high bicarbonate content down to the lower oesophagus. Tertiary contractions are non-peristaltic waves that are infrequent (<10 per cent) during laboratory-based manometry, although readily detected if manometry is undertaken while the patient eats a meal (Figure 62.5).

**Symptoms**

**Dysphagia**

Dysphagia is used to describe difficulty with swallowing. When there is a problem with swallowing in the voluntary (oral or pharyngeal) phases, patients will usually say that they cannot swallow properly, but they do not characteristically describe ‘food sticking’. Instead, when they try to initiate a conscious swallow, food fails to enter the oesophagus, stays in the mouth or enters the airway causing coughing or spluttering. Virtually all causes of this type of dysphagia are chronic neurological or muscular diseases. Oesophageal dysphagia occurs in the involuntary phase and is characterised by a sensation of food sticking. The nature of this type of dysphagia is often informative regarding a likely diagnosis. Dysphagia may occur acutely or in a chronic fashion, can affect solids and/or fluids and be intermittent or progressive. While many patients point to a site of impaction, this is unreliable.

---

**Figure 62.2** A bolus of barium or food usually takes air with it into the stomach.

**Figure 62.3** Correlation between the radiological appearances of a barium column and the lower oesophageal sphincter open and closed. The three curves on the right, set up vertically, show the pH gradient, the mucosal potential difference (PD) marking the junction of squamous and columnar epithelium and the high-pressure zone of the sphincter.
Odynophagia refers to pain on swallowing. Patients with reflux oesophagitis often feel retrosternal discomfort within a few seconds of swallowing hot beverages, citrus drinks or alcohol. Odynophagia is also a feature of infective oesophagitis and may be particularly severe in chemical injury.

Regurgitation and reflux are often used synonymously. It is helpful to differentiate between them, although it is not always possible. Regurgitation should strictly refer to the return of oesophageal contents from above a functional or mechanical obstruction. Reflux is the passive return of gastroduodenal contents to the mouth as part of the symptomatology of gastro-oesophageal reflux disease (GORD). Loss of weight, anaemia, cachexia, change of voice due to refluxed material irritating the vocal cords and cough or dyspnoea due to tracheal aspiration may all accompany regurgitation and/or reflux.

Chest pain similar in character to angina pectoris may arise from an oesophageal cause, especially gastro-oesophageal reflux and motility disorders. Exercise-induced chest pain can be due to reflux (Summary box 62.1).

### Summary box 62.1

**Symptoms of oesophageal disease**

- Difficulty in swallowing described as food or fluid sticking (oesophageal dysphagia) must rule out malignancy
- Pain on swallowing (odynophagia) suggests inflammation and ulceration
- Regurgitation or reflux (heartburn) common in gastro-oesophageal reflux disease
- Chest pain is difficult to distinguish from cardiac pain

**Investigations**

**Radiography**

Contrast radiography has been somewhat overshadowed by endoscopy but remains a useful investigation for demonstrating narrowing, space-occupying lesions, anatomical distortion or abnormal motility. An adequate barium swallow should be tailored to the problem under investigation. It may be helpful to give a solid bolus (bread or marshmallow) if a motility disorder is suspected. Video recording is useful to allow subsequent replay and detailed analysis. Barium radiology is, however, inaccurate in the diagnosis of gastro-oesophageal reflux, unless reflux is gross, and should not be used for this purpose. Plain radiographs will show some foreign bodies.

Cross-sectional imaging by computed tomography (CT) scanning is now an essential investigation in the assessment of neoplasms of the oesophagus and can be used in place of a contrast swallow to demonstrate perforation. The role of CT and other cancer-specific tests is described later.
**Endoscopy**

Endoscopy is necessary for the investigation of most oesophageal conditions. It is required to view the inside of the oesophagus and the oesophagogastric junction, to obtain a biopsy or cytology specimen, for the removal of foreign bodies and to dilate strictures. Traditionally, there are two types of instrument available, the rigid oesophagoscope and the flexible video endoscope, but the rigid instrument is now virtually obsolete.

For flexible video gastro-duodenoscope, general anaesthesia is not required; most examinations can be done on an outpatient basis, and the quality of the magnified image is superb. The technology associated with video endoscopy continues to improve. Novel techniques that rely on fluorescence and narrow band imaging to enhance visual contrast are becoming increasingly used for the identification of mucosal abnormalities that are not easily seen with white light, for instance in patients with Barrett's oesophagus undergoing endoscopic surveillance.

As a matter of routine, the stomach and duodenum are examined as well as the oesophagus. If a stricture is encountered, it may be helpful to dilate it to allow a complete inspection of the upper gastrointestinal tract, but this decision should be dictated by clinical circumstances and an appreciation of the perforation risk.

**Endosonography**

Endoscopic ultrasonography relies on a high-frequency (5–30 MHz) transducer located at the tip of the endoscope to provide highly detailed images of the layers of the oesophageal wall and mediastinal structures close to the oesophagus. Radial echoendoscopes have a rotating transducer that creates a circular image with the endoscope in the centre, and this type of scanner is widely used to create diagnostic transverse sectional images at right angles to the long axis of the oesophagus (Figure 62.6). Linear echoendoscopes produce a sectoral image in the line of the endoscope and are used to biopsy submucosal oesophageal lesions or mediastinal masses such as lymph nodes (Figure 62.7). Radial scanners without optical components are available for passage through narrow strictures over a guidewire, and there are even catheter probes that can be passed down the endoscope biopsy channel.

**Oesophageal manometry**

Manometry is now widely used to diagnose oesophageal motility disorders. Recordings are usually made by passing a multilumen catheter with three to eight recording orifices at different levels down the oesophagus and into the stomach. Electronic microtransducers that are not influenced by changes in patient position during the test have gradually supplanted perfusion systems. With either system, the catheter is withdrawn progressively up the oesophagus, and recordings are taken at intervals of 0.5–1.0 cm to measure the length and pressure of the LOS and assess motility in the body of the oesophagus during swallowing. High-resolution manometry uses a multiple (up to 30) microtransducer catheter with the results displayed as spatiotemporal plots; this system is likely to supplant conventional manometry.

**Twenty-four hour pH and combined pH-impedance recording**

Prolonged measurement of pH is now accepted as the most accurate method for the diagnosis of gastro-oesophageal reflux. It is particularly useful in patients with atypical reflux symptoms, those without endoscopic oesophagitis and when patients respond poorly to intensive medical therapy. A small pH probe is passed into the distal oesophagus and positioned 5 cm above the upper margin of the LOS, as defined by manometry. The probe is connected to a miniature digital recorder that is worn on a belt and allows most normal activities. Patients mark symptomatic events such as heartburn. A 24-hour recording period is usual, and the pH record is analysed by an automated computer program. An oesophageal pH < 4 at the level of the pH electrode is conventionally considered the cut-off value and, in most oesophageal laboratories, the total time when pH is < 4 in a 24-hour period does not exceed 4 per cent in a healthy adult. Patterns of reflux and the correlation between symptoms and oesophageal pH < 4 can be calculated. Most laboratories use a scoring system (Johnson–DeMeester) to create a numerical value, above which reflux is considered pathological.
Radiotelemetry pH probes are also available that can be fixed to the oesophageal wall endoscopically without the need for a transnasal catheter. In the last few years, the introduction of catheter assemblies that incorporate multiple electrodes along the length of the catheter as well as a pH probe has resulted in combined measurement of pH and electrical impedance. Impedance measurement differentiates antegrade from retrograde bolus transit, gas from liquid and provides a reliable measure of non-acid or weakly acidic events that cause symptoms. This may be important in the identification of patients with non-erosive reflux disease on endoscopy.

**Therapeutic procedures**

**Dilatation of strictures**

Stricture dilatation is essentially undertaken for benign conditions and should be used with caution in the context of malignant disease. The risks associated with dilatation for malignant disease are discussed later. The advent of guidewire-directed dilatation of the oesophagus in the 1970s was a major advance over earlier blind dilatation systems. Their use is now considered standard practice. There are many different designs, but essentially they are solid dilators of increasing diameter. To restore normal swallowing, a stricture should be dilated to at least 16 mm in diameter. A guidewire is passed down the biopsy channel of an endoscope and through the stricture under vision. If the stricture is long or tortuous, this should be undertaken under radiological guidance to ensure that the guidewire passes easily into the stomach. The endoscope is withdrawn, leaving the guidewire in place, and graduated dilators are passed over the guidewire, sometimes with radiographic screening for safety purposes. The dilatation of reflux-induced strictures is usually straightforward. These strictures are nearly always short and at the oesophagogastric junction, so that the stomach is visible through the narrowed segment. Radiological control is rarely needed. Conversely, distal oesophageal adenocarcinomas extending into the stomach are often soft, friable and tortuous to negotiate.

Balloons with inflation diameters of 25—40 mm may also be used for dilatation. Pneumatic dilatation is widely used to disrupt the non-relaxing LOS in achalasia.

**Summary box 62.2**

**Foreign bodies**

- The most common is a food bolus, which usually signifies underlying disease
- It is usually possible to remove foreign bodies by flexible endoscopy
- Beware of button batteries in the oesophagus

Foreign bodies that have become stuck in the oesophagus should be removed by flexible endoscopy using suitable grasping forceps, a snare or a basket. If the object may injure the oesophagus on withdrawal, an overtube can be used, and the endoscope and object can be withdrawn into the overtube before removal. Button batteries can be a particular worry as they are difficult to grasp, and it is tempting to push them on into the stomach. However, an exhausted battery may rapidly corrode in the stomach.

**Thermal recanalisation**

Various types of laser (mainly Nd-YAG), bipolar diathermy, injection of absolute alcohol or argon-beam plasma coagulation have all been used successfully to ablate tissue in order to recanalise the oesophagus.

**CONGENITAL ABNORMALITIES**

See Chapter 8.

**FOREIGN BODIES IN THE OESOPHAGUS**

All manner of foreign bodies have become arrested in the oesophagus (Figure 62.8). Button batteries may be a troublesome problem in children. The most common impacted material is food, and this usually occurs above a significant pathological lesion (Figure 62.9). Plain radiographs are often useful for foreign bodies, but modern denture materials are not always radiopaque. A contrast examination is not usually required and only makes endoscopy more difficult (Summary box 62.2).

![Figure 62.7 Linear endosonography with the needle traversing an ultrasound plane for guided biopsy.](image1)

![Figure 62.8 False teeth impacted in the oesophagus. (Note: modern dentures are usually radiolucent.)](image2)
gastrointestinal tract and is best extracted. A multiwire basket of the type used for gallstone retrieval nearly always works. An impacted food bolus will often break up and pass on if the patient is given fizzy drinks and confined to fluids for a short time. The cause of the impaction must then be investigated. If symptoms are severe or the bolus does not pass, it can be extracted or broken up at endoscopy.

**PERFORATION**

Perforation of the oesophagus is usually iatrogenic (at therapeutic endoscopy) or due to 'barotrauma' (spontaneous perforation). Many instrumental perforations can be managed conservatively, but spontaneous perforation is often a life-threatening condition that regularly requires surgical intervention (Summary box 62.3).

### Summary box 62.3

**Perforation of the oesophagus**
- Potentially lethal complication due to mediastinitis and septic shock
- Numerous causes, but may be iatrogenic
- Surgical emphysema is virtually pathognomonic
- Treatment is urgent; it may be conservative or surgical, but requires specialised care

**Barotrauma (spontaneous perforation, Boerhaave syndrome)**

This occurs classically when a person vomits against a closed glottis. The pressure in the oesophagus increases rapidly, and the oesophagus bursts at its weakest point in the lower third, sending a stream of material into the mediastinum and often the pleural cavity as well. The condition was first reported by Boerhaave, who reported the case of a grand admiral of the Dutch fleet who was a glutton and practised autoemesis. Boerhaave syndrome is the most serious type of perforation because of the large volume of material that is released under pressure. This causes rapid chemical irritation in the mediastinum and pleura followed by infection if untreated. Barotrauma has also been described in relation to other pressure events when the patient strains against a closed glottis (e.g. defaecation, labour, weight-lifting).

**Diagnosis of spontaneous perforation**

The clinical history is usually of severe pain in the chest or upper abdomen following a meal or a bout of drinking. Associated shortness of breath is common. Many cases are misdiagnosed as myocardial infarction, perforated peptic ulcer or pancreatitis if the pain is confined to the upper abdomen. There may be a surprising amount of rigidity on examination of the upper abdomen, even in the absence of any peritoneal contamination.

The diagnosis can usually be suspected from the history and associated clinical features. A chest x-ray is often confirmatory with air in the mediastinum, pleura or peritoneum. Pleural effusion occurs rapidly either as a result of free communication with the pleural space or as a reaction to adjacent inflammation in the mediastinum. A contrast swallow or CT is nearly always required to guide management (Figure 62.10).

**Pathological perforation**

Free perforation of ulcers or tumours of the oesophagus into the pleural space is rare. Erosion into an adjacent structure with fistula formation is more common. Aerodigestive fistula is most common and usually encountered in primary malignant disease of the oesophagus or bronchus. Coughing on eating and signs of
aspiration pneumonitis may allow the problem to be recognised at a time when intervention may be appropriate and feasible. Covering the communication with a self-expanding metal stent is the usual solution. Erosion into a major vascular structure is invariably fatal.

**Penetrating injury**

Perforation by knives and bullets is uncommon, even in war, as the oesophagus is a relatively small target surrounded by other vital organs.

**Foreign bodies**

The oesophagus may be perforated during removal of a foreign body but, occasionally, an object that has been left in the oesophagus for several days will erode through the wall.

**Instrumental perforation**

Instrumentation is by far the most common cause of perforation. Modern instrumentation is remarkably safe, but perforation remains a risk that should never be forgotten (Summary box 62.4).

<thead>
<tr>
<th>Summary box 62.4</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Instrumental perforation</strong></td>
</tr>
<tr>
<td>- Prevention of perforation is better than cure</td>
</tr>
</tbody>
</table>

Perforation related to diagnostic upper gastrointestinal endoscopy is unusual with an estimated frequency of about 1:4000 examinations. Perforation can occur in the pharynx or oesophagus, usually at sites of pathology or when the endoscope is passed blindly. A number of patient-related factors are associated with increased risk, including large anterior cervical osteophytes, the presence of a pharyngeal pouch and mechanical causes of obstruction. Perforation may follow biopsy of a malignant tumour.

Patients undergoing therapeutic endoscopy have a perforation risk that is at least ten times greater than those undergoing diagnostic endoscopy. The oesophagus may be perforated by guidewires, graduated dilators or balloons, or during the placement of self-expanding stents. The risk is considerably higher in patients with malignancy.

**Diagnosis of instrumental perforation**

In most cases, a combination of technical difficulties and an interventional procedure should lead to a high index of suspicion. History and physical signs may be useful pointers to the site of perforation.

Cervical perforation may result in pain localised to the neck, hoarseness, painful neck movements and subcutaneous emphysema. Intrathoracic and intra-abdominal perforations, which are more common, can give rise to immediate symptoms and signs either during or at the end of the procedure, including chest pain, haemodynamic instability, oxygen desaturation or visual evidence of perforation. Within the first 24 hours, patients may additionally complain of abdominal pain or respiratory difficulties. There may be evidence of subcutaneous emphysema, pneumothorax or hydropneumothorax. In some patients, the diagnosis may be missed and recognised only at a late stage beyond 24 hours, as unexplained pyrexia, systemic sepsis or the development of a clinical fistula.

Prompt and thorough investigation is the key to management. Careful endoscopic assessment at the end of any procedure combined with a chest x-ray will identify many cases of perforation immediately. If not recognised immediately, then early and late suspected perforations should be assessed by a water-soluble contrast swallow. If this is negative, a dilute barium swallow should be considered. A CT scan can be used to replace a contrast swallow or as an adjunct to accurately delineate specific fluid collections.

**Treatment of oesophageal perforations**

Perforation of the oesophagus usually leads to mediastinitis. The loose areolar tissues of the posterior mediastinum allow a rapid spread of gastrointestinal contents. The aim of treatment is to limit mediastinal contamination and prevent or deal with infection. Operative repair deals with the injury directly, but imposes risks of its own; non-operative treatment aims to limit the effects of mediastinitis and provide an environment in which healing can take place.

The decision between operative and non-operative management rests on four factors. These are:

1. the site of the perforation (cervical versus thoracoabdominal oesophagus);
2. the event causing the perforation (spontaneous versus instrumental);
3. underlying pathology (benign or malignant);
4. the status of the oesophagus before the perforation (fasted and empty versus obstructed with a stagnant residue).

It follows that most perforations that can be managed non-operatively occur in the context of small instrumental perforations of a clean oesophagus without obstruction, where leakage is likely to be confined to the nearby mediastinum at worst (Table 62.1).

Instrumental perforations in the cervical oesophagus are usually small and can nearly always be managed conservatively. The development of a local abscess is an indication for cervical drainage preventing the extension of sepsis into the mediastinum.

The conservative management of an instrumental perforation in the thoracoabdominal parts of the oesophagus can be undertaken when the perforation is detected early and prior to oral alimentation. General guidelines for non-operative management include:
\[ \text{PART 11 | ABDOMINAL} \]

- pain that is readily controlled with opiates;
- absence of crepitus, diffuse mediastinal gas, hydropneumothorax or pneumoperitoneum;
- mediastinal containment of the perforation with no evidence of widespread extravasation of contrast material;
- no evidence of ongoing luminal obstruction or a retained foreign body.

In addition, conservative management might be appropriate in patients who have remained clinically stable despite diagnostic delay. The principles of non-interventional management involve hyperalimentation, preferably by an enteral route, nasogastric suction and broad-spectrum intravenous antibiotics.

Surgical management is required whenever patients:
- are unstable with sepsis or shock;
- have evidence of a heavily contaminated mediastinum, pleural space or peritoneum;
- have widespread intrapleural or intraperitoneal extravasation of contrast material.

Ongoing luminal obstruction (often related to malignancy) in a frail patient considered unfit for major surgery can be dealt with by placement of a covered self-expanding stent. Expanding metal stents should be used with caution in patients with benign disease as they cause significant tissue reaction and some designs are impossible to remove at a later date. Biodegradable and removable stents are being developed and may be used alone or as a bridge to later definitive treatment where perforation accompanies obstruction.

For patients requiring surgery, the choice rests between direct repair, the deliberate creation of an external fistula or, rarely, oesophageal resection with a view to delayed reconstruction. Direct repair is preferred by many surgeons if the perforation is recognised early (within the first 4–6 hours) and the extent of mediastinal and pleural contamination is small. After 12 hours, the tissues become swollen and friable and less suitable for direct suture. The hole in the mucosa is always bigger than the hole in the muscle, and the muscle should be incised to see the mucosal edges clearly. It is essential that there should be no obstruction distal to the repair. A variety of local tissues (gastric fundus, pericardium, intercostal muscle) have been used to buttress such repairs.

Primary repair is inadvisable with late presentation and in the presence of widespread mediastinal and pleural contamination. These patients tend to be more ill as a result of the delay, and the aim of treatment should be to achieve wide drainage with the creation of a controlled fistula and distal enteral feeding. This can usually be achieved by placing a T-tube into the oesophagus along with appropriately located drains and a feeding jejunos.

In unusual circumstances, for instance with extensive necrosis following corrosive ingestion, emergency oesophagectomy may be necessary. Oesophagostomy and gastrotomy should be performed with a view to delayed reconstruction.

**MALLORY–WEISS SYNDROME**

Forceful vomiting may produce a mucosal tear at the cardia rather than a full perforation. The mechanism of injury is different. In Boerhaave's syndrome, vomiting occurs against a closed glottis, and pressure builds up in the oesophagus. In Mallory–Weiss syndrome, vigorous vomiting produces a vertical split in the gastric mucosa, immediately below the squamocolumnar junction at the cardia in 90 per cent of cases. In only 10 per cent is the tear in the oesophagus (Figure 62.11). The condition presents with haematemesis. Usually, the bleeding is not severe, but endoscopic injection therapy may be required for the occasional, severe case. Surgery is rarely required. There are two other injuries to the oesophagus that lie within the spectrum of the mucosal tear of Mallory–Weiss and the full-thickness tear of Boerhaave. Intramural rupture produces a dissection within the oesophageal wall that causes severe chest pain, often with odynophagia. It is best diagnosed by contrast radiology. Intramural haematoma is seen most often in elderly patients on anticoagulants or patients with coagulation disorders, and usually follows an episode of vomiting. Large haematomas causing dysphagia can occur extending from the cardia up to the carina. The diagnosis is readily made on endoscopy. Both intramural rupture and intramural haematoma can be managed conservatively. Symptoms usually resolve in 7–14 days, and oral intake can be re instituted as soon as symptoms allow.

![Figure 62.11 The endoscopic appearance of a mucosal tear at the cardia (Mallory–Weiss).](image)

**CORROSIVE INJURY**

Corrosives such as sodium hydroxide (lye, caustic soda) or sulphuric acid may be taken in attempted suicide. Accidental ingestion occurs in children and when corrosives are stored in bottles labelled as beverages. All can cause severe damage to the mouth, pharynx, larynx, oesophagus and stomach. The type of agent, its concentration and the volume ingested largely determine the extent of damage. In general, alkalies are relatively odourless and tasteless, making them more likely to be ingested in large volume. Alkalies cause liquefaction, saponification of fats, dehydration and thrombosis of blood vessels that usually leads to fibrous scarring. Acids cause coagulative necrosis with eschar formation, and this coagulant may limit penetration to deeper layers of the oesophageal wall. Acids also cause more gastric damage than alkalis because of the induction of intense pylorospasm with pooling in the antrum.

Symptoms and signs are notoriously unreliable in predicting the severity of injury. The key to management is early endoscopy by an experienced endoscopist to inspect the whole of the oesophagus and stomach (Figure 62.12). Deep ulcers and the recognition of a grey or black eschar signify the most severe lesions with the greatest risk of perforation. Minor injuries with only oedema of the mucosa resolve rapidly with no late sequelae. These patients can safely be fed. With more severe injuries, a feeding jejunostomy may be appropriate until the patient...
can swallow saliva satisfactorily. The widespread use of broad-spectrum antibiotics and steroids is not supported by evidence.

Regular endoscopic examinations are the best way to assess stricture development (Figure 62.13). Significant stricture formation occurs in about 50 per cent of patients with extensive mucosal damage (Figure 62.14). The role and timing of repeat endoscopies with or without dilatation in such patients remains controversial. Other than the need for emergency surgery for bleeding or perforation, elective oesophageal resection should be deferred for at least three months until the fibrotic phase is established. Oesophageal replacement is usually required for very long or multiple strictures. Resection can be difficult because of perioesophageal inflammation in these patients. Because of associated gastric damage, colon may have to be used as the replacement conduit.

There is also controversy regarding the risk of developing carcinoma in the damaged oesophagus and stomach and how this might influence management. The lifetime risk is certainly less than 5 per cent. Some surgeons advocate resection and replacement, while others believe that oesophageal bypass and endoscopic surveillance is preferable, as removal of the badly damaged oesophagus from a scarred mediastinum can be hazardous (Summary box 62.5).

**Summary box 62.5**

**Corrosive injury**

---

**DRUG-INDUCED INJURY**

Many medications, such as antibiotics and potassium preparations, are potentially damaging to the oesophagus, as tablets may remain for a long time, especially if taken without an adequate drink. Acute injury presents with dysphagia and odynophagia, which may be severe. The inflammation usually resolves within 2–3 weeks, and no specific treatment is required apart from appropriate nutritional support. A stricture may follow.

---

**GASTRO-OESOPHAGEAL REFUX DISEASE**

**Aetiology**

Normal competence of the gastro-oesophageal junction is maintained by the LOS. This is influenced by both its physiological function and its anatomical location relative to the diaphragm and the oesophageal hiatus. In normal circumstances, the LOS transiently relaxes as a coordinated part of swallowing, as a means of allowing vomiting to occur and in response to stretching of the gastric fundus, particularly after a meal to allow swallowed air to be vented. Most episodes of physiological reflux occur during postprandial transient lower oesophageal sphincter relaxations (TLOSRs). In the early stages of GORD, most pathological reflux occurs as a result of an increased number of
TLOSRs rather than a persistent fall in overall sphincter pressure. In more severe GORD, LOS pressure tends to be generally low, and this loss of sphincter function seems to be made worse if there is loss of an adequate length of intra-abdominal oesophagus.

The absence of an intra-abdominal length of oesophagus results in a sliding hiatus hernia. The normal condensation of peritoneal fascia over the lower oesophagus (the phrenoesophageal ligament) is weak, and the crural opening widens allowing the upper stomach to slide up through the hiatus. The loss of the normal anatomical configuration exacerbates reflux, although sliding hiatus hernia alone should not be viewed as the cause of reflux. Sliding hiatus hernia is associated with GORD and may make it worse but, as long as the LOS remains competent, pathological GORD does not occur. Many GORD sufferers do not have a hernia, and many of those with a hernia do not have GORD. It should be noted that rolling or paraesophageal hiatus hernia is a quite different and potentially dangerous condition (see under Paraesophageal (‘rolling’) hiatus hernia below). A proportion of patients have a rolling hernia and symptomatic GORD or a mixed hernia with both sliding and rolling components. Reflux oesophagitis that is visible endoscopically is a complication of GORD and occurs in a minority of sufferers overall, but in around 40 per cent of patients referred to hospital.

In Western societies, GORD is the most common condition affecting the upper gastrointestinal tract. This is partly due to the declining incidence of peptic ulcer as the incidence of infection with *Helicobacter pylori* has reduced as a result of improved socioeconomic conditions along with a rising incidence of GORD in the last 20–30 years. The cause of the increase is unclear, but may be due in part to increasing obesity. The strong association between GORD, obesity and the parallel rise in the incidence of adenocarcinoma of the oesophagus represents a major health challenge for most Western countries.

**Clinical features**

The classical triad of symptoms is retrosternal burning pain (heartburn), epigastric pain (sometimes radiating through to the back) and regurgitation. Most patients do not experience all three. Symptoms are often provoked by food, particularly those that delay gastric emptying (e.g. fats, spicy foods). As the condition becomes more severe, gastric juice may reflux to the mouth and produce an unpleasant taste often described as ‘acid’ or ‘bitter’. Heartburn and regurgitation can be brought on by stooping or exercise. A proportion of patients have odynophagia with hot beverages, citrus drinks or alcohol. Patients with nocturnal reflux and those who reflux food to the mouth nearly always have severe GORD. Some patients present with less typical symptoms such as angina-like chest pain, pulmonary or laryngeal symptoms. Dysphagia is usually a sign that a stricture has occurred, but may be caused by an associated motility disorder.

Because GORD is such a common disorder, it should always be the first thought when a patient presents with oesophageal symptoms that are unusual or that defy diagnosis after a series of investigations.

**Diagnosis**

In most cases, the diagnosis is assumed rather than proven, and treatment is empirical. Investigation is only required when the diagnosis is in doubt, when the patient does not respond to a proton pump inhibitor (PPI) or if dysphagia is present. The most appropriate examination is endoscopy with biopsy. If the typical appearance of reflux oesophagitis, peptic stricture or Barrett’s oesophagus is seen, the diagnosis is clinched, but visible oesophagitis is not always present, even in patients selected as above. This is compounded in clinical practice by the widespread use of PPIs, which cause rapid healing of early mucosal lesions. Many patients will have received such treatment before referral. The endoscopic appearances of the normal oesophagus, hiatus hernia, oesophagitis and stricture are shown in Figures 62.15, 62.16, 62.17, 62.18, 62.19, 62.20 and 62.21. It is worth remembering that the correlation between symptoms and endoscopic appearances is poor. On the other hand, there is a strong correlation between worsening endoscopic appearances and the duration of oesophageal acidification on pH testing.

In patients with atypical or persistent symptoms despite therapy, oesophageal manometry and 24-hour oesophageal pH recording (ideally with impedance measurement) may be justified to establish the diagnosis and guide management (Summary box 62.6).

**Summary box 62.6**

**Diagnostic measurement in GORD**

- 24-hour pH recording is the ‘gold standard’ for diagnosis of GORD
- TLOSRs are the most important manometric findings in GORD
- The length and pressure of the LOS are also important

As a matter of routine, PPIs are stopped 1 week before oesophageal pH recording, but acid secretion is sometimes reduced for 2 weeks or more, and this can necessitate repeat examination after a prolonged interval without a PPI. Manometry and pH recording are essential in patients being considered for antireflux surgery. While the main purpose of the test is objectively to quantify the extent of reflux disease, it is also used to rule out a diagnosis of achalasia. In the early stages of achalasia, chest pain can dominate the clinical picture and, when associated with...

---

**Figure 62.15** The endoscopic appearance of the normal squamous mucosa in the body of the oesophagus.
intermittent swallowing problems and non-specific symptoms, it is easy to see how a clinical diagnosis of GORD might be made. Patients with achalasia can also have an abnormal pH study as a result of fermentation of food residue in a dilated oesophagus. Usually, the form of the pH trace is different from that of GORD, with slow undulations of pH rather than rapid bursts of reflux, but the complete absence of peristalsis on manometry is pathognomonic of achalasia.

Barium swallow and meal examination gives the best appreciation of gastro-oesophageal anatomy (Figure 62.22). This may be important in the context of surgery for rolling or mixed hiatus hernias, but it is unimportant in most patients with GORD.

**Management of uncomplicated GORD**

**Medical management**

Most sufferers from GORD do not consult a doctor and do not need to do so. They self-medicate with over-the-counter medicines such as simple antacids, antacid–alginate preparations and H2-receptor antagonists. Consultation is more likely when symptoms are severe, prolonged and unresponsive to the above treatments. Simple measures that are often neglected include advice about weight loss, smoking, excessive consumption of alcohol, tea or coffee, the avoidance of large meals late at night and a modest degree of head-up tilt of the bed. Tilting the bed has been shown to have an effect that is similar to taking an H2-receptor antagonist. The common practice of using additional pillows has no significant effect.

PPIs are the most effective drug treatment for GORD. Indeed, they are so effective that, once started, patients are very reluctant to stop taking them. Given an adequate dose for 8 weeks, most patients have a rapid improvement in symptoms (within a few days), and more than 90 per cent can expect full mucosal healing at the end of this time. For this reason, a policy of ‘step-down’ medical treatment is advocated based on the general advice outlined above and a standard dose of a PPI given for 8 weeks. At the end of that time, the dose of PPI is reduced to that which keeps the patient free of symptoms, and this might even mean the cessation of PPI treatment. Because most patients do not make major lifestyle changes and because PPIs are so effective, many remain on long-term treatment. For the minority who do not respond adequately to a standard dose, a trial at an increased dose or the addition of an H2-receptor antagonist is recommended. If unsuccessful, these patients should be formally investigated.

Proton pump inhibitor therapy is also important in patients with reflux-induced strictures, resulting in significant prolongation of the intervals between endoscopic dilatation. As yet, fears that chronic acid suppression might have serious long-term side effects including the risk of gastric cancer seem unwarranted.

**Surgery**

Strictly speaking, the need for surgery should have been reduced as medication has improved so much. Paradoxically, the number of antireflux operations has remained relatively constant and may even be increasing. This is probably due partly to increased patient expectations and partly to the advent of minimal access surgery, which has improved the acceptability of procedures.

**Endoscopic treatments**

A number of endoscopic treatments have been tried in the last ten years that attempt to augment a failing LOS. These involve endoscopic suturing devices that plicate gastric mucosa just below the cardia to accentuate the angle of His, radiofrequency ablation applied to the level of the sphincter and the injection of submucosal polymers into the lower oesophagus. The procedures have generally been applied to patients with only small hiatus hernias or none at all, so only a small proportion of patients who present to hospitals are suitable. While all methods produce some temporary improvement in symptoms and objective assessments of reflux, failure rates at one year are over 50 per cent, and there are no large case series that have reported long-term outcomes.

**Surgical treatments**

The indication for surgery in uncomplicated GORD is
essentially patient choice. The risks and possible benefits need to be discussed in detail. Risks include a small mortality rate (0.1–0.5 per cent, depending on patient selection), failed operation (5–10 per cent) and side effects such as dysphagia, gas bloat or abdominal discomfort (10 per cent). With current operative techniques, 85–90 per cent of patients should be satisfied with the result of an antireflux operation. Patients who are asymptomatic on a PPI need a careful discussion of the risk side of the equation. Those who are symptomatic on a PPI need a careful clinical review to make sure that they will benefit from an operation. Reasons for failure on a PPI include ‘volume’ reflux (a good indication for surgery), a ‘hermit’ lifestyle in which the least deviation from lifestyle rules leads to symptoms (a good indication), psychological distress with intolerance of minor symptoms (a poor indication; these patients are likely to be dissatisfied with surgery), poor compliance (a good indication if the reason for poor compliance is the side effects of treatment, otherwise a bad indication) and misdiagnosis of GORD.

Which operation?

There are many operations for GORD, but they are virtually all based on the creation of an intra-abdominal segment of oesophagus, crural repair and some form of wrap of the upper stomach (fundoplication) around the intra-abdominal oesophagus. The contribution of each component to operative success is widely debated, but it is clear that operations that fail to address all three components have inferior success rates. The major types of antireflux operation were all developed in the 1950s (Figure 62.23). When performed correctly, these are all effective operations. Randomised clinical trials do not show a clear advantage for any one operation over the others. One meta-analysis, however, has come down in favour of the Toupet posterior partial fundoplication over the Nissen total fundoplication when performed laparoscopically.

Total fundoplication (Nissen) tends to be associated with slightly more short-term dysphagia but is the most durable repair in terms of long-term reflux control. Partial fundoplication, whether performed posteriorly (Toupet) or anteriorly (Dor, Watson), has fewer short-term side effects, although this is sometimes at the expense of a slightly higher long-term failure rate. One disadvantage of total fundoplication is the creation of an overcompetent cardia, resulting in the ‘gas bloat’ syndrome, in which belching is impossible. The stomach fills with air, the patient feels very full after small meals and passes excessive flatus. This does not seem to occur with partial fundoplication. The problem has been largely overcome by the ‘floppy’ Nissen technique in which the fundoplication is loose around the oesophagus and is kept short in length. While the other short-term side effects of fundoplication usually resolve within three months of surgery, this is rarely the case for gas bloat. The problem is best remedied by conversion to a partial fundoplication.

As with primary surgery, a variety of revisional procedures have been described. For most patients, recurrent reflux relates to anatomical failure, so the solution is a revisional fundoplication. A very small proportion of patients may undergo more than two operations to correct recurrent reflux or unacceptable side effects. Revisional surgery carries a lower chance of success and, in some patients, local revision is technically impossible. The final resort is partial gastrectomy with a Roux-en-Y reconstruction. This reduces gastric acid secretion and diverts bile and pancreatic secretions away from the stomach. Thus, the volume of potential refluxate in the stomach is reduced and, because of its changed composition, it is less damaging to the oesophagus.

For many years, the relative merits of thoracic and abdominal approaches were hotly debated. The introduction of minimal access surgery has made this debate practically obsolete, and most antireflux operations are now done with a laparoscopic approach.

Laparoscopic fundoplication

Five cannulae are inserted in the upper abdomen (Figure 62.24). The cardia and lower oesophagus are separated from the diaphragmatic hiatus. An appropriate length of oesophagus is mobilised in the mediastinum. The fundus may be mobilised by dividing the short gastric vessels that tether the fundus to the spleen. The hiatus is narrowed by sutures placed behind the oesophagus. In total (Nissen) fundoplication, the fundus is drawn behind the oesophagus and then sutured to itself in front of the oesophagus (Figure 62.25a). In partial fundoplication, the fundus is drawn either behind or in front of the oesophagus and sutured to it on each side, leaving a strip of exposed oesophagus either at the front (Figure 62.25b) or at the back.

Complications of gastro-oesophageal reflux disease

Stricture

Reflux-induced strictures (see Figure 62.21) occur mainly in the late middle-aged and the elderly, but they may present in children. It is important to distinguish a benign reflux-induced stricture from a carcinoma. This is not usually difficult on the basis of location (immediately above the oesophagogastric junction), length (only about 1–2 cm) and smooth mucosa, but sometimes

Rudolph Nissen, 1896–1981, Professor of Surgery, Istanbul, Turkey, and later at Basle, Switzerland.
André M Toupet, born 1915, surgeon, St Cloud Hospital, Senior Consultant, University of Paris, France, proposed his technique in 1963.
Philip Rowland Allison, 1907–1974, Professor of Surgery, Oxford University, Oxford, UK.
Lucius David Hill, surgeon, The Mason Clinic, Seattle, MN, USA.
Ronald Herbert Robert Belsey, 1910–2007, thoracic surgeon, The Frenchay Hospital, Bristol, UK, came to be known by his colleagues as ‘the B’.

Figure 62.23 Various operations for the surgical correction of gastro-oesophageal reflux disease. (a) The original Allison repair of hiatus hernia (this is ineffective and is no longer done); (b) Nissen fundoplication; (c) Hill procedure; (d) Belsey mark IV operation.
a cancer spreads under the oesophageal mucosa at its upper margin, producing a benign-looking stricture.

Peptic strictures generally respond well to dilatation and long-term treatment with a PPI. As most patients are elderly, antireflux surgery is not usually considered. However, it is an alternative to long-term PPI treatment, just as in uncomplicated GORD in younger and fitter patients. Most patients do not require anything other than a standard operation (Summary box 62.7).

**Summary box 62.7**

**Peptic stricture**
- Day-case dilatation and PPI for peptic stricture

**Oesophageal shortening**

The issue of oesophageal shortening continues to provoke debate. There can be no doubt that, in the presence of a large sliding hiatus hernia, the oesophagus is short, but this does not necessarily mean that, with mobilisation from the mediastinum, it cannot easily be restored to its normal length. The extent to which severe inflammation in the wall of the oesophagus causes fibrosis and real shortening is less clear. If a good segment of intra-abdominal oesophagus cannot be restored without tension, a Collis gastroplasty should be performed (Figure 62.26). This produces a neo-oesophagus around which a fundoplication can be done (Collis–Nissen operation) (Summary box 62.8).

**Summary box 62.8**

**GORD**
- Is due to loss of competence of the LOS and is extremely common
- May be associated with a hiatus hernia, which may be sliding or, less commonly, rolling (paraesophageal)
- The most common symptoms are heartburn, epigastric discomfort and regurgitation, often made worse by stooping and lying
- Achalasia and GORD are diagnostically easily confused
  - Dysphagia may occur, but a neoplasm must be excluded
  - Diagnosis and treatment can be instituted on clinical grounds
- Endoscopy may be required and 24-hour pH is the ‘gold standard’
  - Management is primarily medical (PPIs being the most effective), but surgery may be required; laparoscopic fundoplication is the most popular technique
- Stricture may develop in time

**Barrett’s oesophagus (columnar-lined lower oesophagus)**

Barrett’s oesophagus is a metaplastic change in the lining mucosa of the oesophagus in response to chronic gastro-oesophageal reflux (Figure 62.27). Many of these patients do not have particularly severe symptoms, although they do have the most abnormal pH profiles. This adaptive response involves a mosaic of cell types, probably beginning as a simple columnar epithelium that becomes ‘specialised’ with time. The hallmark of ‘specialised’ Barrett’s epithelium is the presence of mucus-secreting goblet cells (intestinal metaplasia). One of the great mysteries of GORD is why some people develop oesophagitis and others develop Barrett’s oesophagus, often without significant oesophagitis. In Barrett’s oesophagus, the junction between squamous oesophageal mucosa and gastric mucosa moves proximally. It may be difficult to distinguish a Barrett’s oesophagus from a tubular, sliding hiatus hernia during endoscopy, as the two often coexist (Figure 62.28) or where the visible Barrett’s segment is very short. The key is where the gastric mucosal folds end. The mucosa in the body of the stomach has longitudinal
folds; the columnar lining of Barrett’s oesophagus is smooth. Strictures can occur in Barrett’s oesophagus and nearly always appear at the new squamocolumnar junction (Figure 62.29). Rarely, a stricture may occur in the columnar segment after healing of a Barrett’s ulcer (Figure 62.30). When intestinal metaplasia occurs, there is an increased risk of adenocarcinoma of the oesophagus (Summary box 62.9), which is about 25 times that of the general population (Figures 62.30, 62.31 and 62.32).

Patients who are found to have Barrett’s oesophagus may be submitted to regular surveillance endoscopy with multiple biopsies in the hope of finding dysplasia or in situ cancer rather than allowing invasive cancer to develop and cause symptoms. There

Figure 62.27 Barrett’s oesophagus with proximal migration of the squamocolumnar junction (a) and with a view of the distal oesophagus (b).

Figure 62.28 (a) The relationship between the lower oesophageal sphincter, the squamocolumnar junction and the diaphragm in sliding hiatus hernia. (b) Barrett’s oesophagus and sliding hernia.

Figure 62.29 The radiological appearance of a mid-oesophageal stricture in a patient with Barrett’s oesophagus (a) and in a patient with a normal lumen following dilatation (b).
is as yet no general agreement about the benefits of surveillance endoscopy, nor about its ideal frequency. Annual endoscopy has been widely practised, but two-year intervals are probably adequate, provided no dysplasia has been detected. A significant problem is that the incidence of Barrett’s oesophagus in the community is estimated to be at least ten times the incidence discovered in dyspeptic patients referred for endoscopy. Thus, adenocarcinoma in Barrett’s oesophagus often presents with invasive cancer without any preceding reflux symptoms.

Until recently, Barrett’s oesophagus was not diagnosed until there was at least 3 cm of columnar epithelium in the distal oesophagus. With the better appreciation of the importance of intestinal metaplasia, Barrett’s oesophagus may be diagnosed if there is any intestinal metaplasia in the oesophagus. The relative risk of cancer probably increases with increasing length of abnormal mucosa. The following terms are widely used:

- classic Barrett’s (3 cm or more columnar epithelium);
- short-segment Barrett’s (less than 3 cm of columnar epithelium);
- cardia metaplasia (intestinal metaplasia at the oesophagogastric junction without any macroscopic change at endoscopy).

When Barrett’s oesophagus is discovered, the treatment is that of the underlying GORD. There has been considerable interest in recent years in endoscopic methods of ablating Barrett’s mucosa in the hope of eliminating the risk of cancer development. Laser, photodynamic therapy, argon-beam plasma coagulation and endoscopic mucosal resection (EMR) have all been used. In conjunction with high-dose PPI treatment or an antireflux operation, these endoscopic methods can result in a neosquamous lining. There is no evidence yet that any of these methods is reliable in eliminating cancer risk. Residual islands of Barrett’s epithelium can persist, glands may be buried beneath the new lining, and damage to the oesophageal wall may cause stricturing.

**Summary box 62.9**

**Barrett’s oesophagus**

- Intestinal metaplasia is an important risk factor for the development of adenocarcinoma
- Do not confuse Barrett’s ulcer with oesophagitis

True paraoesophageal hernias in which the cardia remains in its normal anatomical position are rare. The vast majority of rolling hernias are mixed hernias in which the cardia is displaced into the chest and the greater curve of the stomach rolls into the mediastinum (Figure 62.33). Sometimes, the whole of the stomach lies in the chest (Figure 62.34). Colon or small intestine may sometimes lie in the hernia sac. The hernia is most common in the elderly, but may occur in young fit people. As the stomach rolls up into the chest, there is always an element of rotation (volvulus) (Summary box 62.10).
Paraoesophageal ('rolling') hiatus hernia

Summary box 62.10

‘Rolling’ hiatus hernia

■ Potentially dangerous, because of volvulus

The symptoms of rolling hernia are mostly due to twisting and distortion of the oesophagus and stomach. Dysphagia is common. Chest pain may occur from distension of an obstructed stomach. Classically, the pain is relieved by a loud belch. Symptoms of GORD are variable. Strangulation, gastric perforation and gangrene can occur. Emergency presentation with any of these complications carries high mortality on account of a combination of late diagnosis, generally elderly patients with comorbid diseases and the complexity of surgery involved.

The hernia may be visible on a plain radiograph of the chest as a gas bubble, often with a fluid level behind the heart (Figure 62.35). A barium meal is the best method of diagnosis. The endoscopic appearances may be confusing, especially in large hernias when it is easy to become disorientated. Symptomatic rolling hernias nearly always require surgical repair as they are potentially dangerous. The risk of an asymptomatic patient developing a significant problem when a rolling hiatus hernia is discovered incidentally has probably been overestimated in the past. The annual risk is probably no more than 1 per cent. Patients who present as an emergency with acute chest pain may be treated initially by nasogastric tube to relieve the distension that causes the pain, followed by operative repair. If the pain is not relieved or perforation is suspected, immediate operation is mandatory.

Emergency surgery needs to be tailored to the problem encountered and the fitness of the patient. Elective surgery involves reduction of the hernia, excision of the sac, reducing the crural defect and some form of retention of the stomach in the abdomen. Some surgeons perform a fundoplication, arguing that this is a very effective means of maintaining reduction and that it deals with the associated GORD. Others argue that fundoplication should only be done if reflux can be conclusively demonstrated beforehand. Surprisingly, both philosophies achieve good results. Laparoscopic repair has recently become popular. Full anatomical repair of a large rolling hernia can be difficult by this approach and requires considerable expertise. Secure closure of the hiatal defect can be a problem, and some surgeons advocate mesh to reinforce the repair.

NEOPLASMS OF THE OESOPHAGUS

Benign tumours

Benign tumours of the oesophagus are relatively rare. True papillomas, adenomas and hyperplastic polyps do occur, but the majority of ‘benign’ tumours are not epithelial in origin and arise from other layers of the oesophageal wall (gastrointestinal stromal tumour (GIST), lipoma, granular cell tumour). Most benign oesophageal tumours are small and asymptomatic, and even a large benign tumour may cause only mild symptoms (Figure 62.36). The most important point in their management is usually to carry out an adequate number of biopsies to prove beyond reasonable doubt that the lesion is not malignant (Figure 62.37).

Malignant tumours

Non-epithelial primary malignancies are also rare, as is malignant melanoma. Secondary malignancies rarely involve the oesophagus with the exception of bronchogenic carcinoma by direct invasion of either the primary and/or contiguous lymph nodes.

Carcinoma of the oesophagus

Cancer of the oesophagus is the sixth most common cancer in the world. In general, it is a disease of mid to late adulthood, with a poor survival rate. Only 5–10 per cent of those diagnosed will survive for five years (Summary box 62.11).

Pathology and aetiology

Squamous cell cancer (Figures 62.38 and 62.39) and adenocarcinoma (Figures 62.40 and 62.41) are the most common types. Squamous cell carcinoma generally affects the upper two-thirds of the oesophagus and adenocarcinoma the lower one-third. Worldwide, squamous cell cancer is most common, but adenocarcinoma predominates in the West and is increasing in incidence.

Geographical variation in oesophageal cancer

The incidence of oesophageal cancer varies more than that of any other cancer. Squamous cell cancer is endemic in the
Transkei region of South Africa and in the Asian 'cancer belt' that extends across the middle of Asia from the shores of the Caspian Sea (in northern Iran) to China. The highest incidence in the world is in Linxian in Henan province in China, where it is the most common single cause of death, with more than 100 cases per 100,000 population per annum. The cause of the disease in the endemic areas is not known, but it is probably due to a combination of fungal contamination of food and nutritional deficiencies. In Linxian, supplementation of the diet with beta-carotene, vitamin E and selenium has been shown to reduce the incidence.

Away from the endemic areas, tobacco and alcohol are major factors in the occurrence of squamous cancer. Incidence rates vary from less than 5:100,000 in white people in the US to 26.5:100,000 in some regions of France.

In many Western countries, the incidence of squamous cell cancer has fallen or remained static, but the incidence of adenocarcinoma of the oesophagus has increased dramatically since the mid-1970s at a rate of 5–10 per cent per annum. The change is greater than that of any other neoplasm in this time. Adenocarcinoma now accounts for 60–75 per cent of all oesophageal cancers in several countries. The reason for this change is not understood. A similar rate of increase in GORD over the same period, which mirrors an increase in obesity in the West, is likely to be an important factor, particularly through the link to Barrett’s oesophagus. There has been a similar increase in the incidence of carcinoma of the cardia of the stomach, which suggests that cancer of the cardia and adenocarcinoma of the oesophagus may share common aetiological factors. With a falling incidence of cancer in the rest of the stomach, more than 60 per cent of all upper gastrointestinal cancers in the West involve the cardia or distal oesophagus.

Both adenocarcinomas and squamous cell carcinomas tend to disseminate early. Sadly, the classical presenting symptoms of dysphagia, regurgitation and weight loss are often absent until the primary tumour has become advanced, and so the tumour is often well established before the diagnosis is made. Tumours can spread in three ways: invasion directly through the oesophageal wall, via lymphatics or in the bloodstream. Direct spread occurs both laterally, through the component layers of the oesophageal wall, and longitudinally within the oesophageal wall. Longitudinal spread is mainly via the submucosal lymphatic channels of the oesophagus. The pattern of lymphatic drainage is therefore not segmental, as in other parts of the gastrointestinal tract. Consequently, the length of oesophagus involved by tumour is frequently much longer than the macroscopic length of the malignancy at the epithelial surface. Lymph node spread occurs commonly. Although the direction of spread to regional lymphatics is predominantly caudal, the involvement of lymph nodes is potentially widespread and can also occur in a cranial direction. Any regional lymph node from the superior mediastinum to the coeliac axis and lesser curve of the stomach may be involved regardless of the location of the primary lesion within the oesophagus. Haematogenous spread may involve a
vomiting, odynophagia and weight loss. Clinical findings suggestive of advanced malignancy include recurrent laryngeal nerve palsy, Horner’s syndrome, chronic spinal pain and diaphragmatic paralysis. Other factors making surgical cure unlikely include weight loss of more than 20 per cent and loss of appetite. Cutaneous tumour metastases or enlarged supraclavicular lymph nodes may be seen on clinical examination and indicate disseminated disease. Hoarseness due to recurrent laryngeal nerve palsy is a sign of advanced and incurable disease. Palpable lymphadenopathy in the neck is likewise a sign of advanced disease.

Patients with early disease may have non-specific dyspeptic symptoms or a vague feeling of ‘something that is not quite right’ during swallowing. Some are diagnosed during endoscopic surveillance of patients with Barrett’s oesophagus and, while this does identify patients with the earliest stages of disease, such programmes have little overall impact, as most patients with Barrett’s oesophagus are unknown to the medical profession and make their first presentation with a symptomatic and therefore usually locally advanced oesophageal cancer. The widespread use of endoscopy as a diagnostic tool does, nevertheless, provide an opportunity for early diagnosis (Figure 62.42). Biopsies should be taken of all lesions in the oesophagus (Figures 62.43 and 62.44), no matter how trivial they appear and irrespective of the indication for the examination.

Figure 62.40 Adenocarcinoma of the lower oesophagus, spreading upwards from the cardia.

Figure 62.41 Computed tomography scan showing a primary tumour of the lower oesophagus.

Clinical features
Most oesophageal neoplasms present with mechanical symptoms, principally dysphagia, but sometimes also regurgitation, variety of different organs including the liver, lungs, brain and bones. Tumours arising from the intra-abdominal portion of the oesophagus may also disseminate transperitoneally.

Johann Friedrich Horner, 1831–1886, Professor of Ophthalmology, Zurich, Switzerland, described this syndrome in 1869.

PART 11

ABDOMINAL Neoplasms of the oesophagus

Investigation

Endoscopy is the first-line investigation for most patients. It provides an unrivalled direct view of the oesophageal mucosa and any lesion allowing its site and size to be documented. Cytology and/or histology specimens taken via the endoscope are crucial for accurate diagnosis. The combination of histology and cytology increases the diagnostic accuracy to more than 95 per cent. The chief limitation of conventional endoscopy is that only the mucosal surface can be studied and biopsied. Other investigations are therefore usually required to define the extent of local or distant spread. The improved image resolution of modern endoscopes and novel techniques involving magnification and the use of dyes to enhance surface detail may lead to more early lesions being recognised (see Figure 62.42).

General assessment and staging

Once the initial diagnosis of a malignant oesophageal neoplasm has been made, patients should be assessed first in terms of their general health and fitness for potential therapies. Their preferences should also be considered. Most potentially curative therapies include radical surgery, although chemoradiotherapy is an alternative in squamous cell carcinoma. Patients who are unfit for, or who do not wish to contemplate, radical treatments should not be investigated further, but should be diverted to appropriate palliative therapies, depending on symptoms and current quality of life. Only those patients suitable for potentially curative therapies should proceed to staging investigations to rule out haematogenous spread and then to assess locoregional stage (endoscopic ultrasound (EUS) ± laparoscopy). This will distinguish between early (T1/T2, N0) and advanced lesions (T3/T4, N1) and indicate whether surgery alone or multimodal therapy is most appropriate. Where attempted cure is deemed possible, the aim should be to provide the best chance of cure while minimising perioperative risks. In general, surgery alone should be reserved for patients with early disease, and multimodal therapy should be used in patients with locally advanced disease, in whom the chance of cure by surgery alone is small (generally less than 20 per cent).

The most widely used pathological staging system is the World Health Organization (tumour–nodes–metastasis TNM) classification.

Table 62.2 shows the TNM system for oesophageal cancer in its most updated form. Like all pathological systems, it is reliant on the nature and extent of the surgery performed. For example, performing more extensive radical surgical lymphadenectomy provides a more accurate assessment of the ‘N’ stage. There is evidence that many patients described as N0 in the past were probably N1, a phenomenon described as stage migration.

Staging information may be gathered before the commencement of therapy, during therapy (e.g. at open operation) or following treatment (histology or post-mortem). The techniques commonly used to provide preoperative staging data are described in Figure 62.45, along with a suggested algorithm.

Blood tests

These are of limited value. Blood tests reveal nothing about local invasion or regional lymph node spread and, to date, no reliable tumour marker for oesophageal cancer has been isolated from peripheral blood. The presence of abnormal liver function tests (LFTs) may suggest the presence of liver metastases, but this is generally too insensitive to be diagnostic. Many patients with known liver metastases have normal LFTs. At best, abnormal LFTs only reinforce the clinical suspicion of spread to the liver, and further imaging is usually required to confirm the diagnosis.

Transcutaneous ultrasound

It is difficult to visualise mediastinal structures with transcutaneous ultrasound. With the relatively low-frequency sound waves
used, good depth of tissue penetration is achieved at the expense of poor image resolution. In addition, the mediastinal organs are surrounded by bone and air, which renders them largely inaccessible to external ultrasound. The technique is therefore used mainly to assess spread to the liver, the whole of which can be clearly visualised by standard transcutaneous ultrasound. Haematogenous spread can be more fully assessed by combining ultrasound with chest radiography, although this combination is less accurate than CT scanning.

**Bronchoscopy**

Many middle- and upper-third oesophageal carcinomas (and therefore usually squamous carcinomas) are sufficiently advanced at the time of diagnosis that the trachea or bronchi are already involved (Figure 62.46). Bronchoscopy may reveal either impingement or invasion of the main airways in over 30 per cent of new patients with cancers in the upper third of the oesophagus. In some cases, therefore, bronchoscopy alone can confirm that the tumour is locally unresectable.

**Laparoscopy**

This is a useful technique for the diagnosis of intra-abdominal and hepatic metastases. It has the advantage of enabling tissue samples or peritoneal cytology to be obtained and is the only modality reliably able to detect peritoneal tumour seedlings (Figure 62.47). This is particularly important for tumours arising from the intra-abdominal portion of the oesophagus, cardia and where there is a potential communication between a full-thickness tumour and the peritoneal cavity, for instance where there is a hiatus hernia.

**Figure 62.45** Algorithm for the management of oesophageal cancer.

**Figure 62.46** Invasion into the posterior wall of the trachea from an oesophageal carcinoma.

**Figure 62.47** Adenocarcinoma of the cardia. Transcoelomic spread may occur with this type of lesion.
Computed tomography
Computed tomography scanning is the modality most used to identify haematogenous metastases (Figure 62.48). Distant organs are easily seen and metastases within them visualised with high accuracy (94–100 per cent). The normal thoracic oesophagus is easily demonstrated by CT scanning. The mediastinal fat planes are usually clearly imaged in healthy individuals, and any blurring or distortion of these images is a fairly reliable indicator of abnormality. In cachectic patients with dysphagia and malnutrition, the mediastinal fat plane may be virtually absent, making local invasion difficult to assess. Spiral and thin-slice CT permit structures such as lymph nodes to be adequately imaged, down to a minimum diameter of about 5 mm. Smaller nodes cannot be reliably visualised, and it is not possible to distinguish between enlarged lymph nodes that have reactive changes only and metastatic nodes. Similarly, micrometastases within normal-sized nodes cannot be detected.

Magnetic resonance imaging
Magnetic resonance imaging (MRI) does not expose the patient to ionising radiation and needs no intravascular contrast medium, although intraoesophageal air or contrast media may help to assess wall thickness. Distant metastases to organs such as the liver are usually reliably identified by MRI but, at the present time, there do not seem to be additional benefits over CT.

Endoscopic ultrasound
After haematogenous spread, the two principal prognostic factors for oesophageal cancer are the depth of tumour penetration through the oesophageal wall and regional lymph node spread. Although CT will detect distant metastasis, its limited axial resolution precludes a reliable assessment of both the depth of wall penetration and lymph node involvement. Endoscopic ultrasound can determine the depth of spread of a malignant tumour through the oesophageal wall (T1–3), the invasion of adjacent organs (T4) and metastasis to lymph nodes (N0 or N1) (Figures 62.49, 62.50 and 62.51). It can also detect contiguous spread downward into the cardia and more distant metastases to the left lobe of the liver.

Endoscopic ultrasound visualises the oesophageal wall as a multilayered structure. The layers represent ultrasound interfaces rather than true anatomical layers, but there is close enough agreement between those determined by ultrasound and those demonstrated by conventional histological sections.

\[\text{Figure 62.48} \quad \text{Computed tomography scan demonstrating liver metastases.}\]

\[\text{Figure 62.49} \quad \text{Endosonography demonstrating an ‘early’ tumour. Note the preservation of the outer dark wall layer that represents the muscle coat.}\]

\[\text{Figure 62.50} \quad \text{Endosonography demonstrating an ‘advanced’ local tumour. Note the breach of the outer white line that represents the interface between the oesophageal wall and the mediastinum.}\]

\[\text{Figure 62.51} \quad \text{Endosonography demonstrating malignant nodes. These are usually large, hypoechoic and round compared with normal nodes.}\]
correlation to allow accurate assessment of the depth of invasion through the oesophageal wall. Structures smaller than 5 mm can be clearly seen enabling very small nodes to be imaged. The EUS image morphology of such structures provides an additional means of distinguishing malignant from reactive or benign lymph nodes. For submucosal lesions, EUS can demonstrate the wall layer of origin of a lesion, suggesting the likely histological type.

Narrow EUS instruments are available for insertion over a guidewire to minimise the risk of technical failure, and linear array echoendoscopes can be used to biopsy lesions that might signify incurability outside the wall of the gastrointestinal tract (e.g. coeliac lymph nodes).

**Positron emission tomography/computed tomography scanning**

Positron emission tomography (PET) in the context of cancer staging relies on the generally high metabolic activity (particularly in the glycolytic pathway) of tumours compared with normal tissues. The patient is given a small dose of the radiopharmaceutical agent 18F-fluorodeoxyglucose (FDG). This enters cells and is phosphorylated. FDG-6-phosphate cannot be metabolised further and, because it is a highly polar molecule, it cannot easily diffuse back out of the cell. After intravenous injection of FDG, it continuously accumulates in metabolically active cells. Primary oesophageal cancers are usually sufficiently active to be easily visible, and spatial resolution of positive PET areas occurs down to about 5–8 mm. When used in isolation, there are problems with the anatomical location of these areas. This has been significantly improved by combining PET with CT (Figure 62.52). Although there are wide variations between centres, a change in stage is frequently reported in around 15 per cent of patients. It has also been suggested that a reduction in PET activity following chemotherapy might be a way of predicting ‘responders’ to this approach.

**Treatment of malignant tumours**

**Principles**

At the time of diagnosis, around two-thirds of all patients with oesophageal cancer will already have incurable disease. The aim of palliative treatment is to overcome debilitating or distressing symptoms while maintaining the best quality of life possible for the patient. Some patients do not require specific therapeutic interventions, but do need supportive care and appropriate liaison with community nursing and hospice care services.

As dysphagia is the predominant symptom in advanced oesophageal cancer, the principal aim of palliation is to restore adequate swallowing. A variety of methods are available and, given the short life expectancy of most patients, it is important that the choice of treatment should be tailored to each individual. Tumour location and endoscopic appearance are important in this regard, as is the general condition of the patient.

Once oesophageal neoplasms reach the submucosal layer of the oesophagus, the tumour has access to the lymphatic system, meaning that, even at this early local stage, there is an incidence of nodal positivity for both squamous cell carcinoma and adenocarcinomas of between 10 and 50 per cent. The principle of oesophagectomy is to deal adequately with the local tumour in order to minimise the risk of local recurrence and achieve an adequate lymphadenectomy to reduce the risk of staging error. Although studies in Japan would indicate that more extensive lymphadenectomy is associated with better survival, this may simply reflect more accurate staging. A number of studies support the view that the proximal extent of resection should ideally be 10 cm above the macroscopic tumour and 5 cm distal. When such a margin cannot be achieved proximally, particularly with squamous cell carcinoma, there is evidence that postoperative radiotherapy can minimise local recurrence, although not improve survival.

Adenocarcinoma commonly involves the gastric cardia and may therefore extend into the fundus or down the lesser curve. Some degree of gastric excision is essential in order to achieve adequate local clearance and accomplish an appropriate lymphadenectomy. Excision of contiguous structures, such as crura, diaphragm and mediastinal pleura, needs to be considered as a method of creating negative resection margins.

The rarity of intramucosal cancer in symptomatic patients means that there are no randomised studies to compare different approaches to this type of very early disease. Even in Barrett’s oesophagus, where high-grade dysplasia and early cancer coexist, many centres favour oesophagectomy in fit patients. Endoscopic mucosal resection for these apparently early lesions has become increasingly popular, providing either a cure or at least sufficient histological information upon which to base a further management strategy. Photodynamic therapy (PDT) is an alternative approach that has largely been used in patients who were either unfit or unwilling to undergo surgery. This endoscopic technique relies on the administration of a photosensitiser that is taken up preferentially by dysplastic and malignant cells followed by exposure of an appropriate segment of the oesophagus to laser light. The main drawback is skin photosensitisation, so patients must avoid sunlight exposure in the short term. PDT is also associated with a risk of stricture formation although, as the technique and photosensitising agents improve, these problems are reducing.

Surgery alone is best suited to patients with disease confined to the oesophagus (T1, T2) without nodal metastasis (N0). As a result of careful preoperative investigation, most of these patients are now identifiable and can be offered surgery alone, with a prospect of cure between 50 and 80 per cent. Patients with more advanced stages of disease require either multimodal approaches or entry into appropriate trials.

It is essential that oesophagectomy should be performed with a low hospital mortality and complication rate. Case selection, volume and experience of the surgical team are all important. Preoperative risk analysis has shown that this can play a major part in reducing hospital mortality. There are really no circum-
stances in the Western world in which surgery should be undertaken if it is not part of an overall treatment plan aimed at cure (Summary box 62.12).

**Summary box 62.12**

**Treatment of carcinoma of the oesophagus**
- Radical oesophagectomy is the most important aspect of curative treatment
- Neoadjuvant treatments before surgery may improve survival in a proportion of patients
- Chemoradiotherapy alone may cure selected patients, particularly those with squamous cell cancers
- Useful palliation may be achieved by chemo/radiotherapy or endoscopic treatments

### Treatments with curative intent

**Surgery**

Histological tumour type, location and the extent of the proposed lymphadenectomy all influence the operative approach. This is largely an issue of surgical preference, although it should be recognised that a left thoracoabdominal approach is limited proximally by the aortic arch and should be avoided when the primary tumour is at or above this level. Similarly, transthiatal oesophagectomy is unsuitable for most patients with squamous cell carcinoma because a complete mediastinal lymphadenectomy is not easily achieved by this approach. The most widely practised approach in the West is the two-phase Ivor Lewis (sometimes called Lewis–Tanner) operation (Figure 62.53), with an initial laparotomy and construction of a gastric tube, followed by a right thoracotomy to excise the tumour and create an oesophago gastric anastomosis. The closer this is placed to the apex of the thoracic cavity, the fewer problems there are with reflux disease. Three-phase oesophagectomy (McKeown) may be more appropriate for more proximal tumours in order to achieve better longitudinal clearance, although the additional distance gained is less than many surgeons believe. A third cervical incision also permits lymphadenectomy in this region.

The extent of lymphadenectomy is highly controversial. For squamous cell carcinoma, because a higher proportion of patients will have middle- and upper-third tumours in the thoracic oesophagus, the rationale behind a three-phase operation with three-field lymphadenectomy is more understandable, even though this approach has not been widely adopted in the West. For adenocarcinoma, the incidence of metastases in the neck is relatively low in the context of patients who would otherwise be curable. For this reason, two-phase operations with two-field lymphadenectomy seem the most logical operations. While two-field lymphadenectomy does not substantially increase operative morbidity or mortality, the same cannot be said for more extended operations.

The introduction of minimal access techniques has been pioneered in Australia by Gtley and Smithers and in North America by Luketich. In experienced hands, the open operation can be reproduced without significant compromise. As yet, benefits seem to be confined to reduced wound pain and the absence of specific complications associated with long incisions.

While many centres have reduced hospital mortality to single figures following oesophagectomy, the complication rate remains high. At least one-third of all patients will develop some significant complication after surgery. The most common of these is respiratory, followed by anastomotic leakage, chylothorax and injury to the recurrent laryngeal nerves. The most common late problem is benign anastomotic stricture, which seems to be higher with cervical rather than with intrathoracic anastomoses, although the problem is usually easily dealt with by endoscopic dilatation.

Lesions of the cardia that do not involve the oesophagus to any significant extent may be dealt with by extended total gastrectomy to include the distal oesophagus, or by proximal gastrectomy and distal oesophagectomy (Summary box 62.13).

![Image of the two usual approaches for surgery of the oesophagus. The thoracoabdominal (a), which opens the abdominal and thoracic cavities together, and the two-stage Ivor Lewis approach (b), in which the abdomen is opened first, closed and then the thoracotomy is performed. In the McKeown operation, a third incision in the neck is made to complete the cervical anastomosis.](image)

### Summary box 62.13

**Oesophagogastric surgery**
- Beware of satellite nodules proximal to the primary lesion
- Carefully preserve the blood supply of the stomach, both venous and arterial
- Right thoracic approach gives easy access to the oesophagus

**Two-phase oesophagectomy (abdomen and right chest, Ivor Lewis)**

Mobilisation of the stomach must be done with care as it is essential to have a tension-free, well-vascularised stomach for transposition. The left gastric, short gastric and left gastroepiploic arteries are all divided. The viability of the transposed stomach mainly depends on the right gastroepiploic and, to a lesser extent, the right gastric vessels. It should be noted that venous drainage is as important as arterial supply, and it is essential to perform an accurate anatomical dissection that preserves the

---

**Ivor Lewis**, 1895–1982, surgeon, the North Middlesex Hospital, London, UK, and later at Rhyl, North Wales, UK.

**Kenneth Charles McKeown**, 1912–1995, surgeon, Darlington Memorial Hospital, Darlington, County Durham, UK.
right gastroepiploic vein as well as the artery. The stomach is divided to remove the cardia and the upper part of the lesser curve, including the whole of the left gastric artery and its associated lymph nodes.

The approach to the oesophagus through the right chest is straightforward. A thoracotomy with entry above the fifth rib gives excellent access to the mediastinum and the thoracic inlet. The azygos vein is divided, and the whole of the intrathoracic oesophagus can be mobilised along with the thoracic duct (which is ligated by most surgeons) and the mediastinal lymph nodes. The oesophagus is divided just below the thoracic inlet. As most lesions are in the lower or middle thirds, this usually gives adequate proximal clearance of at least 5 cm. Carcinomas of the upper thoracic oesophagus are almost always incurable at the time of diagnosis, and invasion of the trachea is common. If one of these lesions is resectable, it is essential to use an incision in the neck (McKeown or three-phase operation) and to resect more of the oesophagus than is customary in the operation of subtotal oesophagectomy.

Oesophago-gastric anastomosis may be performed equally well by hand or by stapler. Both methods require attention to detail. In experienced hands, clinical anastomotic leakage should be less than 5 per cent. Most surgeons still prefer to keep the patient nil-by-mouth for 5–7 days. Most centres have abandoned the use of routine contrast swallows in patients who are clinically well. Conversely, aggressive investigation of a suspected leak is mandatory for any unexplained fever or clinical event. This may involve contrast radiology, CT scan or endoscopy to resolve the situation adequately.

Postoperative nutritional support remains controversial. There is general agreement that parenteral feeding is associated with more nosocomial infection, including pneumonia, than enteral feeding. It is also expensive. If nutritional support is given, a feeding jejunostomy is probably the best method.

Transhiatal oesophagectomy (without thoracotomy)
This approach was popularised for cancer by Orringer, adapting a technique developed in Brazil by Pinotti for the removal of Chagasian megaesophagus (see below under Achalasia). The stomach is mobilised through a midline abdominal incision, and the cervical oesophagus is mobilised through an incision in the neck. The diaphragm is then opened from the abdomen, and the posterior mediastinum is entered. The lower oesophagus and the tumour are mobilised under direct vision, and the upper oesophagus is mobilised by blunt dissection. This approach can provide an adequate removal of the tumour and lymph nodes in the lower mediastinum, but it is not possible to remove the nodes in the middle or upper mediastinum. It may be a useful procedure for lesions of the lower oesophagus, but is hazardous for a middle-third lesion that may be adherent to the bronchus or to the azygos vein.

Neoadjuvant treatments with surgery
Apart from the earliest stages of disease, surgery alone produces relatively few cures in either squamous cell carcinoma or adenocarcinoma patients. This led to a number of trials throughout the 1980s and 1990s to investigate the value of chemotherapy and surgery or chemoradiotherapy and surgery compared with surgery alone. Some studies relate only to squamous cell cancer, and many are open to criticism on the grounds of trial design or patient numbers. Nevertheless, positive results in favour of neo-

adjuvant therapy for adenocarcinoma in two studies as well as a limited meta-analysis indicate that it is no longer appropriate to consider surgery alone as the ‘gold standard’ treatment for most patients who are surgical candidates with adenocarcinoma. The exact role of surgery in a multimodal approach to squamous cell carcinoma is an unresolved issue.

Gastro-oesophageal reflux following oesophago-gastric resection
Gastro-oesophageal reflux may be a major problem following any operation that involves resecting the cardia. Reflux may present with the typical symptoms of GORD or with a peptic stricture at the site of the anastomosis. However, the presentation may be different with a miserable patient who fails to thrive following the operation and who is then suspected of having recurrent cancer. This atypical presentation is particularly common following total gastrectomy with an inadequate reconstruction that allows bile reflux (Summary box 62.14).

Summary box 62.14

**Postoesophagectomy**
- Reflux may be a problem following resection
- Symptoms may be atypical
- Reflux may be limited or avoided by subtotal oesophagectomy and gastric transposition high in the chest

**Non-surgical treatments**
Radiotherapy alone was widely used as a single-modality treatment for squamous cell carcinoma of the oesophagus until the late 1970s. The five-year survival rate overall was 6 per cent. As a result, multimodal approaches were adopted throughout the 1980s, initial trials indicating that similar long-term survival rates could be obtained with surgery. Subsequent randomised studies essentially confined to patients with squamous cell carcinoma have indicated significant survival advantages with chemoradiotherapy over radiotherapy alone. While it is clear that chemoradiotherapy does offer a prospect of cure for patients who may not be fit for surgery, particularly in squamous cell carcinoma, the high rate of locoregional failure has meant that surgery remains the mainstay of attempted curative treatments for both adenocarcinoma and squamous cell carcinoma in patients who have potentially resectable disease and are fit for oesophagectomy. In most Western series, this represents about one-third of patients with adenocarcinoma and a slightly lower percentage of patients with squamous cell carcinoma. There has been no formal comparison of the results of definitive radiotherapy or chemoradiotherapy and surgical resection, and it is therefore impossible to make dogmatic statements about the relative merits of each form of treatment (Summary box 62.15).

Summary box 62.15

**Alternative therapeutic approaches**
- Chemoradiotherapy may be a useful alternative to surgery, especially in unfit patients

Palliative treatment

Surgical resection and external beam radiotherapy may be used for palliation, but are not suitable when the expected survival is short, as most of the remainder of life will be spent recovering from the ‘treatment’. Surgical bypass is likewise too major a procedure for use in a patient with limited life expectancy. A variety of relatively simple methods of palliation are now available that will produce worthwhile relief of dysphagia with minimal disturbance to the patient (Summary box 62.16).

Summary box 62.16

Palliation

- Palliation should be simple and effective

Intubation has been used for many years following the invention of the Souttar tube, which was made of coiled silver wire. A variety of rigid plastic or rubber tubes were developed for placement under endoscopic and/or radiological control. The technology of intubation has now moved on with the development of various types of expanding metal stent (Figure 62.54). These are also inserted under radiographic or endoscopic control. The stent is collapsed during insertion and released when it is in the correct position. Expanding stents produce a wider lumen for swallowing than rigid tubes. More importantly, it is not necessary to dilate the oesophagus to beyond 8 mm to insert the unexpanded stent through the tumour, so there is a lower risk of injury to the oesophagus.

Endoscopic laser treatment may be used to core a channel through the tumour. It is based on thermal tumour destruction. It produces a worthwhile improvement in swallowing, but has the disadvantage that it has to be repeated every few weeks. Lasers may also be used to unblock a stent that has become occluded by tumour overgrowth. Other endoscopic methods include bipolar diathermy, argon-beam plasma coagulation and alcohol injection.

Brachytherapy is a method of delivering intraluminal radiation with a short penetration distance (hence the term brachy) to a tumour. An introduction system is inserted through the tumour, and the treatment is then delivered in a single session lasting approximately 20 minutes. The equipment is expensive to purchase, but running costs are low.

While the above methods are suitable for patients with very advanced disease, the elderly and those with significant comorbidities that would make more aggressive strategies inappropriate, an increasing proportion of patients (particularly with adenocarcinoma) are being treated by platinum-based chemotherapy. In general, this leads to only a modest prolongation of survival but a better quality of life than in those receiving an endoscopic treatment alone.

Malignant tracheo-oesophageal fistula

Malignant tracheo-oesophageal fistula is a sign of incurable disease. Some have advocated surgical bypass and oesophageal exclusion, but this is a major procedure. An expanding metal stent is probably the best treatment.

Post-cricoid carcinoma

Post-cricoid carcinoma is considered in Chapter 48 in neoplasms of the pharynx.

MOTILITY DISORDERS AND DIVERTICULA

Oesophageal motility disorders

A motility disorder can be readily understood when a patient has dysphagia in the absence of a stricture, and a barium-impregnated food bolus is seen to stick in the oesophagus. If this can be correlated with a specific abnormality on oesophageal manometry, accepting that this is the cause of the patient’s symptoms may be straightforward. Unfortunately, this is often not the case. Pain, with or without a swallowing problem, is frequently the dominant symptom, and patients often undergo extensive hospital investigation before the oesophagus is considered as a source of symptoms. Symptoms are often intermittent, and the correlation between symptoms and test ‘abnormalities’ is poor. Much harm may be done by inappropriate enthusiastic surgery for ill-defined conditions. It should also be remembered that oesophageal dysmotility may be only a feature of a general disturbance in gastrointestinal function (Summary box 62.17).

Summary box 62.17

Oesophageal motility disorders

- May be part of a more diffuse gastrointestinal motility problem
- May be associated with GORD

It is convenient to classify oesophageal motility disorders as in Table 62.3.

Functional pain and the oesophagus

Pain that is assumed to arise from dysfunction of the gastrointestinal tract may reflect abnormal motor activity, abnormal perception or a combination of the two. There is evidence that all three exist. Very high-pressure uncoordinated contractions (‘spasm’) have been shown to correlate with pain. Distension of a balloon in the oesophagus indicates that some patients have a low threshold for the sensation of pain (visceral hypersensitivity), and this itself may reflect local or central neuronal dysfunction. In practice, the difficulty is in understanding the relative contributions of these elements, so that a logical treatment might follow.

Figure 62.54 Expanding metal stents, covered and uncovered.
Achalasia (Greek ‘failure to relax’) is uncommon, but merits prominence because it is reasonably understood and responds to treatment. It is due to loss of the ganglion cells in the myenteric (Auerbach’s) plexus, the cause of which is unknown. In South America, chronic infection with the parasite Trypanosoma cruzi causes Chagas’ disease, which has marked clinical similarities to achalasia. Achalasia differs from Hirschsprung’s disease of the colon because the dilated oesophagus usually contains few ganglion cells, whereas the dilated colon contains normal ganglion cells proximal to a constricted, aganglionic segment. Histology of muscle specimens generally shows a reduction in the number of ganglion cells (and mainly inhibitory neurones) with a variable degree of chronic inflammation. In so-called ‘vigorously acha-
lasia’, which may be an early stage of the disease, there is inflammation and neural fibrosis, but normal numbers of ganglion cells (Summary box 62.18).

The classic physiological abnormalities are a non-relaxing LOS and absent peristalsis in the body of the oesophagus. While most patients have almost no recognisable contractions, ‘vigor-
ous’ achalasia has been recognised for many years as a condition where, in its earliest stages, the oesophagus is of normal calibre and still exhibits contractile (although non-peristaltic) activity. In some patients, these uncoordinated contractions result in pain as much as a sense of food sticking. High-resolution manometry indicates that there are a number of contraction patterns and these may be important in predicting the outcome of treatment. With time, the oesophagus dilates and contractions disappear, so that the oesophagus empties mainly by the hydro-
static pressure of its contents. This is nearly always incomplete, leaving residual food and fluid. The gas bubble in the stomach is frequently absent, as no bolus with its accompanying normal gas passes through the sphincter. The ‘megaoesophagus’ becomes tortuous with a persistent retention oesophagitis due to fermentation of food residues (Figure 62.55), and this may account for the increased incidence of carcinoma of the oesophagus (Summary box 62.19).

Pseudoachalasia is an achalasia-like disorder that is usually produced by adenocarcinoma of the cardia (Figure 62.56), but has also been described in relation to benign tumours at this level. It has been presumed that the inability of the sphincter to relax is linked to the loss of body peristalsis, but other cancers outside the oesophagus (bronchus, pancreas) have also been associated with pseudoachalasia.

Clinical features

The disease is most common in middle life, but can occur at any age. It typically presents with dysphagia, although pain (often mistaken for reflux) is common in the early stages. Patients often present late and, having had relatively mild symptoms, remain untreated for many years. Regurgitation is frequent, and there may be overspill into the trachea, especially at night.

Diagnosis

Achalasia may be suspected at endoscopy by finding a tight cardia and food residue in the oesophagus. Barium radiology may show hold-up in the distal oesophagus, abnormal contractions in the oesophageal body and a tapering stricture in the distal oesophagus, often described as a ‘bird’s beak’ (see Figure 62.55). The gastric gas bubble is usually absent. These typical features of well-developed achalasia are often absent, and endoscopy and radiology can be normal. A firm diagnosis is established by oesophageal manometry. Classically, the LOS does not relax completely on swallowing, there is no peristalsis and there is a raised resting pressure in the oesophagus (Figure 62.57). The LOS pressure may be elevated, but is often normal.
Treatment

Alone among motility disorders, achalasia responds well to treatment. The two main methods are forceful dilatation of the cardia and Heller’s myotomy. Comparative studies suggest equivalence in terms of safety, effectiveness and cost when considered over a number of years.

Pneumatic dilatation

This involves stretching the cardia with a balloon to disrupt the muscle and render it less competent. The treatment was first described by Plummer. Many varieties of balloon have been used but, nowadays, plastic balloons with a precisely controlled external diameter are used. If the pressure in the balloon is too high, the balloon is designed to split along its length rather than expanding further. Balloons of 30–40 mm in diameter are available and are inserted over a guidewire (Figure 62.58).

Perforation is the major complication. With a 30-mm balloon, the incidence of perforation should be less than 0.5 per cent. The risk of perforation increases with bigger balloons, and they should be used cautiously for progressive dilatation over a period of weeks. Forceful dilatation is curative in 75–85 per cent of cases. The results are best in patients aged more than 45 years (Summary box 62.20).

Ernst Heller, 1877–1964, surgeon, St George’s Krankenhaus, Leipzig, Germany, described his operation in 1914 when he performed a double myotomy. In 1923, JH Zaaijer from Leiden in The Netherlands reported that a single anterior myotomy is as good which is performed today.

Henry Stanley Plummer, 1874–1937, physician, the Mayo Clinic, Rochester, MN, USA.

Figure 62.55 Achalasia of the oesophagus. (a) Barium swallow showing the smooth outline of the stricture, which narrows to a point at its lower end. (b) Tortuosity and sigmoid appearance of the lower oesophagus. (c) Mediastinal shadow due to a large, fluid-filled oesophagus.
Heller's myotomy
This involves cutting the muscle of the lower oesophagus and cardia (Figure 62.59). The major complication is gastro-oesophageal reflux, and most surgeons therefore add a partial anterior fundoplication (Heller-Dor's operation). The procedure is ideally suited to a minimal access laparoscopic approach, and most surgeons use intraoperative endoscopy to judge the extent of the myotomy and to ensure that the narrow segment is abolished.

It is successful in more than 90 per cent of cases and may be used after failed dilatation.

Botulinum toxin
This is done by endoscopic injection into the LOS. It acts by interfering with cholinergic excitatory neural activity at the LOS. The effect is not permanent, and the injection usually
PART 11
ABDOMINAL
Motility disorders and diverticula

Drugs
Drugs such as calcium channel antagonists have been used but are ineffective for long-term use. However, sublingual nifedipine may be useful for transient relief of symptoms if definitive treatment is postponed.

Other oesophageal motility disorders

Disorders of the pharyngo-oesophageal junction
With the exception of Zenker’s diverticulum (see below), most patients with oropharyngeal dysphagia have generalised neurological or muscular disorders with pharyngeal involvement. A small number of patients who have sustained a cerebrovascular accident benefit from myotomy of the cricopharyngeus to alleviate pooling of saliva and nocturnal aspiration, but they should have good deglutition and phonation before this is performed. The operation is also effective in patients with oculopharyngeal muscular dystrophy.

Disorders of the body of the oesophagus

Diffuse oesophageal spasm and nutcracker oesophagus

Diffuse oesophageal spasm is a condition in which there are incoordinate contractions of the oesophagus, causing dysphagia and/or chest pain. The condition may be dramatic, with spastic pressures on manometry of 400–500 mmHg, marked hypertrophy of the circular muscle and a corkscrew oesophagus on barium swallow (Figure 62.60). These abnormal contractions are more common in the distal two-thirds of the oesophageal body, and this may have some relevance to treatment. Making the diagnosis when chest pain is the only symptom may be difficult. Prolonged ambulatory oesophageal manometry that correlates episodes of chest pain with manometric abnormalities may establish the diagnosis.

There is no proven pharmacological or endoscopic treatment. Calcium channel antagonists, vasodilators and endoscopic dilatation have only transient effects. While the severity and frequency of symptoms may be tolerated by most patients, sometimes the combination of chest pain and dysphagia is sufficiently severe that malnutrition begins. In these patients, extended oesophageal myotomy up to the aortic arch may be required. Surgical treatment of diffuse spasm is more successful in improving dysphagia than chest pain, and caution should be exercised in patients in whom chest pain is the only symptom.

Nutcracker oesophagus is a condition in which peristaltic pressures of more than 180 mmHg develop. It is said to cause chest pain, but there is still some debate as to whether it is a real disorder.

Oesophageal involvement in autoimmune disease
Oesophageal involvement is mainly seen in systemic sclerosis, but may be a feature of polymyositis, dermatomyositis, systemic lupus erythematosus, polyarteritis nodosa or rheumatoid disease. While most involve weak peristalsis, swallowing difficulties may be compounded by pharyngeal problems in the disorders that primarily affect skeletal muscle (e.g. polymyositis) or extraoesophageal problems such as involvement of the cricoarytenoid joint in rheumatoid disease or dry mouth in Sjögren’s syndrome. In systemic sclerosis, smooth muscle atrophy causes hypoperistalsis (Figure 62.61). The LOS is involved, leading to a loss of the antireflux barrier. A wide range of symptoms can follow from mild to severe dysphagia accompanied by regurgitation and aspiration. Reflux can be severe and is exacerbated by weak acid clearance so that strictures can occur. There are no drugs that specifically correct the motor disorder, and medical treatment is mainly directed at minimising reflux-induced damage with PPIs. A small number of patients may require antireflux surgery.

Eosinophilic oesophagitis is a disorder that occurs in children and adults either alone or as a manifestation of eosinophilic gastroenteritis. It is characterised by eosinophilic infiltration of the oesophageal wall, presumably of allergic or idiopathic origin. The most common presenting symptom is dysphagia,
and more than half have some history of atopy. The oesophagus often seems narrow and friable on endoscopy and may include mucosal rings. The most important feature is the development of deep ulcers leading to stricture development, especially in the proximal oesophagus. The diagnosis is established by endoscopic biopsy.

Elimination diets, topical and systemic steroids all seem to be helpful in the short term, but there is scant information on the long-term impact of any particular approach. Immunotherapy directed against interleukin (IL)-5, which has a major role in eosinophil recruitment, seems to be a promising innovative approach. Although endoscopic dilatation has been recommended, this can create deep ulcers and further scarring, so should be used with caution and only when the above therapies fail.

**Pharyngeal and oesophageal diverticula**

Most oesophageal diverticula are pulsion diverticula that develop at a site of weakness as a result of chronic pressure against an obstruction. Symptoms are mostly caused by the underlying disorder unless the diverticulum is particularly large. Traction diverticula (Figure 62.62) are much less common. They are mostly a consequence of chronic granulomatous disease affecting the tracheobronchial lymph nodes due to tuberculosis, atypical mycobacteria or histoplasmosis. Fibrotic healing of the lymph nodes exerts traction on the oesophageal wall and produces a focal outpouching that is usually small and has a conical shape. There may be associated bronchiolithiasis, and additional complications may occur, such as aerodigestive fistulation (Figure 62.63) and bleeding.

**Zenker’s diverticulum (pharyngeal pouch)** is not really an oesophageal diverticulum as it protrudes posteriorly above the cricopharyngeal sphincter through the natural weak point (the dehiscence of Killian) between the oblique and horizontal (cricopharyngeus) fibres of the inferior pharyngeal constrictor (Figures 62.64 and 62.65). The exact mechanism that leads to its formation is unknown, but it involves loss of the coordination between pharyngeal contraction and opening of the upper sphincter. When the diverticulum is small, symptoms largely reflect this incoordination with predominantly pharyngeal dysphagia. As the pouch enlarges, it tends to fill with food on eating, and the fundus descends into the mediastinum. This leads to halitosis and oesophageal dysphagia. Treatment can be undertaken endoscopically with a linear cutting stapler to divide the septum between the diverticulum and the upper oesophagus, producing a diverticulo-oesophagostomy, or can be done by open surgery involving pouch excision, pouch suspension (diverticu-lopexy) and/or myotomy of the cricopharyngeus. All techniques have good results.

**Mid-oesophageal diverticula** are usually small pulsion diverticula of no particular consequence. The underlying motility disorder does not usually require treatment. Some pulsion diverticula may fistulate into the trachea (Figure 62.63), but this is more common with traction diverticula in granulomatous disease.

---

*Gustav Killian*, 1860–1921, Professor of Laryngology at Freiburg, and later at Berlin, Germany.
Epiphrenic diverticula are pulsion diverticula situated in the lower oesophagus above the diaphragm (Figure 62.66). They may be quite large, but cause surprisingly few symptoms. They again probably reflect some loss of coordination between an incoming pressure wave and appropriate relaxation of the LOS. This needs to be acknowledged in the surgical management of the patient. The diverticulum, in isolation, should not be assumed to account for a patient’s illness just because it looks dramatic on a radiograph. Large diverticula may be excised, and this should be combined with a myotomy from the site of the diverticulum down to the cardia to relieve functional obstruction (Summary box 62.21).

**Summary box 62.21**

**Oesophageal diverticula**

- Diverticula are indicators of a motor disorder and not necessarily the cause of symptoms

Diffuse intramural pseudodiverticulosis is a rare condition in which there are multiple tiny outpouchings from the lumen of the oesophagus. The pseudodiverticula are dilated excretory ducts of oesophageal sebaceous glands. It is questionable whether the condition produces any symptoms in its own right.

**OTHER NON-NEOPLASTIC CONDITIONS**

**Schatzki’s ring**

Schatzki’s ring is a circular ring in the distal oesophagus (Figure 62.67), usually at the squamocolumnar junction. The cause is obscure, but there is a strong association with reflux disease. The core of the ring consists of variable amounts of fibrous tissue and cellular infiltrate. Most rings are incidental findings. Some are associated with dysphagia and respond to dilatation in conjunction with medical antireflux therapy.

**Richard Schatzki**, 1901–1992, American radiologist, a German by birth and medical training, he became Chief of Radiology Department, Mount Auburn Hospital, Cambridge, MA, USA.
Oesophageal infections

Bacterial infection of the oesophagus is rare, but fungal and viral infections do occur. They are particularly important in immunocompromised patients.

Oesophagitis due to *Candida albicans* is relatively common in patients taking steroids (especially transplant patients) or those undergoing cancer chemotherapy. It may present with dysphagia or odynophagia. There may be visible thrush in the throat. Endoscopy shows numerous white plaques that cannot be moved, unlike food residues (Figure 62.68). Biopsies are diagnostic. In severe cases, a barium swallow may show dramatic mucosal ulceration and irregularity that is surprisingly similar to the appearance of oesophageal varices (Figures 62.69 and 62.70).

Treatment is with a topical antifungal agent.

Dysphagia and odynophagia can also be caused by herpes simplex virus and cytomegalovirus (CMV). With the former, there may be a history of a herpetic lesion on the lip some days earlier, and endoscopy may reveal vesicles or small ulcers with raised margins, usually in the upper half of the oesophagus. CMV infection may be apparent in graft-versus-host disease following bone marrow transplantation. It has a characteristic endoscopic appearance with a geographical, serpiginous border. In both cases, endoscopic biopsy is diagnostic.

Chagas’ disease

This condition is confined to South American countries, but is of interest because oesophageal symptoms occur that are similar
to severe achalasia. It is caused by a protozoan, Trypanosoma cruzi, transmitted by an insect vector. Parasites reach the bloodstream and, after a long latent period, there is damage particularly to cardiac and smooth muscle. Destruction of both Auerbach’s and Meissner’s plexuses leads to acquired megaoesophagus.

**Crohn’s disease**

The oesophagus is not commonly affected by symptomatic Crohn’s disease. However, pathological studies indicate that it may be present in 20 per cent of patients without symptoms. Symptoms are often severe, and a diagnosis of reflux oesophagitis is usually made on the basis of retrosternal pain and dysphagia. Endoscopy shows extensive oesophagitis that extends much further proximally than reflux oesophagitis. Biopsies may be diagnostic, but may show only non-specific inflammation. In severe cases, deep sinuses occur, and fistulation has been described. Crohn’s oesophagitis is said to respond poorly to medical treatment and, although balloon dilatation of strictures and surgical resection for multiple internal fistulae have both been described, these interventions should be used with great caution.

**Plummer–Vinson syndrome**

This is also called the Paterson–Kelly syndrome or sideropenic dysphagia. The original descriptions are vague and poorly supported by evidence of a coherent syndrome. Dysphagia is said to occur because of the presence of a postcricoid web that is associated with iron deficiency anaemia, glossitis and koilonychia. The classical syndrome is rarely complete. Some patients may have oropharyngeal leukoplakia, and this may account for an alleged increased risk of developing hypopharyngeal cancer.

---

**Porter Pasley Vinson**, 1890–1959, physician, the Mayo Clinic, Rochester, MN, who later practised in Richmond, VA, USA.

**Adam Brown Kelly**, 1865–1941, surgeon, the Ear, Nose and Throat Department, the Royal Victoria Infirmary, Glasgow, UK.

**Donald Rose Paterson**, 1863–1939, surgeon, the Ear, Nose and Throat Department, the Royal Infirmary, Cardiff, Wales, UK.

**Vinson, Kelly and Paterson**, all described this syndrome independently in 1919.
Webs certainly occur in the upper and middle oesophagus, usually without any kind of associated syndrome. They are nearly always thin diaphanous membranes identified coincidentally by contrast radiology. Even symptomatic webs that cause a degree of obstruction may be inadvertently ruptured at endoscopy. Few require formal endoscopic dilatation.

**Vascular abnormalities affecting the oesophagus**

Several congenital vascular anomalies may produce dysphagia by compression of the oesophagus. Classically, this results from an aberrant right subclavian artery (arteria lusoria). However, the oesophagus is more commonly compressed by vascular rings, such as a double aortic arch. Dysphagia occurs in only a minority of cases and usually presents early in childhood, although it can occur in the late teens. Treatment is usually by division of the non-dominant component of the ring.

In adults, acquired causes include aneurysm of the aorta, diffuse cardiac enlargement and pressure from the left common carotid or vertebral arteries. It is rare that symptom severity justifies surgical intervention.

**Mediastinal fibrosis**

This rare condition can occur alone or in conjunction with retroperitoneal fibrosis. The cause is unknown and, while the major consequences are usually cardiovascular as a result of caval compression, dysphagia can occur. The existence of irreparable cardiovascular problems usually precludes surgical intervention on the oesophagus.

**FURTHER READING**

INTRODUCTION

The function of the stomach is to act as a reservoir for ingested food. It also serves to break down foodstuffs mechanically and commence the processes of digestion before these products are passed on into the duodenum.

GROSS ANATOMY OF THE STOMACH AND DUODENUM

Blood supply

Arteries

The stomach has an arterial supply on both lesser and greater curves (Figure 63.1). On the lesser curve, the left gastric artery, a branch of the coeliac axis, forms an anastomotic arcade with the right gastric artery, which arises from the common hepatic artery. Branches of the left gastric artery pass up towards the cardia. The gastroduodenal artery, which is also a branch of the hepatic artery, passes behind the first part of the duodenum, highly relevant with respect to the bleeding duodenal ulcer. Here it divides into the superior pancreaticoduodenal artery and the right gastroepiploic artery. The superior pancreaticoduodenal artery supplies the duodenum and pancreatic head, and forms an anastomosis with the inferior pancreaticoduodenal artery, a branch of the superior mesenteric artery. The right gastroepiploic artery runs along the greater curvature of the stomach, eventually forming an anastomosis with the left gastroepiploic artery, a branch of the splenic artery. This vascular arcade, important for the construction of the gastric conduit in oesophageal resection, is often variably incomplete. The fundus of the stomach is supplied by the vasa brevia (or short gastric arteries), which arise from near the termination of the splenic artery.

Veins

In general, the veins are equivalent to the arteries, those along the lesser curve ending in the portal vein and those on the greater curve joining via the splenic vein. On the lesser curve, the coronary vein is particularly important. It runs up the lesser
curve towards the oesophagus and then passes left to right to join the portal vein. This vein becomes markedly dilated in portal hypertension.

**Lymphatics**
The lymphatics of the stomach are of considerable importance in the surgery of gastric cancer and are therefore described in detail in the section Spread of carcinoma of the stomach.

**Nerves**
As with the entire gastrointestinal tract, the stomach and duodenum possess both intrinsic and extrinsic nerve supplies. The intrinsic nerves exist principally in two plexuses, the myenteric plexus of Auerbach and the submucosal plexus of Meissner. Compared with the rest of the gut, the submucosal plexus of the stomach contains relatively few ganglionic cells, as does the myenteric plexus in the fundus. However, in the antrum the ganglia of the myenteric plexus are well developed. The extrinsic supply is derived mainly from the vagus nerves (CN XI), fibres of which originate in the brainstem. The vagal plexus around the oesophagus condenses into bundles that pass through the oesophageal hiatus (Figure 63.2), the posterior bundle being usually identifiable as a large nerve trunk. Vagal fibres are both afferent (sensory) and efferent. The efferent fibres are involved in the receptive relaxation of the stomach and the stimulation of gastric motility, as well as having the well-known secretory function. The sympathetic supply is derived mainly from the coeliac ganglia.

**MICROSCOPIC ANATOMY OF THE STOMACH AND DUODENUM**
The gastric epithelial cells are mucus producing and are turned over rapidly. In the pyloric part of the stomach, and also the duodenum, mucus-secreting glands are found. Most of the specialised cells of the stomach (parietal and chief cells) are found in the gastric crypts (Figure 63.3). The stomach also has numerous endocrine cells.

**Parietal cells**
These are in the body (acid-secreting portion) of the stomach and line the gastric crypts, being more abundant distally. They are responsible for the production of hydrogen ions to form hydrochloric acid. The hydrogen ions are actively secreted by the proton pump, a hydrogen–potassium-ATPase (Sachs), which exchanges intraluminal potassium for hydrogen ions. The potassium ions enter the lumen of the crypts passively, but the hydrogen ions are pumped against an immense concentration gradient (1,000,000:1).

**Chief cells**
These lie principally proximally in the gastric crypts and produce pepsinogen. Two forms of pepsinogen are described: pepsinogen I and pepsinogen II. Both are produced by the chief cell, but pepsinogen I is produced only in the stomach. The ratio between pepsinogens I and II in the serum decreases with gastric atrophy. Pepsinogen is activated in the stomach to produce the digestive protease, pepsin.

**Endocrine cells**
The stomach has numerous endocrine cells, which are critical to its function. In the gastric antrum, the mucosa contains G cells, which produce gastrin. Throughout the body of the stomach, enterochromaffin-like (ECL) cells are abundant and produce histamine, a key factor in driving gastric acid secretion. In addition, there are large numbers of somatostatin-producing D cells throughout the stomach, and somatostatin has a negative regulatory role. The peptides and neuropeptides produced in the stomach are discussed later.

**Duodenum**
The duodenum is lined by a mucus-secreting columnar epithelium. In addition, Brunner’s glands lie beneath the mucosa and are similar to the pyloric glands in the pyloric part of the stomach. Endocrine cells in the duodenum produce cholecystokinin and secretin.
Physiology of the stomach and duodenum

The stomach mechanically breaks up ingested food and, together with the actions of acid and pepsin, forms chyme that passes into the duodenum. In contrast with the acidic environment of the stomach, the environment of the duodenum is alkaline, due to the secretion of bicarbonate ions from both the pancreas and the duodenum. This neutralises the acid chyme and adjusts the luminal osmolarity to approximately that of plasma. Endocrine cells in the duodenum produce cholecystokinin, which stimulates the pancreas to produce trypsin and the gall bladder to contract. Secretin is also produced by the endocrine cells of the duodenum. This hormone inhibits gastric acid secretion and promotes production of bicarbonate by the pancreas (Summary box 63.1).

Gastric acid secretion

The secretion of gastric acid and pepsin tends to run in parallel, although the understanding of the mechanisms of gastric acid secretion is considerably greater than that of pepsin. Numerous factors are involved to some degree in the production of the gastric acid. These include neurotransmitters, neuropeptides and peptide hormones. This complexity need not detract from the fact that there are basic principles that are relatively easily understood (Figure 63.4). Hydrogen ions are produced by the parietal cell by the proton pump. Although numerous factors can act on the parietal cell, the most important of these is histamine, which acts via the H₂-receptor. Histamine is produced, in turn, by the ECL cells of the stomach and acts in a paracrine (local) fashion on the parietal cells. These relationships explain why proton pump inhibitors can abolish gastric acid secretion, as they act on the final common pathway – hydrogen ion secretion. H₂-receptor antagonists have profound effects on gastric acid secretion, but this is not insurmountable (Figure 63.4). The ECL cell produces histamine in response to a number of stimuli that include the vagus nerve and gastrin. Gastrin is released by the G cells in response to the presence of the food in the stomach. The production of gastrin is inhibited by acid, hence creating a negative feedback loop. Various other peptides, including secretin, inhibit gastric acid secretion.

Classically, three phases of gastric secretion are described. The cephalic phase is mediated by vagal activity, secondary...
to sensory arousal as first demonstrated by Pavlov. The gastric phase is a response to food within the stomach, which is mediated principally, but not exclusively, by gastrin. In the intestinal phase, the presence of chyme in the duodenum and small bowel inhibits gastric emptying and, the acidification of the duodenum leads to the production of secretin, which inhibits gastric acid secretion, along with numerous other peptides originating from the gut. The stomach also possesses somatostatin-containing D cells. Somatostatin is released in response to a number of factors including acidification. This peptide acts probably on the G cell, the ECL cell and the parietal cell itself to inhibit the production of acid.

**Gastric mucus and the gastric mucosal barrier**

The gastric mucous layer is essential to the integrity of the gastric mucosa. It is a viscid layer of mucopolysaccharides produced by the mucus-producing cells of the stomach and the pyloric glands. Gastric mucus is an important physiological barrier to protect the gastric mucosa from mechanical damage, and also the effects of acid and pepsin. Its considerable buffering capacity is enhanced by the presence of bicarbonate ions within the mucus. Many factors can lead to the breakdown of this gastric mucous barrier. These include bile, non-steroidal anti-inflammatory drugs (NSAIDs), alcohol, trauma and shock. Tonometry studies have shown that, of all the gastrointestinal tract, the stomach is the most sensitive to ischaemia following a hypovolaemic insult and also the slowest to recover. This may explain the high incidence of stress ulceration in the stomach.

**Peptides and neuropeptides in the stomach and duodenum**

As with most of the gastrointestinal tract, the endocrine cells of the stomach produce peptide hormones and neurotransmitters. Previously, nerves and endocrine cells were considered distinct in terms of their products. However, it is increasingly realised that there is enormous overlap within these systems. Many peptides recognised as hormones may also be produced by neurones, hence the term neuropeptides. The term ‘messenger’ can be used to describe all such products. There are three conventional modes of action that overlap.

1. **Endocrine**. The messenger is secreted into the circulation, where it affects tissues that may be remote from the site of origin (Bayliss and Starling).
2. **Paracrine**. Messengers are produced locally and have local effects on tissues. Neurones and endocrine cells both act in this way.
3. **Neurocrine** (classical neurotransmitter). Messengers are produced by the neurone via the synaptic knob and pass across the synaptic cleft to the target.

Many peptide hormones act on the intrinsic nerve plexus of the gut (see later) and influence motility. Similarly, neuropeptides may influence the structure and function of the mucosa. Some of these peptides, neuropeptides and neurotransmitters are shown in Table 63.1.

**Gastroduodenal motor activity**

The motility of the entire gastrointestinal tract is modulated to a large degree by its intrinsic nervous system. Critical in this process is the migrating motor complex (MMC). In the fasted state, and after food has cleared, in the small bowel there is a period of quiescence lasting in the region of 40 minutes (phase I). There follows a series of waves of electrical and motor activity, also lasting for about 40 minutes, propagated from the fundus of the stomach in a caudal direction at a rate of about 3 per minute (phase II). These pass as far the pylorus, but not beyond. Duodenal slow waves are generated in the duodenum at a rate of about 10 per minute, which carry down the small bowel. The amplitude of these contractions increases to a maximum in phase III, which lasts for about 10 minutes. This 90-minute

Ernst Henry Starling, 1866–1927, Professor of Physiology, University College, London, UK.
cycle of activity is then repeated. From the duodenum, the MMC moves distally at 5–10 cm/min, reaching the terminal ileum after 1.5 hours.

Following a meal, the stomach exhibits receptive relaxation, which lasts for a few seconds. Following this, adaptive relaxation occurs, which allows the proximal stomach to act as a reservoir. Most of the peristaltic activity is found in the distal stomach (the antral mill) and the proximal stomach demonstrates only tonic activity. The pylorus, which is most commonly open, contracts with the peristaltic wave and allows only a few millilitres of chyme through at a time. The antral contraction against the closed sphincter is important in the milling activity of the stomach. Although the duodenum is capable of generating ten waves per minute, after a meal it only contracts after an antral wave reaches the pylorus. The coordination of the motility of the antrum, pylorus and duodenum means that only small quantities of food reach the small bowel at a time. Motility is influenced by numerous factors, including mechanical stimulation and neuronal and endocrine influences (Table 63.1).

INVESTIGATION OF THE STOMACH AND DUODENUM

Flexible endoscopy

Flexible endoscopy is the 'gold standard' investigation of the upper gastrointestinal tract. The original flexible endoscopes were fiberoptic (Hirschowitz), but now most use a solid-state camera mounted at the instrument’s tip (Figures 63.5 and 63.6). Other members of the endoscopy team see the image and this is useful when taking biopsies or performing interventional techniques, and also facilitates teaching and training (Summary box 63.2).

Summary box 63.2

The investigation of gastric disorders

- Flexible endoscopy is the most commonly used and sensitive technique for investigating the stomach and duodenum
- Great care needs to be exercised in performing endoscopy to avoid complications and missing important pathology
- Axial imaging, particularly multislice CT, is useful in the staging of gastric cancer, although it may be less sensitive in the detection of liver metastases than other modalities
- CT/PET is useful in staging gastric cancer
- Endoscopic ultrasound is the most sensitive technique in the evaluation of the 'T' stage of gastric cancer and in the assessment of duodenal tumours
- Laparoscopy is very sensitive in detecting peritoneal metastases, and laparoscopic ultrasound provides an accurate evaluation of lymph node and liver metastases

Flexible endoscopy is more sensitive than conventional radiology in the assessment of the majority of gastroduodenal conditions. This is particularly the case for peptic ulceration, gastritis and duodenitis. In upper gastrointestinal bleeding, endoscopy is far superior to any other investigation and offers the possibility of endoscopic therapy. In most circumstances it is the only investigation required.

Fiberoptic endoscopy is generally a safe investigation, but it is important that all personnel undertaking these procedures are adequately trained and that resuscitation facilities are always available. Careless and rough handling of the endoscope during intubation of a patient may result in perforations of the pharynx and oesophagus. Any other part of the upper gastrointestinal tract may also be perforated. An inadequately performed endoscopy is also dangerous as a serious condition may be overlooked. This is particularly the case in respect of early and curable gastric cancer, the appearances of which may often be extremely subtle and may be missed by inexperienced endoscopists. A more experienced endoscopist will have a higher index of suspicion for any mucosal abnormalities and will take more biopsies. Spraying the mucosa with dye endoscopically may allow better discrimination between normal and abnormal mucosa, so allowing a small cancer to be more easily seen. In the future, advances in technology may allow ‘optical biopsy’ to determine the nature of mucosal abnormalities in real time.

Basil I Hirschowitz, born 1925 in South Africa, Professor Emeritus of Medicine, Physiology and Biophysics, University of Alabama, Birmingham, AL, USA and given Lifetime Achievement Award as Physician of the Year.
Upper gastrointestinal endoscopy can be performed without sedation, but when sedation is required incremental doses of a benzodiazepine are usually administered. Sedation is of particular concern in the case of gastrointestinal bleeding as it may have a more profound effect on the patient’s cardiovascular stability. It has now become the standard to use pulse oximetry to monitor patients during upper gastrointestinal endoscopy, and nasal oxygen is often also administered. Buscopan is useful to abolish duodenal motility for examinations of the second and third parts of the duodenum. Examinations of this type are best carried out using a side-viewing endoscope such as is used for endoscopic retrograde cholangiopancreatography (ERCP).

Some patients are relatively resistant to sedation with benzodiazepines, particularly those who are accustomed to drinking alcohol. Increasing the dose of benzodiazepines in these patients may not result in any useful sedation, but merely make the patient more restless and confused. Such patients are sometimes better endoscoped fully awake using a local anaesthetic throat spray and a narrow-gauge endoscope. Whatever the circumstances, it is important that resuscitation facilities are available, including agents that reverse the effects of benzodiazepines, such as flumazenil.

The technology associated with upper gastrointestinal endoscopy is continuing to advance. Instruments which allow both endoscopy and endoluminal ultrasound to be performed simultaneously (see below) are used routinely. Bleeding from the stomach and duodenum can be treated with a number of haemostatic measures. These include injection with various substances, diathermy, heater probes and lasers. These approaches appear to be useful in the treatment of bleeding ulcers, although there are few good controlled trials in this area. There is no good evidence that such interventional procedures at the moment work in patients who are bleeding from very large vessels, such as the gastroduodenal artery or splenic artery, although technology may overcome this problem in the future.

**Contrast radiology**

Upper gastrointestinal radiology is not used as much as in previous years, as endoscopy is a more sensitive investigation for most gastric problems. Computed tomography (CT) imaging with oral contrast has also replaced contrast radiology in many of the areas where anatomical information is sought, e.g. large hiatus hernias of the rolling type and chronic gastric volvulus. In these conditions it may be difficult for the endoscopist to determine exactly the anatomy or, indeed, negotiate the deformity to see the distal stomach.

**Ultrasonography**

Standard ultrasound imaging can be used to investigate the stomach, but used conventionally it is less sensitive than other modalities. In contrast, endoluminal ultrasound and laparoscopic ultrasound are probably the most sensitive techniques available in the preoperative staging of gastric cancer. In endoluminal ultrasound, the transducer is usually attached to the distal tip of the instrument. However, devices have been developed which may be passed down the biopsy channel, albeit with poorer image quality. Five layers (Figure 63.7) of the gastric wall may be identified on endoluminal ultrasound and the depth of invasion of a tumour can be assessed with exquisite accuracy (90 per cent accuracy for the 'T' component of the staging). Enlarged lymph nodes can also be identified and the technique’s accuracy in this situation is about 80 per cent. Finally, it may be possible to identify liver metastases not seen on axial imaging. Laparoscopic ultrasound is also a very sensitive imaging modality to a large measure because of the laparoscopy itself (see below). It is one of the most sensitive methods of detecting liver metastases from gastric cancer.

An additional use of ultrasound is in the assessment of gastric emptying. Swallowed contrast is utilised, which is designed to be easily seen using an ultrasound transducer. The emptying of this contrast is then followed directly. The accuracy of the technique is similar to that of radiotrace gastric emptying studies (see below).

**CT scanning and magnetic resonance imaging**

The resolution of CT scanners is continuing to improve, and multislice CT is of increasing value in the investigation of the stomach, especially gastric malignancies (Figure 63.8). The presence of gastric wall thickening associated with a carcinoma....
of any reasonable size can be easily detected by CT, but the investigation lacks sensitivity in detecting smaller and curable lesions. It is much less accurate in ‘T’ staging than endoluminal ultrasound. Lymph node enlargement can be detected and, based on the size and shape of the nodes, it is possible to be reasonably accurate in detecting nodal involvement with tumour. However, as with all imaging techniques, it is limited. Microscopic tumour deposits in lymph nodes cannot be detected when the node is not enlarged and, in contrast, lymph nodes may undergo reactive enlargement but not contain tumour. These problems apply to all imaging techniques.

The detection of small liver metastases is improving, although in general terms metastases from gastric cancer are less easy to detect using CT than those, for instance, from colorectal cancer. This is because metastases from gastric cancer may be of the same density as liver and may not handle the intravenous contrast any differently. At present, magnetic resonance imaging (MRI) scanning does not offer any specific advantage in assessing the stomach, although it has a higher sensitivity for the detection of gastric cancer liver metastases than conventional CT imaging.

**CT/positron emission tomography**

Positron emission tomography (PET) is a functional imaging technique which relies on the uptake of a tracer in most cases by metabolically active tumour tissue. Fluorodeoxyglucose (FDG) is the most commonly used tracer. This tracer has a short half-life hence manufacture and use have to be carefully coordinated. To be of value, anatomical and functional informations need to be linked hence PET/CT is now used universally. It is increasingly being used in the preoperative staging of gastro-oesophageal cancer as it will demonstrate occult spread which renders the patient surgically incurable in up to 10 per cent of patients who would otherwise have undergone major resections (Figure 63.9). PET/CT may also be used to determine the response to neoadjuvant chemotherapy in oesophago gastric malignancies although this is the subject of ongoing studies.

**Laparoscopy**

This technique is now well used in the assessment of patients with gastric cancer. Its particular value is in the detection of peritoneal disease, which is difficult by any other technique, unless the patient has ascites or bulky intra peritoneal disease. Its main limitation is in the evaluation of posterior extension but other techniques are available to evaluate posterior invasion, especially CT and endoluminal ultrasound. Usually laparoscopy is combined with peritoneal cytology unless laparotomy follows immediately.

**Gastric emptying studies**

These are useful in the study of gastric dysmotility problems, particularly those that follow gastric surgery. The principle of the examination is that a radioisotope-labelled liquid and solid meal are ingested by the patient and the emptying of the stomach is followed on a gamma camera. This allows the proportion of activity in the remaining stomach to be assessed numerically, and it is possible to follow liquid and solid gastric emptying independently (Figure 63.10).
Angiography

Angiography is used most commonly in the investigation of upper gastrointestinal bleeding that is not identified using endoscopy. Therapeutic embolisation may also be of value in the treatment of bleeding in patients in whom surgery is difficult or inadvisable.

HELMICOBACTER PYLORI

Over the last 30 years, this organism has proved to be of overwhelming importance in the aetiology of a number of common gastroduodenal diseases such as chronic gastritis, peptic ulceration and gastric cancer. The organism had unquestionably been observed by a number of workers since Bircher's first description in 1874, but it was not until 1980 that Warren and Marshall, with enthusiasm but perhaps a lack of caution, ingested the organism to confirm that Koch's postulates could be fulfilled with respect to the gastritis that they succeeded in causing in themselves. Eradication therapy was then employed with mixed success, but both received the Nobel Prize for Medicine and Physiology in 2005. The organism is spiral shaped and is fastidious in its requirements, being difficult to culture outside the mucous layer of the stomach.

One of the characteristics of the organism is its ability to hydrolyse urea, resulting in the production of ammonia, a strong alkali. The effect of ammonia on the antral G cells is to cause the release of gastrin via the previously described negative-feedback loop. This is probably responsible for the modest, but inappropriate, hypergastrinaemia in patients with peptic ulcer disease, which, in turn, may result in gastric acid hypersecretion. The organism's obligate urease activity is utilised by various tests used to detect the presence of the organism, including the 13C and 14C breath tests and the CLO test (a commercially available urease test kit), which is performed on gastric biopsies. The organism can also be detected histologically (Figure 63.11), using the Giemsa or the Ethin–Starey silver stains, and cultured using appropriate media. Previous or current infection with the organism may also be detected serologically. Breath tests or faecal antigen tests are recommended for the pretreatment diagnosis of H. pylori infection in the community. Less accurate, hospital-based serology tests have a place within the non-invasive test and treat strategy.

Infection with H. pylori leads to the disruption of the gastric mucous barrier by the enzymes produced by the organism, and the inflammation induced in the gastric epithelium is the basis of many of the associated disease processes. The association of Warren and Marshall were awarded (among many other awards) the Nobel Prize for Physiology or Medicine in 2005 'for their discovery of the bacterium Helicobacter pylori and its role in gastritis and peptic ulcer disease'. Marshall ingested the bacteria to prove that H. pylori was indeed the causative organism. Robert Koch, 1843–1910, Professor of Hygiene and Bacteriology, Berlin, Germany, stated his postulates in 1882. These define the conditions which must be met before an organism can be shown to be the causal agent for a particular disease.

Barry James Marshall, born 1951, physician, the Royal Perth Hospital, Perth, WA, Australia.
Gustav Giemsa, 1867–1948, a bacteriologist who became Privatdozent in Chemotherapy at the University of Hamburg, Hamburg, Germany.
the organism with chronic (type B) gastritis is not in doubt. Some strains of *H. pylori* produce cytotoxins, notably the Cag A and Vac A products, and the production of cytotoxins seem to be associated with the ability of the organism to cause gastritis, peptic ulceration and cancer. The effect of the organism on the gastric epithelium is to incite a classical inflammatory response that involves the migration and degranulation of acute inflammatory cells, such as neutrophils, and also the accumulation of chronic inflammatory cells, such as macrophages and lymphocytes.

It is evident how *H. pylori* infection results in chronic gastritis and also how this may progress to gastric ulceration, but for a while it remained an enigma as to how the organism could be involved in duodenal ulceration, as the normal duodenum is not colonised. As mentioned above, the production of ammonia does increase the level of circulating gastrin and it has been shown subsequently that eradication of the organism in patients with duodenal ulcer disease will reduce the acid levels to normal. However, the overlap in gastric acid secretion between normal subjects and those with duodenal ulcers is considerable and the modestly increased acid levels in patients with *Helicobacter*-associated antral gastritis are insufficient to explain the aetiology of duodenal ulceration.

The explanation can probably be found in the phenomenon of duodenal gastric metaplasia. Gastric metaplasia is the normal response of the duodenal mucosa to excess acidity. It can be thought of in the same way as any other metaplasia in the gastrointestinal tract: an attempt by the mucosa to resist an injurious stimulus. Although normal duodenal mucosa cannot be infected with *H. pylori*, gastric metaplasia in the duodenum is commonly infected and this infection results in the same inflammatory process that is observed in the gastric mucosa. The result is duodenitis, which is almost certainly the precursor of duodenal ulceration.

Infection with *H. pylori* may be the most common human infection. The incidence of infection within a population increases with age, and in many populations infection rates of 80–90 per cent are not unusual. Up to 50 per cent of the world’s population may be infected with helicobacter. It appears that most infection is acquired in childhood and the possibility of infection is inversely related to socioeconomic group. The means of spread has not been identified, but the organism can occur in the faeces and faecal–oral spread seems most likely. The organism is not normally found in saliva or dental plaque. There is evidence in different environments and in different population groups that the manifestations of the infection may be different. Predominantly antral gastritis, which is commonly seen in the West, results initially in increased levels of acid production and peptic ulcer disease, whereas gastritis affecting the body, common in the developing world, may lead to hypochlorhydria and gastric neoplasia.

It has been known since 1984 that *Helicobacter* infection is amenable to treatment with antibiotics. The profound hypochlorhydria produced by proton pump inhibitors combined with antibiotics is also effective in eradicating the organism. Commonly used eradication regimes include a proton pump inhibitor and two antibiotics, such as metronidazole and amoxicillin. Very high eradication rates, in the region of 90 per cent, can be achieved without combinatorial differences, and the inclusion of clarithromycin, although it may be that in the future antibiotic resistance will become a problem. Reinfection following successful eradication appears rare (<0.5 per cent) but incomplete eradication is a more important clinical problem.

At present, eradication therapy is recommended for patients with duodenal ulcer disease, but not for patients with non-ulcer dyspepsia or in asymptomatic patients who are infected. However, recent data suggest that a proportion of patients with non-ulcer dyspepsia do respond to treatment. *H. pylori* is now classed by the World Health Organisation as a class 1 carcinogen and it may be that further epidemiological studies on the risk of gastric cancer change the current advice on treatment.

### GASTRITIS

The understanding of gastritis has increased markedly following elucidation of the role of *H. pylori* in chronic gastritis (Summary box 63.3).

#### Summary box 63.3

**Gastritis**

- The spiral bacterium *H. pylori* is critical in the development of type B gastritis, peptic ulceration and gastric cancer
- Infection appears to be acquired mainly in childhood and the infection rate is inversely associated with socioeconomic status
- Eradication, recommended specifically in patients with peptic ulcer disease, can be achieved in up to 90 per cent of patients with a combination of a proton pump inhibitor and antibiotics, and reinfection is uncommon (<0.5 per cent)
- Erosive gastritis is usually related to the use of NSAIDs
- Type A gastritis is an autoimmune process and is associated with the development of pernicious anaemia and gastric cancer

#### Type A gastritis

This is an autoimmune condition in which there are circulating antibodies to the parietal cell. This results in the atrophy of the parietal cell mass, hence hypochlorhydria and ultimately achlorhydria. As intrinsic factor is also produced by the parietal cell there is malabsorption of vitamin B12, which, if untreated, may result in pernicious anaemia. In type A gastritis, the antrum is not affected and the hypochlorhydria leads to the production of high levels of gastrin from the antral G cells. This results in chronic hypergastrinaemia. This, in turn, results in hypertrophy of the ECL cells in the body of the stomach, which are not affected by the autoimmune damage. Over time it is apparent that microadenomas develop in the ECL cells of the stomach, sometimes becoming identifiable tumour nodules. Very rarely, these tumours can become malignant. Patients with type A gastritis are predisposed to the development of gastric cancer, and screening such patients endoscopically may be appropriate.

#### Type B gastritis

There are abundant epidemiological data to support the association of this type of gastritis with *H. pylori*. Most commonly, type B gastritis affects the antrum, and it is these patients who are prone to peptic ulcer disease. *Helicobacter*-associated pan-gastritis is also a very common manifestation of infection, but
gastritis affecting the corpus alone does not seem to be associated. However, there are some data to suggest that Helicobacter may be involved in the initiation of the process. Patients with pangastritis seem to be most prone to the development of gastric cancer.

Intestinal metaplasia is associated with chronic pangastritis with atrophy. Although intestinal metaplasia per se is common, intestinal metaplasia associated with dysplasia has significant malignant potential and, if this condition is identified, endoscopic screening may be appropriate.

**Reflux gastritis**

This is caused by enterogastric reflux and is particularly common after gastric surgery. Its histological features are distinct from other types of gastritis. Although commonly seen after gastric surgery, it is occasionally found in patients with no previous surgical intervention or who have had a cholecystectomy. Bile chelating or prokinetic agents may be useful in treatment and as a temporising measure to avoid consideration of revisional surgery. Operation for the condition should be reserved for the most severe cases.

**Erosive gastritis**

This is caused by agents that disturb the gastric mucosal barrier; NSAIDs and alcohol are common causes. The NSAID-induced gastric lesion is associated with inhibition of the cyclo-oxygenase type 1 (COX-1) receptor enzyme, hence reducing the production of cytoprotective prostaglandins in the stomach. Many of the beneficial anti-inflammatory activities of NSAIDs are mediated by COX-2, and the use of specific COX-2 inhibitors reduces the incidence of these side effects. However, taken long term, COX-2 inhibitors are associated with cardiovascular complications in common with many NSAIDs.

**Stress gastritis**

This is a common sequel of serious illness or injury and is characterised by a reduction in the blood supply to superficial mucosa of the stomach. Although common, this is not usually recognised unless stress ulceration and bleeding supervene, in which case treatment can be extremely difficult. The condition also sometimes follows cardiopulmonary bypass. Prevention of the stress bleeding from the stomach is much easier than treating it, and hence the routine use of H₂-antagonists with or without barrier agents, such as sucralfate, in patients who are on intensive care. These measures have been shown to reduce the incidence of bleeding from stress ulceration.

**Ménétrier’s disease**

This is an unusual condition characterised by gross hypertrophy of the gastric mucosal folds, mucus production and hypochlorhydria. The condition is premalignant and may present with hypoproteinaemia and anaemia. There is no treatment other than a gastrectomy. The disease seems to be caused by overexpression of transforming growth factor alpha (TGF-α). Like epidermal growth factor (EGF), this peptide also binds to the EGF receptor. The histological features of Ménétrier’s disease may be reproduced in transgenic mice overexpressing TGF-α.

**Lymphocytic gastritis**

This type of gastritis is seen rarely. It is characterised by the infiltration of the gastric mucosa by T cells and is probably associated with H. pylori infection. The pattern of inflammation resembles that seen in coeliac disease or lymphocytic colitis.

**Other forms of gastritis**

Eosinophilic gastritis appears to have an allergic basis, and is treated with steroids and cromoglycate. Granulomatous gastritis is seen rarely in Crohn’s disease and also may be associated with tuberculosis. Acquired immunodeficiency syndrome (AIDS) gastritis is secondary to infection with cryptosporidiosis. Phlegmonous gastritis is a rare bacterial infection of the stomach found in patients with severe intercurrent illness. It is usually an agonal event.

</tbody>
</table>

Common sites for peptic ulcers are the first part of the duodenum and the lesser curve of the stomach, but they also occur on the stoma following gastric surgery, the oesophagus and even in a Meckel’s diverticulum, which contains ectopic gastric epithelium. In general, the ulcer occurs at a junction between different types of epithelia, the ulcer occurring in the epithelium least resistant to acid damage.

In the past, much distinction has been made between acute and chronic peptic ulcers, but this difference can sometimes be difficult to determine clinically. It is probably best to consider that there is a spectrum of disease from the superficial gastric and duodenal ulceration, frequently seen at endoscopy, to deep chronic penetrating ulcers. This does not minimise the importance of acute stress ulceration. These ulcers can both perforate and bleed.

For many years, the cause of peptic ulceration remained an unresolved question.
enigma. When comparing groups of patients with duodenal and prepyloric peptic ulcers with normal subjects, gastric acid levels are higher, but the overlap is very considerable. Patients with gastric ulceration have relatively normal levels of gastric acid secretion. As peptic ulceration will occur in the presence of very high acid levels, such as those found in patients with a gastrinoma (Zollinger–Ellison syndrome), and as all ulcers can be healed in the absence of acid, it is clear that acid is important. In patients with a gastrinoma it may be the only aetiologic factor, but this is not the case in the majority of patients. As with many diseases, genetic factors may be involved to a limited degree and social stress has also been falsely implicated (Asher).

It is now widely accepted that infection with \textit{H. pylori} and the consumption of NSAIDs are the most important factors in the development of peptic ulceration. In combination, \textit{H. pylori} and NSAIDs act synergistically to promote ulcer development and ulcer bleeding. Cigarette smoking predisposes to peptic ulceration and increases the relapse rate after treatment, with either gastric antisecretory agents or, in the past, elective surgery. Multiple other factors may be involved in transition between the superficial and the deep penetrating chronic ulcer, but they are of lesser importance.

**Duodenal ulceration**

**Incidence**

There have been marked changes in the last two decades in the demography of patients presenting with duodenal ulceration in the West. First, even before the introduction of \textit{H}\textsubscript{2}-receptor antagonists, the incidence of duodenal ulceration and the frequency of elective surgery for the condition were falling. This trend has continued and now, in the West, dyspeptic patients presenting with a duodenal ulcer at gastroscopy are uncommon. In part, this may relate to the widespread use of gastric antisecretory agents and \textit{H. pylori} eradication therapy for patients with dyspepsia. Second, the peak incidence is now in a much older age group than previously and, although it is still more common in men, the difference is less marked. These changes mirror the changes, at least in part, in the epidemiology of \textit{H. pylori} infection. In Eastern Europe, the disease remains common and, from having been uncommon in some developing nations, it is now observed more frequently. Again, the relationship with \textit{H. pylori} appears convincing.

**Pathology**

Most occur in the first part of the duodenum (Figures 63.12 and 63.13). A chronic ulcer penetrates the mucosa and into the muscle coat, leading to fibrosis. The fibrosis causes deformities such as pyloric stenosis. When an ulcer heals, a scar can be observed in the mucosa. Sometimes there may be more than one duodenal ulcer. The situation in which there is both a posterior and an anterior duodenal ulcer is referred to as 'kissing ulcers'. Anteriorly placed ulcers tend to perforate and, in contrast, posterior duodenal ulcers tend to bleed, sometimes by eroding into the gastroduodenal artery. Occasionally, the ulceration may be so extensive that the entire duodenal cap is ulcerated and devoid of mucosa. With respect to the giant duodenal ulcer, malignancy in this region is so uncommon that under normal circumstances surgeons can be confident that they are dealing with benign disease, even though from external palpation it may not appear so. In the stomach the situation is different.

**Histopathology**

Microscopically, destruction of the muscular coat is observed and the base of the ulcer is covered with granulation tissue, the arteries in this region showing the typical changes of endarteritis obliterans. Sometimes the terminations of nerves can be seen among the fibrosis. The pathological appearances of the healing ulcer must be carefully interpreted as some of the epithelial downgrowths can be misinterpreted as invasion. This is unlikely to be important in duodenal ulcers when malignancy rarely, if ever, occurs, but it is much more important with gastric ulcers.

Richard Asher, 1912–1969, physician, the Central Middlesex Hospital, London, UK. Ridiculed the concept that the stress of modern living caused peptic ulceration by pointing out that the same claim was made for syphilis! It is an interesting coincidence that both diseases have strong aetiologic associations with spiral organisms.

Robert Milton Zollinger, 1903–1992, Professor of Surgery, the Ohio State University, Columbus, OH, USA.

Edwin Homer Ellison, 1918–1970, Professor of Surgery, Marquette University, WI, USA.

Zollinger and Ellison described this condition in a joint paper in 1955 when they were both working at the Ohio State University.
**Gastric ulcers**

**Incidence**
As with duodenal ulceration, *H. pylori* and NSAIDs are the important aetiological factors. Gastric ulceration is also associated with smoking; other factors are of lesser importance.

There are marked differences between the populations afflicted by chronic gastric ulceration compared with duodenal ulceration. First, gastric ulceration is substantially less common than duodenal ulceration. The sex incidence is equal and the population with gastric ulcers tends to be older. It is more prevalent in low socioeconomic groups and is considerably more common in the developing world than in the West.

**Pathology**
This is essentially similar to that of a duodenal ulcer, except that gastric ulcers tend to be larger. Fibrosis, when it occurs, may result in the now rarely seen hourglass contraction of the stomach. Large chronic ulcers may erode posteriorly into the pancreas and, on other occasions, into major vessels such as the splenic artery. Less commonly, they may erode into other organs such as the transverse colon. Chronic gastric ulcers are much more common on the lesser curve (especially at the incisura angularis; Figures 63.14 and 63.15) than on the greater curve and, even when high on the lesser curve, they tend to be at the boundary between the acid-secreting and the non-acid-secreting epithelia. With atrophy of parietal cell mass, non-acid-secreting epithelium migrates up the lesser curvature.

**Malignancy in gastric ulcers**
Chronic duodenal ulcers are not associated with malignancy and, in contrast, gastric ulcers are. Widely varying estimates are made of the incidence of gastric malignancy in gastric ulcers. The reason for this is that the authors reporting such diverse incidences are describing different clinical situations. Two clinical extremes must be distinguished to understand this problem properly. First, there is the situation in which a benign chronic gastric ulcer undergoes malignant transformation. This is known to happen, albeit rarely. The contrasting clinical extreme is the patient identified as having an ulcer in the stomach, either endoscopically or on contrast radiology, which is assessed as benign but biopsies reveal malignancy. In this situation the patient does not have, and probably never has had, chronic peptic ulceration in the stomach but has presented with an ulcerated cancer. This situation is common, although whether a lesion found in the stomach is described as being benign or malignant on clinical grounds depends very much on the skill and experience of the endoscopist or radiologist.

It is fundamental that any gastric ulcer should be regarded as being malignant, no matter how classic the features of a benign gastric ulcer. Multiple biopsies should always be taken, perhaps as many as ten well-targeted biopsies, before an ulcer can be tentatively accepted as being benign. Even then it is important that further biopsies are taken while the ulcer is healing and when healed. Modern antisecretory agents can frequently heal the ulceration associated with gastric cancer but, clearly, are ineffective in treating the malignancy itself. At operation, even experienced surgeons may have difficulty distinguishing between the gastric cancer and a benign ulcer. Operative strategies differ so radically that it is essential, if at all possible, that a confident diagnosis is made before operation. If, at operation, it is determined that the ulcer is probably benign it should, nonetheless, be excised, in totality if possible, and submitted for histological examination. It is not known whether a patient’s survival is compromised by this approach if the ulcer turns out to be malignant on biopsy, as convincing data are not available.

**Other peptic ulcers**
The prepyloric gastric ulcer was in the past difficult to treat, a problem overcome with the introduction of proton pump inhibitors. Pyloric channel ulcers are similar to duodenal ulcers. Both prepyloric and pyloric ulcers may be malignant, and biopsy is essential. Stomal ulcers occur after a gastroenterostomy or a gastrectomy of the Billroth II type. The ulcer is usually found on the jejunal side of the stoma.

**Clinical features of peptic ulcers**
Although many textbooks try to create differences in the clinical features of gastric and duodenal ulceration, detailed
analysis has shown that they cannot be differentiated on the basis of symptoms. The demographic characteristics of groups of patients with gastric and duodenal ulceration do differ but this does not allow discrimination.

**Pain**
The pain is epigastric, often described as gnawing and may radiate to the back. Eating may sometimes relieve the discomfort. The pain is normally intermittent rather than intractable.

**Periodicity**
One of the classic features of untreated peptic ulceration is periodicity. Symptoms may disappear for weeks or months to return again. This periodicity may be related to the spontaneous healing of the ulcer.

**Vomiting**
While this occurs, it is not a notable feature unless stenosis has occurred.

**Alteration in weight**
Weight loss or, sometimes, weight gain may occur. Patients with gastric ulceration are often underweight but this may precede the occurrence of the ulcer.

**Bleeding**
All peptic ulcers may bleed. The bleeding may be chronic and presentation with microcytic anaemia is not uncommon. All such patients should be investigated with endoscopy. Acute presentation with haematemeses and melaena is discussed below under Haematemeses and melaena.

**Clinical examination**
Examination of the patient may reveal epigastric tenderness but, except in extreme cases (for instance gastric outlet obstruction), there is unlikely to be much else to find.

**Investigation of the patient with suspected peptic ulcer**

**Gastroduodenoscopy**
This is the investigation of choice in the management of suspected peptic ulceration and in the hands of a well-trained operator is highly sensitive and specific.

In the stomach, any abnormal lesion should be multiple biopsied, and in the case of a suspected benign gastric ulcer numerous biopsies must be taken in order to exclude, as far as possible, the presence of a malignancy. Commonly, biopsies of the antrum will be taken to see whether there is histological evidence of gastritis and a CLO test performed to determine the presence of *H. pylori*. A ‘U’ manoeuvre should be performed to exclude ulcers around the gastro-oesophageal junction. This is important as the increasing incidence of cancer at the gastro-oesophageal junction requires that all mucosal abnormalities in this region should undergo multiple biopsy. Similarly, if a stoma is present, for instance after gastroenterostomy or Billroth II gastrectomy, it is important to enter both afferent and efferent loops. Almost all stomal ulcers will be very close to the junction between the jejunal and gastric mucosa. Attention should be given to the pylorus to note whether there is any prepyloric or pyloric channel ulceration, and also whether it is deformed, which is often the case with chronic duodenal ulceration. In the duodenum, care must be taken to view all of the first part. It is not infrequent for an ulcer to be just beyond the pylorus and easily overlooked.

**Treatment of peptic ulceration**
The vast majority of uncomplicated peptic ulcers are treated medically. Surgical treatment of uncomplicated peptic ulceration has decreased markedly since the 1960s and is now seldom performed in the West. Surgical treatment was aimed principally at reducing gastric acid secretion and, in the case of gastric ulceration, removing the diseased mucosa. When originally devised, medical treatment also aimed to reduce gastric acid secretion, initially using the highly successful *H*$_2$-*receptor antagonist and, subsequently, proton pump inhibitors. This has now largely given way to eradication therapy.

**Medical treatment**
It is reasonable that a doctor managing a patient with an uncomplicated peptic ulcer should suggest modifications to the patient’s lifestyle, particularly the cessation of cigarette smoking. This advice is rarely followed and pharmacological measures form the mainstay of treatment.

**H$_2$-receptor antagonists and proton pump inhibitors**
*H*$_2$-antagonists (Black) revolutionised the management of peptic ulceration. Most duodenal ulcers and gastric ulcers can be healed by a few weeks of treatment with these drugs provided that they are taken and absorbed. There remained, however, a group of patients who were relatively refractory to conventional doses of *H*$_2$-*receptor antagonists. This is largely now irrelevant as proton pump inhibitors can effectively render a patient achlorhydric and all benign ulcers will heal using these drugs, the majority within 2 weeks. Symptom relief is impressively rapid, most patients being asymptomatic within a few days. Like *H*$_2$-antagonists, proton pump inhibitors are safe and relatively devoid of serious side effects. The problem with all gastric antisecretory agents is that following cessation of therapy relapse is almost universal.

**Eradication therapy**
Eradication therapy is now routinely given to patients with peptic ulceration, and this is described earlier in this chapter. Evidence suggests that if a patient has a peptic ulcer and *H. pylori* is the principal aetiological factor (essentially the patient not taking NSAIDs), then complete eradication of the organism will cure the disease and reinfection as an adult is uncommon. Eradication therapy is therefore the mainstay of treatment for peptic ulceration. It is extremely economical by comparison with prolonged courses of antisecretory agents or surgery. It is also considerably safer than surgical treatment.

There are some patients with peptic ulcers in whom eradication therapy may not be appropriate and this includes patients with NSAID-associated ulcers. Such patients should avoid these drugs if possible and, if not, they should be co-prescribed with a potent antisecretory agent. Similarly, patients with stomal ulceration are not effectively treated with eradication therapy and would benefit from surgery.

*Sir James Whyte Black, 1924–2002, Professor of Analytical Pharmacology, King’s College Hospital Medical School, London, UK, introduced beta-blockers and *H*$_2$-receptor antagonists. For this work he shared the 1988 Nobel Prize for Physiology or Medicine with Gertrude Bior and George Hitchings.*
require prolonged prescription of antisecretory agents. Patients with Zollinger–Ellison syndrome should be treated in the long term with proton pump inhibitors unless the tumour can be adequately managed by surgery.

**Ulcers that fail to heal**
The introduction of antisecretory agents and effective treatments for *H. pylori* have revolutionized the management of peptic ulcers. Despite these advances, peptic ulceration fails to heal in a small minority of patients. Endoscopic re-evaluation should be regarded as mandatory to confirm healing of gastric ulcers. Furthermore, endoscopy permits the differentiation between a refractory ulcer and persistent symptoms despite ulcer healing. The most common cause of failed healing is persistent *H. pylori* infection. Biopsies should be repeated at the time of endoscopy as false-negative results with breath tests may be expected soon after eradication therapy and serum antibody titres may not fall for six months after successful eradication. Failure of eradication is usually due to poor compliance or bacterial resistance and bacteriological culture will guide further attempts at *H. pylori* eradication. The ingestion of NSAIDs should once again be addressed. A diagnosis of Zollinger–Ellison syndrome (described in detail below under Zollinger–Ellison syndrome) should be suspected in *H. pylori* negative, non-NSAID-related peptic ulceration and serum gastrin levels should be measured.

**Surgical treatment of uncomplicated peptic ulceration**
From its peak in the 1960s, the incidence of surgery for uncomplicated peptic ulceration has fallen markedly, to the extent that peptic ulcer surgery is now of little more than historical interest. A description of operations used in the treatment of peptic ulcers is still necessary because surgery is occasionally employed for the complicated ulcer and, in addition, many patients are left suffering from the consequences of the more destructive operations.

**Operations for duodenal ulceration**

*Duodenal ulcer surgery (rationale)*
Procedures devised for the treatment of duodenal ulcers have the common aim of excluding the damaging effects of acid from the duodenum. This has been achieved by diversion of the acid away from the duodenum, reducing the secretory potential of the stomach, or both. All of the operations devised achieved their aim to some extent, but with varying degrees of morbidity, mortality and postoperative side effects. There is now no role for acid-reducing operations in the routine management of peptic ulcer disease but, occasionally, operations which involve gastrectomy have to be performed in the emergency situation. In addition, many patients have had such operations performed and suffer from the sequelae. Hence it is important for the clinician to understand the anatomical and physiological consequences of surgery. The operations are described in historical sequence.

*Billroth II gastrectomy*
The first successful gastrectomy was performed by Billroth in January 1881, and Wollfer performed the first gastroenterostomy in the same year. The original Billroth operations consisted of a gastric resection with gastroduodenal anastomosis (Billroth I technique) (Figure 63.16). The Billroth II operation was devised more by accident than design (Figure 63.17). A gastroenterostomy (Figure 63.18) was performed on a gravely ill patient with a pyloric cancer, who was not expected to survive. Contrary to expectations, the patient improved and the stomach distal to the anastomosis was resected. It soon became evident that the use of a gastrojejunal anastomosis after gastric resection could be safer and easier than the Billroth I procedure, and it became popular and effective in the surgical treatment of duodenal ulcer. Because of its disadvantages, such as higher operative mortality and morbidity, it has not been used for many years in the patient with an uncomplicated ulcer, but it is still used occasionally in the treatment of a complicated ulcer with a 'difficult' duodenum. In Billroth II gastrectomy, or its close relation Poly gastrectomy, the antrum and distal body of the stomach are

![Figure 63.16 Billroth I gastrectomy. The lower half of the stomach is removed and the cut stomach anastomosed to the first part of the duodenum.](Image)

![Figure 63.17 Billroth II. Two-thirds of the stomach removed, the duodenal stump is closed and the stomach anastomosed to the jejunum.](Image)
mobilised by opening the greater and lesser omentum and divid-
ing the gastropiploic arteries, right gastric artery and the left
gastric artery arcade at the limit of the resection. The duodenum
is closed off either by suture or using staples, sometimes with
difficulty in patients with a very deformed duodenum. Various
techniques are available to close the difficult duodenum and, in
extremis, a catheter may be placed in the duodenal stump, the
duodenum closed around it and a catheter brought out through
the abdominal wall. Following resection, the distal end of the
stomach is narrowed by the closure of the lesser curve aspect
of the remnant. The greater curve aspect is then anastomosed,
usually in a retrocolic fashion, to the jejunal loop as short an
afferent loop as feasible (Figure 63.17). Even when well per-
formed, this procedure has an operative mortality rate of a few
per cent and morbidity is not unusual. A common cause of mor-
bidity is leakage from the duodenal stump, which is particularly
associated with kinking of the afferent loop. Leakage from the
gastrojejunal anastomosis is unusual unless it is under tension or
the stomach has been devascularised during the mobilisation.
The incidence of side effects following gastrectomy is consid-
erable, as shown in Table 63.2. Recurrence of the ulcer at the
stoma is uncommon but can occur, especially as this procedure
is traditionally not combined with the vagotomy.

**Gastrojejunostomy**

Because of the potential for mortality after gastrectomy, the use
of gastrojejunostomy alone in the treatment of duodenal ulcer-
ation was developed (Figure 63.18). Reflux of alkali from the
small bowel into the stomach reduced duodenal acid exposure
and was often successful in healing the ulcer. However, because
the jejunal loop was exposed directly to gastric acid, stomal
ulceration was extremely common, hence the procedure in iso-
lation was ineffective.

**Truncal vagotomy and drainage**

Truncal vagotomy was first introduced in 1943 by Dragstedt
and, for many years, combined with drainage, was the mainstay
of treatment of duodenal ulceration (Figure 63.19). The princi-
ple of the operation is that section of the vagus nerves, which
are critically involved in the secretion of gastric acid, reduces
the maximal acid output by approximately 50 per cent. Because
the vagal nerves are motor to the stomach, denervation of the
antropyloroduodenal segment results in gastric stasis in a sub-
stantial proportion of patients on whom truncal vagotomy alone
is performed. This was first noted by Dragstedt, who did not
perform a drainage procedure when he first introduced the opera-
tion. The most popular drainage procedure is the Heineke–
Mikulicz pyloroplasty (Figure 63.20). It is simple to perform and
involves the longitudinal section of the pyloric ring. The inci-
sion is closed transversely. Gastrojejunostomy (Figure 63.18)
was the alternative drainage procedure to pyloroplasty. This is
performed through opening the lesser sac and performing an
anastomosis between the most dependent part of the antrum
and the first jejunal loop. An isoperistaltic anastomosis was most
commonly performed. The operation of truncal vagotomy and
drainage is substantially safer than gastrectomy (Table 63.2).
However, the side effects of surgery are, in fact, little different
from those that follow gastrectomy.

**Highly selective vagotomy**

In 1968, Johnston and Amdrup independently devised the
operation of highly selective vagotomy in which only the pari-
etal cell mass of the stomach was denervated (Figure 63.21).
This proved to be the most satisfactory operation for duodenal
ulceration, with a low incidence of side effects and acceptable
recurrence rates when performed to a high technical standard.
This operation became the ‘gold standard’ for operations on
duodenal ulceration in the 1970s. The operative mortality was

Lester Reynolds Dragstedt, 1893–1975, Professor of Surgery, Chicago, IL, USA. He
was a physiologist to start with and later became a surgeon. His physiological mind
made him consider that vagotomy would be a treatment for peptic ulcer. Accordingly, he
performed the first vagotomy in 1943.

Walther Hermann Heineke, 1834–1901, surgeon of Erlangen, Germany.
Johann von Mikulicz-Radecki, 1850–1905, Professor of Surgery, Breslau, Germany (now Wroclaw, Poland).
lower than any other definitive operation for duodenal ulceration, in all probability because the gastrointestinal tract was not opened during this procedure. The unpleasant effects of peptic ulcer surgery were largely avoided, although loss of receptive relaxation of the stomach did occur, leading to epigastric fullness and sometimes mild dumping. However, the severe symptoms that occur after other more destructive gastric operations did not occur. It is often said that recurrent ulceration is the Achilles heel of this operation although, when performed well, recurrence was no more common than after truncal vagotomy. The operation disappeared from routine use with the advent of antisecretory agents and eradication therapy.

**Truncal vagotomy and antrectomy**

For completeness, this operation should be mentioned as at one stage it was popular in the USA. In addition to a truncal vagotomy, the antrum of the stomach is removed, thus removing the source of gastrin, and the gastric remnant is joined to the duodenum. The recurrence rates after this procedure are exceedingly low. However, the operative mortality is higher than after vagotomy and drainage (Table 63.2) and the incidence of unpleasant side effects is similar.

**Operations for gastric ulcer**

In contrast with duodenal ulcer surgery, when the principal objective was to reduce duodenal acid exposure, in gastric ulceration the diseased tissue is usually removed as well. This has the advantage that malignancy can then be confidently excluded. As with duodenal ulceration, such surgery is not now performed except for complications of gastric ulcer.

**Billroth I gastrectomy**

This was the standard operation (Figure 63.16) for gastric ulceration until medical treatments became prevalent. The distal stomach is mobilised and resected in the same way as in the Billroth II gastrectomy. This resection should include the ulcer that is usually situated on the lesser curve. The cut edge of the remnant is then partially closed from the lesser curve aspect, leaving a stoma at the greater curve aspect, which should be similar in size to the duodenum. Reconstruction may be facilitated by mobilising the duodenum using Kocher’s manoeuvre. The incidence of recurrent ulceration after this operation is low, but it carries with it the morbidity and mortality associated with any gastric resection.

**Sequelae of peptic ulcer surgery**

There are a number of sequelae of peptic ulcer surgery, which include recurrent ulceration, small stomach syndrome, bilious vomiting, early and late dumping, diarrhoea and malignant transformation. These sequelae principally follow from the more destructive operations that are now seldom performed. However, a substantial number of patients suffer from side effects from operations undertaken in the past. Approximately 30 per cent of patients can expect to suffer a degree of dysfunc-
tion following peptic ulcer surgery (Table 63.2) and, in about 5 per cent of such patients, the symptoms will be intractable.

**Recurrent ulceration**

Although mentioned first, this is by far the easiest problem to treat. Just as all peptic ulcers will heal with potent antisecretory agents, so will ulcers that are recurrent after ulcer surgery.

As with other peptic ulcers, recurrent ulcers may present with complications, particularly bleeding and perforation. In this respect, the complication of gastrojejunocolic fistula requires a particular mention. In this rare condition, the anastomotic ulcer penetrates into the transverse colon. Patients suffer from diarrhoea that is severe and follows every meal. They have foul breath and may vomit formed faeces. Severe weight loss and dehydration are rapid in onset, and for this reason the condition may be mistaken for malignancy. The major factor producing the nutritional disturbance is the severe contamination of the jejunum with colonic bacteria. A number of imaging techniques can be used to detect the fistula, most commonly CT with oral contrast or indeed a barium enema. Endoscopy may not convincingly demonstrate the fistula and, in about one-half of such cases, the barium meal will not reveal the problem. The treatment of gastrocolic fistula consists of first correcting the dehydration and malnutrition and then performing revisional surgery.

**Small stomach syndrome**

Early satiety follows most ulcer operations to some degree, including highly selective vagotomy. In this latter circumstance, although there is no anatomical disturbance of the stomach, there is loss of receptive relaxation. Fortunately, this problem does tend to get better with time and revisional surgery is not necessary.

**Bile vomiting**

Bile vomiting can occur after any form of vagotomy with drainage or gastrectomy. Commonly, the patient presents with vomiting a mixture of food and bile or sometimes some bile alone after a meal. Often, eating will precipitate abdominal pain and reflux symptoms are common. Bile chelating agents can be tried but are usually ineffective. In intractable cases, revisional surgery may be indicated. The nature of that revisional surgery depends very much on the original operation. Following gastrectomy, Roux-en-Y diversion is probably the best treatment. In patients with a gastroenterostomy, this can be taken down and, in most circumstances a small pyloroplasty can be performed. In patients with a pyloroplasty, reconstruction of the pylorus has been attempted but, in general terms, the results of this operation have been rather poor. Antrectomy and Roux-en-Y reconstruction may be the better option.

**Early and late dumping**

Although considered together because the symptoms are similar, early and late dumping have different aetiologies. A common feature, however, is early rapid gastric emptying. Many patients have both early and late dumping.

**Early dumping**

Early dumping consists of abdominal and vasomotor symptoms that are found in about 10 per cent of patients following gastrectomy or vagotomy and drainage. It also affects a small percentage of patients following highly selective vagotomy due to the loss of receptive relaxation of the stomach. The small bowel is filled with foodstuffs from the stomach, which have a high osmotic load, and this leads to the sequestration of fluid from the circulation into the gastrointestinal tract. This can be observed by the rise in the packed cell volume while the symptoms are present. All of the symptoms shown in Table 63.3 can be related to this effect on the gut and the circulation.

The principal treatment is dietary manipulation. Small, dry meals are best, and avoiding fluids with a high carbohydrate content also helps. Fortunately, following operation, the syndrome tends to improve with time. For some reason, however, there is a group of patients who suffer intractable dumping regardless of any of these measures. The somatostatin analogue octreotide given before meals has been shown to be useful in some individuals and the long-acting preparation may also be useful. However, this treatment can lead to the development of gallstones and it does not help the diarrhoea from which many patients with dumping also suffer.

Revisional surgery may be occasionally required. In patients with a gastroenterostomy, the drainage may be taken down or, in the case of a pyloroplasty, repaired. Alternatively, antrectomy with Roux-en-Y reconstruction is often effective, although the procedure is of greater magnitude; following gastrectomy, it is the revisional procedure of choice.

**Late dumping**

This is reactive hypoglycaemia. The carbohydrate load in the small bowel causes a rise in the plasma glucose, which, in turn, causes insulin levels to rise, causing a secondary hypoglycaemia. This can be easily demonstrated by serial measurements of blood glucose in a patient following a test meal. The treatment is essentially the same as for early dumping. Octreotide is very effective in dealing with this problem.

**Postvagotomy diarrhoea**

This can be the most devastating symptom to afflict patients having peptic ulcer surgery. Most patients will suffer some looseness of bowel action to some degree (with the exception of highly selective vagotomy) but, in about 5 per cent, it may be
intractable. Despite much investigation, the precise aetiology of the problem is uncertain. It is related, to some degree, to rapid gastrointestinal emptying. In all probability, the denervation of the upper gastrointestinal tract as a result of the vagotomy is also important. Exaggerated gastrointestinal peptide responses may also aggravate the condition.

The diarrhoea in postvagotomy patients may take several forms. It may be severe and explosive, the patient experiencing a considerable degree of urgency. The patients sometimes describe the diarrhoea as feeling like passing boiling water. At the other extreme, some patients only have minor episodes of diarrhoea, which are not as directly related to food.

Many authors regard diarrhoea and dumping as being essentially the same problem. However, many patients with severe diarrhoea do not have any of the other symptoms of dumping and likewise some patients with dumping do not experience any significant diarrhoea.

The condition is difficult to treat. The patient should be managed as for early dumping and antidiarrhoeal preparations may be of some value. Octreotide is not effective in this condition and the results of revisional surgery are too unpredictable to make this an attractive treatment option.

**Malignant transformation**

Many large studies now confirm that operations such as gastrectomy or vagotomy and drainage are independent risk factors for the development of gastric cancer. The increased risk appears to be approximately four times that of the control population.

It is not difficult to understand the increased incidence of gastric cancer, as bile reflux gastritis, intestinal metaplasia and gastric cancer are linked. The lag phase between operation and the development of malignancy is at least ten years. Highly selective vagotomy does not seem to be associated with an increased incidence of gastric cancer in the long term.

**Nutritional consequences**

Nutritional disorders are more common after gastrectomy than after vagotomy and drainage. Weight loss is common after gastrectomy and the patient may, in fact, never return to their original weight. Nutritional advice advising the taking of small meals is often more useful. Anaemia may be due to either iron or vitamin B12 deficiency.

Iron-deficiency anaemia occurs after both gastrectomy and vagotomy and drainage is probably multifactorial in origin. Reduced iron absorption is probably the most important factor, although the loss of blood from the gastric mucosa may also be important. Vitamin B12 deficiency is prone to occur after total gastrectomy. However, because of the very large vitamin B12 stores that most patients have, this may be very late in occurring. Vitamin B12 supplementation after total gastrectomy is essential. Rarely, vitamin B12 deficiency may occur after lesser forms of gastrectomy. In such patients the cause is probably a combination of reduced intrinsic factor production and also the fact that some patients have bacterial colonisation, which results in the destruction of the vitamin B12 in the gut.

Bone disease is seen principally after gastrectomy, and mainly in women. The condition is essentially indistinguishable from the osteoporosis commonly seen in postmenopausal women. It is only the frequency and magnitude of the disorder that distinguish it. Treatment is with dietary supplementation, calcium and vitamin D, and exercise.

**Gallstones**

The development of gallstones is strongly associated with truncal vagotomy. Following truncal vagotomy, the biliary tree, as well as the stomach, is denervated, leading to stasis and hence stone formation. Patients developing symptomatic gallstones will require cholecystectomy. However, this may induce or worsen other postpeptic ulcer surgery syndromes such as bilious vomiting and postvagotomy diarrhoea.

**The complications of peptic ulceration**

The common complications of peptic ulcer are perforation, bleeding and stenosis. Bleeding and stenosis are considered below in the relevant sections.

**Perforated peptic ulcer**

**Epidemiology**

Despite the widespread use of gastric antisecretory agents and eradication therapy, the incidence of perforated peptic ulcer has changed little. However, there has been a considerable change in the epidemiology of perforated peptic ulcer in the West over the last two decades. Previously, most patients were middle aged, with a ratio of 2:1 of male:female. With time, there has been a steady increase in the age of the patients suffering this complication and an increase in the numbers of females, such that perforations now occur most commonly in elderly female patients. NSAIDs appear to be responsible for most of these perforations.

**Clinical features**

The classic presentation of perforated duodenal ulcer is instantly recognisable (Figure 63.22). The patient, who may have a history of peptic ulceration, develops sudden onset severe generalised abdominal pain due to the irritant effect of gastric acid on the peritoneum. Although the contents of an acid-producing stomach are relatively low in bacterial load, bacterial peritonitis supervenes over a few hours, usually accompanied by a deterioration in the patient’s condition. Initially, the patient may be shocked with a tachycardia but a pyrexia is not usually observed until some hours after the event. The abdomen exhibits a board-like rigidity and the patient is disinclined to move because of the pain. The abdomen does not move with respiration.

Patients with this form of presentation need an operation, without which the patient will deteriorate with a septic peritonitis. This classic presentation of the perforated peptic ulcer is observed less commonly than in the past. Very frequently, the

---

**Figure 63.22** A sketch of Mr Hamilton Bailey watching for abdominal movement on respiration. In the case of a classically presenting perforated ulcer, the abdominal movement is restricted or absent.
elderly patient who is taking NSAIDs will have a less dramatic presentation, perhaps because of the use of potent anti-inflammatory drugs (steroids). The board-like rigidity seen in the abdomen of younger patients may also not be observed and a higher index of suspicion is needed to make the correct diagnosis. In other patients, the leak from the ulcer may not be massive. They may present only with pain in the epigastrium and right iliac fossa as the fluid may track down the right paracolic gutter. Sometimes perforations will seal owing to the inflammatory response and adhesion within the abdominal cavity, and so the perforation may be self-limiting. All of these factors may combine to make the diagnosis of perforated peptic ulcer difficult.

By far the most common site of perforation is the anterior aspect of the duodenum. However, the anterior or incisural gastric ulcer may perforate and, in addition, gastric ulcers may perforate into the lesser sac, which can be particularly difficult to diagnose. These patients may not have obvious peritonitis.

**Investigations**

An erect plain chest radiograph will reveal free gas under the diaphragm in an excess of 50 per cent of cases with perforated peptic ulcer (Figure 63.23) but CT imaging is more accurate (see below). All patients should have serum amylase performed, as distinguishing between peptic ulcer, perforation and pancreatitis can be difficult. Measuring the serum amylase, however, may not remove the diagnostic difficulty. It can be elevated following perforation of a peptic ulcer although, fortunately, the levels are not usually as high as the levels commonly seen in acute pancreatitis. Several other investigations are useful if doubt remains. A CT scan will normally be diagnostic in both conditions.

**Treatment**

The initial priorities are resuscitation and analgesia. Analgesia should not be withheld for fear of removing the signs of an intra-abdominal catastrophe. In fact, adequate analgesia makes the clinical signs more obvious. It is important, however, to titrate the analgesic dose. Following resuscitation, the treatment is principally surgical. Laparotomy is performed, usually through an upper midline incision if the diagnosis of perforated peptic ulcer can be made with confidence. This is not always possible and hence it may be better to place a small incision around the umbilicus to localise the perforation with more certainty. Alternatively, laparoscopy may be used. The most important component of the operation is a thorough peritoneal toilet to remove all of the fluid and food debris. If the perforation is in the duodenum it can usually be closed by several well-placed sutures, closing the ulcer in a transverse direction as with a pyloroplasty. It is important that sufficient tissue is taken in the suture to allow the edges to be approximated, and the sutures should not be tied too tight that they tear out. It is common to place an omental patch over the perforation in the hope of enhancing the chances of the leak sealing. If the perforation is difficult to close primarily, it is frequently possible to seal the leak with an omental patch alone, and many surgeons now employ this strategy for all perforations. When securing the omental patch it is important not to tie the sutures too tight so as to obliterate the omental blood supply. Gastric ulcers should, if possible, be excised and closed, so that malignancy can be excluded. Occasionally, a patient is seen who has a massive duodenal or gastric perforation such that simple closure is impossible; in these patients a Billroth II gastrectomy or subtotal gastrectomy with Roux-en-Y reconstruction are useful operations.

All patients should be treated with systemic antibiotics in addition to a thorough peritoneal lavage. In the past, many surgeons performed definitive procedures such as either truncal vagotomy and pyloroplasty or, more recently and probably more successfully, highly selective vagotomy during the course of an operation for a perforation. Studies show that in well-selected patients and in expert hands this is a very safe strategy. However, nowadays, surgery is confined to first-aid measures most commonly, and the peptic ulcer is treated medically as described earlier in this chapter. Following operation, gastric antisecretory agents should be started immediately.

Perforated peptic ulcers can often be managed by minimally invasive techniques if the expertise is available. The principles of operation are, however, the same; thorough peritoneal toilet is performed and the perforation is closed by intracorporeal suturing. Whatever technique is used, it is important that the stomach is kept empty postoperatively by nasogastric suction, and that gastric antisecretory agents are commenced to promote healing of the residual ulcer.

A great deal has been written about the conservative management of perforated ulcer. Some writers say that virtually all patients can be managed conservatively, whereas most surgeons have difficulty in understanding how a patient who is ill with widespread peritonitis and who has food debris widely distributed through the abdominal cavity will improve without an operation. However, undoubtedly, there are patients who have small leaks from a perforated peptic ulcer and relatively mild peritoneal contamination, who may be managed with intravenous fluids, nasogastric suction and antibiotics. These patients are in the minority. A number of factors have been associated with poor outcome after perforated peptic ulcer, including:

- delay in diagnosis (>24 hours)
- medical comorbidities
- shock
- increasing age (>75).

There is little evidence to advocate the conservative management of patients who exhibit any of these characteristics.

Patients who have suffered one perforation may suffer another one. Therefore, they should be managed aggressively to
ensure that this does not happen. In patients with Helicobacter-associated ulcers, eradication therapy is appropriate. Life-long treatment with proton pump inhibitors is a reasonable option, especially in those who have to continue with NSAID treatment (Summary box 63.4).

**HAEMATEMESIS AND MELAENA**

Upper gastrointestinal haemorrhage remains a major medical problem with an incidence of over 100/100,000 per year in Western practice that increases with increasing age. Haemorrhage is strongly associated with NSAID use. Despite improvements in diagnosis and the proliferation in treatment modalities over the last few decades, an in-hospital mortality of 5–10 per cent can be expected. This rises to 33 per cent when bleeding is first observed in patients who are hospitalised for other reasons. In patients in whom the cause of bleeding can be found, the most common causes are peptic ulcer, erosions, Mallory–Weiss tear and bleeding oesophageal varices (Table 63.4).

Whatever the cause, the principles of management are identical. First, the patient should be adequately resuscitated and, following this, the patient should be investigated urgently to determine the cause of the bleeding. Only then should treatment of a definitive nature be instituted. For any significant gastrointestinal bleed, intravenous access should be established and, for those with severe bleeding, central venous pressure monitoring should be set up and bladder catheterisation performed. Blood should be cross-matched and the patient transfused as clinically indicated, usually when >30 per cent of blood volume has been lost. There is no evidence for the use of intravenous proton pump inhibitors prior to endoscopy. As a general rule, most gastrointestinal bleeding will stop, albeit temporarily, but there are sometimes instances when this is not the case. In these circumstances, resuscitation, diagnosis and treatment should be carried out simultaneously. There are occasions when life-saving manoeuvres have to be undertaken without the benefit of an absolute diagnosis. For instance, in patients with known oesophageal varices and uncontrollable bleeding, a Sengstaken–Blakemore tube may be inserted before an endoscopy has been carried out. This practice is not to be encouraged, except in extremis. In some patients, bleeding is secondary to a coagulopathy. The most important current causes of this are liver disease and inadequately controlled warfarin therapy. In these circumstances the coagulopathy should be corrected, if possible, with fresh-frozen plasma or concentrated clotting factors.

Upper gastrointestinal endoscopy should be carried out by an experienced operator as soon as practicable after the patient has been stabilised. In patients in whom the bleeding is relatively mild, endoscopy may be carried out on the morning after admission. In all cases of severe bleeding it should be carried out immediately. A number of scoring systems have been advocated for the assessment of rebleeding and death after upper gastrointestinal haemorrhage. Perhaps the most useful of these is the Rockall score. This can be used in a pre-endoscopy format to stratify patients to safe early discharge and postendoscopy it can relatively accurately predict rebleeding and death.

**Bleeding peptic ulcers**

The epidemiology of bleeding peptic ulcers exactly mirrors that of perforated ulcers. In recent years, the population affected has become much older and the bleeding is commonly associated with the ingestion of NSAIDs. Diagnosis can normally be made endoscopically, although occasionally the nature of the blood loss precludes accurately identifying the lesion. However, the more experienced the endoscopist, the less likely this is to be a problem.

**Medical and minimally interventional treatments**

Medical treatment has limited efficacy. All patients are commonly started on either an H₂-antagonist or a proton pump antagonist, and recent evidence confirms the benefit of proton pump inhibitor administration to prevent rebleeding after endoscopy. Furthermore, meta-analysis of studies suggests that tranexamic acid, an inhibitor of fibrinolysis, may reduce overall mortality.

Therapeutic endoscopy can achieve haemostasis in approximately 70 per cent of cases, with the best evidence supporting a combination of adrenaline injection with heater probe and/or clips. Therapeutic endoscopy will probably never be effective in patients who are bleeding from large vessels and with which the majority of the mortality is associated.

In patients where the source of bleeding cannot be identified or in those who rebleed after endoscopy, angiography with transcather embolisation may offer a valuable alternative to surgery in expert centres. The risk of significant ischaemia following embolisation is low because of the rich collateral blood supply of the stomach and duodenum. The surgeon should be mindful that rescue surgery after failed embolisation is associated with poor outcome and it may be advantageous to proceed directly to surgery.

**Surgical treatment**

Criteria for surgery are well worked out. A patient who continues to bleed requires surgical treatment. The same applies to a
significant rebleed. Patients with a visible vessel in the ulcer base, a spurting vessel or an ulcer with a clot in the base are statistically likely to require surgical treatment to stop the bleeding. Elderly and unfit patients are more likely to die as a result of bleeding than younger patients. Ironically, they should have early surgery. A patient who has required more than six units of blood in general needs surgical treatment.

The aim of the operation is to stop the bleeding. The advent of endoscopy has greatly helped in the management of upper gastrointestinal bleeding as a surgeon can usually be confident about the site of bleeding prior to operation. The most common site of bleeding from a peptic ulcer is the duodenum. In tackling this, it is essential that the duodenum is fully mobilised. This should be done before the duodenum is opened as it makes the ulcer much more accessible and also allows the surgeon's hand to be placed behind the gastroduodenal artery, which is commonly the source of major bleeding. Following mobilisation, the duodenum, and usually the pylorus, is opened longitudinally as in a pyloroplasty (Figure 63.20). This allows good access to the ulcer, which is usually found posteriorly or superiorly. Accurate haemostasis is important and can be achieved initially by direct pressure. It is the vessel within the ulcer that is bleeding and this should be controlled using well-placed sutures on a small round-bodied needle that under-run the vessel. The placing of more and more inaccurately positioned sutures is counterproductive. Following under-running, it is often possible to close the mucosa over the ulcer. The pyloroplasty is then closed with interrupted sutures in a transverse direction as in the usual fashion. In a giant ulcer the first part of the duodenum may be destroyed making primary closure impossible. In this circumstance one should proceed to subtotal gastrectomy with Roux-en-Y reconstruction. The duodenal stump may then be closed using the Nissen technique with T-tube drainage.

The principles of management of bleeding gastric ulcers are essentially the same. The stomach is opened at an appropriate position anteriorly and the vessel in the ulcer under-run. If the ulcer is not excised then a biopsy of the edge needs to be taken to exclude malignant transformation. Sometimes the bleeding is from the splenic artery and if there is a lot of fibrosis present then the operation may be challenging. However, most patients can be managed by conservative surgery. Gastric haemorrhage of bleeding has been widely practised in the past, but is associated with a high perioperative mortality even if the incidence of recurrent bleeding is less.

Bearing in mind that most patients nowadays are elderly and unfit, the minimum surgery that stops the bleeding is probably optimal. Acid can be inhibited by pharmacological means and appropriate eradication therapy will prevent ulcer recurrence. Definitive acid-lowering surgery is not now required. Patients on long-term NSAIDs can be managed as outlined earlier.

**Stress ulceration**

This commonly occurs in patients with major injury or illness, who have undergone major surgery or who have major comorbidity. Many such patients are found in intensive care units. There seems little doubt that the incidence of this problem has reduced in recent years due to the widespread use of prophylaxis. Acid inhibition and the nasogastric or oral administration of sucralfate has been shown to reduce the incidence of stress ulceration. There is no doubt that it is far better to prevent this condition than to try to treat it once it occurs. Endoscopic means of treating stress ulceration may be ineffective and operation may be required. The principles of management are the same as for the chronic ulcer.

**Gastric erosions**

Erosive gastritis has a variety of causes, especially NSAIDs. Fortunately, most such bleeding settles spontaneously, but when it does not it can be a major problem to treat. In general terms, although there is a diffuse erosive gastritis, there is one (or more) specific lesion that has a significant-sized vessel within it. This should be dealt with appropriately, preferably endoscopically, but sometimes surgery is necessary.

**Mallory–Weiss tear**

This is a longitudinal tear at the gastro-oesophageal junction, which is induced by repetitive and strenuous vomiting. Doubtless, many such lesions occur and do not cause bleeding. When it is a cause of haematemesis, the lesion may often be missed as it can be difficult to see as it is just below the gastro-oesophageal junction, a position that can be difficult for the inexperienced endoscopist. Occasionally, these lesions continue to bleed and require surgical treatment. Often the situation arises in which the surgeon does not have guidance from the endoscopists as regards the site of bleeding, and a high index of suspicion in such circumstances is important. The experienced surgeon will perform endoscopy before embarking on surgery. The stomach is opened by longitudinal gastrotomy and the upper section is carefully inspected. It is normally possible to palpate the longitudinal mucosal tear with a little induration at the edges, which gives a clue to the lesion's location. Under-running is all that is required.

**Dieulafoy’s disease**

This is essentially a gastric arterial venous malformation that has a characteristic histological appearance. Bleeding due to this malformation is one of the most difficult causes of upper gastrointestinal bleeding to treat. The lesion itself is covered by normal mucosa and, when not bleeding, it may be invisible. If it can be seen while bleeding, all that may be visible is profuse bleeding coming from an area of apparently normal mucosa. If this occurs, the cause is instantly recognisable. If the lesion can be identified endoscopically there are various means of dealing with it, including injection of sclerosant and endoscopic clips. If it is identified at operation then only a local excision is necessary. Occasionally, a lesion is only recognised after gastrectomy and sometimes not even then. The pathologist, as well as the endoscopist, may have difficulty in finding it.

**Tumours**

All of the gastric tumours described below may present with chronic or acute upper gastrointestinal bleeding. Bleeding is not normally torrential but can be unremitting. Gastric stromal tumours commonly present with bleeding and have a characteristic appearance, as the mucosa breaks down over the tumour in the gastric wall (Figure 63.24). Whatever the nature, the tumours should be dealt with as appropriate.

**Portal hypertension and portal gastropathy**

The management of bleeding gastric varices is very challenging. Fortunately, most bleeding from varices is oesophageal and this...
is much more amenable to sclerotherapy, banding and balloon tamponade. Gastric varices may also be injected, although this is technically more difficult. Banding can also be used, again with difficulty. The gastric balloon of the Sengstaken–Blakemore tube can be used to arrest the haemorrhage if it is occurring from the fundus of the stomach or gastro-oesophageal junction. Octreotide is a somatostatin analogue that reduces portal pressure in patients with varices, and trials suggest that it is of value in arresting haemorrhage in these patients, although its overall effect on mortality remains in doubt. Glypressin is also said to be of use.

Most surgeons prefer to avoid acute surgery on bleeding varices as, in contrast with elective operations for portal hypertension, acute shunts are attended by considerable operative mortality. For this reason the acute TIPSS procedure (trans-jugular intrahepatic portosystemic shunt), which is described in Chapter 65, can be an extremely useful, although technically demanding, procedure.

### Portal gastropathy

Portal gastropathy is essentially the same disease process as described above. The mucosa is affected by the increased portal pressure and may exude blood, even in the absence of well-developed visible varices. The treatment is as above.

### Aortic enteric fistula

This diagnosis should be considered in any patient with haematemesis and melaena that cannot be otherwise explained. Contrary to expectation, the bleeding from such patients is not always massive, although it can be. Very often there is nothing much to distinguish between the bleeding from the aortic enteric fistula and any other recurrent upper gastrointestinal bleeding. The vast majority of patients will have had an aortic graft and, in the absence of this, the diagnosis is unlikely. However, it is occasionally seen in patients with an untreated aortic aneurysm. A well-performed CT scan will commonly allow the diagnosis to be made with certainty. The condition should be managed by an expert vascular surgeon as, whether secondary or primary, the morbidity and mortality are high.

### GASTRIC OUTLET OBSTRUCTION

The two common causes of gastric outlet obstruction are gastric cancer (see below) and pyloric stenosis secondary to peptic ulceration. Previously, the latter was more common. Now, with the decrease in the incidence of peptic ulceration and the advent of potent medical treatments, gastric outlet obstruction should be considered malignant until proven otherwise, at least in the West.

The term 'pyloric stenosis' is normally a misnomer. The stenosis is seldom at the pylorus. Commonly, when the condition is due to underlying peptic ulcer disease, the stenosis is found in the first part of the duodenum, the most common site for a peptic ulcer. True pyloric stenosis can occur due to fibrosis around a pyloric channel ulcer. However, in recent years, the most common cause of gastric outlet obstruction has been gastric cancer. In this circumstance the metabolic consequences may be somewhat different from those of benign pyloric stenosis because of the relative hypochlorhydria found in patients with gastric cancer (Summary box 63.5).

### Summary box 63.5

**Gastric outlet obstruction**

- Gastric outlet obstruction is most commonly associated with long-standing peptic ulcer disease and gastric cancer.
- The metabolic abnormality of hypochloroaemic alkalosis is usually only seen with peptic ulcer disease and should be treated with isotonic saline with potassium.
- Endoscopic biopsy is essential to determine whether the cause of the problem is malignancy.
- Aggressive medical therapy for peptic ulcer disease often leads to resolution.
- Endoscopic dilatation of the gastric outlet may be effective in the less severe cases of benign stenosis.
- Operation is frequently required, with a drainage procedure being performed for benign disease and appropriate resectional surgery if malignant.

### Clinical features

In benign gastric outlet obstruction there is usually a long history of peptic ulcer disease. Nowadays, as most patients with peptic ulcer symptoms are treated medically, it is easy to understand why the condition is becoming much less common. In some patients the pain may become unremitting and in other cases it may largely disappear. The vomiting is characteristically unpleasant in nature and is totally lacking in bile. Very often it is possible to recognise foodstuff taken several days previously. The patient commonly complains of losing weight, and appears unwell and dehydrated. When examining the patient, it may be possible to see the distended stomach and a succussion splash may be audible on shaking the patient’s abdomen.

### Metabolic effects

These are most interesting as the metabolic consequences of benign pyloric stenosis are unique. The vomiting of hydrochloric acid results in hypochloroaemic alkalosis. Initially, the sodium and potassium may be relatively normal. However, as dehydration progresses, more profound metabolic abnormalities arise,...
partly related to renal dysfunction. Initially, the urine has a low chloride and high bicarbonate content, reflecting the primary metabolic abnormality. This bicarbonate is excreted along with sodium, and so with time the patient becomes progressively hypona-traeamic and more profoundly dehydrated. Because of the dehydration, a phase of sodium retention follows and potassium and hydrogen are excreted in preference. This results in the urine becoming paradoxically acidic and hypokalaemia ensues. Alkalosis leads to a lowering in the circulating ionised calcium, and tetany can occur.

Management

Treating the patient involves correcting the metabolic abnormality and dealing with the mechanical problem. The patient should be rehydrated with intravenous isotonic saline with potassium supplementation. Replacing the sodium chloride and water allows the kidney to correct the acid–base abnormality. Following rehydration, it may become obvious that the patient is also anaemic, the haemoglobin being spuriously high on presentation.

It is notable that the metabolic abnormalities may be less if the obstruction is due to malignancy, as the acid–base disturbance is less pronounced.

The stomach should be emptied using a wide-bore gastric tube. A large nasogastric tube may not be sufficiently large to deal with the contents of the stomach, and it may be necessary to pass an orogastric tube and lavage the stomach until it is completely emptied. This then allows investigation of the patient with endoscopy and contrast radiology. Biopsy of the area around the pylorus is essential to exclude malignancy. The patient should also have a gastric antisecretory agent, initially given intravenously to ensure absorption.

Early cases may settle with conservative treatment, presumably as the oedema around the ulcer diminishes as the ulcer is healed. Traditionally, severe cases are treated surgically, usually with a gastroenterostomy rather than a pyloroplasty. Endoscopic treatment with balloon dilatation has been practised and may be more useful in early cases. However, this treatment is not devoid of problems. Dilating the duodenal stenosis may result in perforation. The dilatation may have to be performed several times and may not be successful in the long term. Occasionally, duodenal stent insertion will be considered in specialist centres.

Other causes of gastric outlet obstruction

Adult pyloric stenosis

This is a rare condition and its relationship to the childhood condition is unclear, although some patients have a long history of problems with gastric emptying. It is commonly treated by pyloroplasty rather than pyloromyotomy.

Pyloric mucosal diaphragm

The origin of this rare condition is unknown. It usually does not become apparent until middle age. When found, simple excision of the mucosal diaphragm is all that is required.

GASTRIC POLYPS

A number of conditions manifest as gastric polyps. Their main importance is that they may actually represent early gastric cancer. Biopsy is essential.

The most common type of gastric polyp is metaplastic. These are associated with H. pylori infection and regress following eradication therapy. Inflammatory polyps are also common. Fundic gland polyps deserve particular attention. They seem to be associated with the use of proton pump inhibitors and are also found in patients with familial polyposis. None of the above polyloid lesions has proven malignant potential. True adenomas have malignant potential and should be removed, but they account for only 10 per cent of polyloid lesions. Gastric carcinoids arising from the ECL cells are seen in patients with pernicious anaemia and usually appear as small polyps.

GASTRIC CANCER

Carcinoma of the stomach is a major cause of cancer mortality worldwide. Its prognosis tends to be poor, with cure rates little better than 5–10 per cent, although better results are obtained in Japan, where the disease is common. Gastric cancer is actually an eminently curable disease provided that it is detected at an appropriate stage and treated adequately. It rarely disseminates widely before it has involved the lymph nodes and, therefore, there is an opportunity to cure the disease prior to dissemination. Early diagnosis is therefore the key to success with this disease. Unfortunately, the late presentation of many cases is the cause of the poor overall survival figures. The only treatment modality able to cure the disease is resectional surgery (Summary box 63.6).

Summary box 63.6

Gastric cancer

- Gastric cancer is one of the most common causes of cancer death in the world
- The outlook is generally poor, owing to the advanced stage of the tumour at presentation
- Better results are obtained in Japan, which has a high population incidence, screening programmes and a high-quality surgical treatment
- The aetiology of gastric cancer is multifactorial, but H. pylori is an important factor for distal but not proximal gastric cancer
- Early gastric cancer is associated with very high cure rates
- Gastric cancer can be classified into intestinal and diffuse types, the latter having a worse prognosis
- In the West, proximal gastric cancer is now more common than distal cancer and is usually of the diffuse type
- Spread may be by lymphatics, blood, transcoelomic or direct, but distant metastases are uncommon in the absence of lymph node involvement
- The treatment of curable cases is by radical surgery and removal of the second tier of nodes (around the principal arterial trunks) may be advantageous
- Gastric cancer is chemosensitive and chemotherapy improves survival in patients having surgery for the condition and in advanced disease

Incidence

There are marked variations in the incidence of gastric cancer worldwide. In the UK, it is approximately 15/100 000 per year, in the USA 10/100 000 per year and in Eastern Europe 40/100 000 per year. In Japan, the disease is much more
common, with an incidence of approximately 70/100,000 per year, and there are small geographical areas in China where the incidence is double that in Japan. These underlying epidemiological data make it clear that this is an environmental disease. In general, men are more affected by the disease than women and, as with most solid-organ malignancies, the incidence increases with age.

At present, marked changes are being observed in the West in terms of the incidence and site of gastric cancer and the population affected, changes that to date have not been observed in Japan. First, the incidence of gastric cancer is continuing to fall at about 1 per cent per year. This reduction exclusively affects carcinoma arising in the body and distal stomach. In contrast, there appears to be an increase in the incidence of carcinoma in the proximal stomach, particularly the oesophagogastric junction. Carcinoma of the distal stomach and body of the stomach is most common in low socioeconomic groups, whereas the increase in proximal gastric cancer seems to affect principally higher socioeconomic groups. Proximal gastric cancer does not seem to be associated with *H. pylori* infection, in contrast with carcinoma of the body and distal stomach.

### Aetiology

Gastric cancer is a multifactorial disease (Correa). Epidemiological studies point to a role for *H. pylori*, although there is argument about how important this factor is. Studies reveal a correlation between the incidence of gastric cancer in various populations and the prevalence of *H. pylori* infection, but other factors are also important. There is insufficient evidence at the moment to support eradication programmes in asymptomatic patients who are infected with *Helicobacter*, with a view to reducing the population incidence of gastric cancer. However, clinical trials may subsequently change this view. As mentioned above, *Helicobacter* seems to be principally associated with carcinoma of the body and distal stomach rather than the proximal stomach. As *Helicobacter* is associated with gastritis, gastric atrophy and intestinal metaplasia, the association with malignancy is perhaps not surprising.

Several other risk factors have been identified as being important in the aetiology of gastric cancer. Patients with pignicious anaemia and gastric atrophy are at increased risk, as are those with gastric polyps. Patients who have had peptic ulcer surgery, particularly those who have had drainage procedures such as Billroth II or Polya gastrectomy, gastroenterostomy or pyloroplasty, are at approximately four times the average risk. Presumably, duodenogastric reflux and reflux gastritis are related to the increased risk of malignancy in these patients. Intestinal metaplasia is a risk factor. Carcinoma is associated with cigarette smoking and dust ingestion from a variety of industrial processes. Diet appears to be important, as illustrated by the often quoted example of the change in the incidence of gastric cancer in Japanese families living in the USA. The high incidence of gastric cancer in some pockets in China is probably environmental and probably diet related. The ingestion of substances such as spirits may induce gastritis and, in the long term, cancer. Excessive salt intake, deficiency of antioxidants and exposure to N-nitrosic compounds are also related. The aetiology of proximal gastric cancer remains an enigma. It is not associated with *Helicobacter* but is associated with obesity and higher socioeconomic status. Genetic factors are also important but imperfectly elucidated (see below).

### Clinical features

The features of advanced gastric cancer are usually obvious. However, curable gastric cancer has no specific features to distinguish it symptomatically from benign dyspepsia. The key to improving the outcome of gastric cancer is early diagnosis and, although in Japan there is a screening programme, most curable cases are picked up by the liberal use of gastroscopy in patients with dyspepsia. In the West it is much more difficult as the population incidence is much lower. Hence the cost-effectiveness of performing gastroscopy for mild dyspeptic symptoms is low. However, a high index of suspicion is necessary as only endoscoping patients with symptoms of advanced cancer is unlikely to be beneficial as such patients are not surgically curable. It is important to note that gastric antisecretory agents will improve the symptoms of gastric cancer so the disease should be excluded preferably before therapy is started.

In advanced cancer, early satiety, bloating, distension and vomiting may occur. The tumour frequently bleeds, resulting in iron deficiency anaemia. Obstruction leads to dysphagia, epigastric fullness or vomiting. With pyloric involvement the presentation may be of gastric outlet obstruction, although the alkalosis is usually less pronounced or absent compared with when duodenal ulceration leads to obstruction. In recent years, gastric outlet obstruction is more commonly associated with malignancy than benign disease. Non-metastatic effects of malignancy are seen, particularly thrombophlebitis (Trousseau’s sign) and deep venous thrombosis. These features result from the effects of the tumour on thrombotic and haemostatic mechanisms.

### Site

The proximal stomach is now the most common site for gastric cancer in the West. Because so many malignancies occur at the oesophagogastric junction, and because the lower oesophagus is also a very common site of adenocarcinoma, it is artificial to separate the stomach from the oesophagus. Therefore, it is best to consider the whole of the upper gastrointestinal tract from the cricopharyngeus to the pylorus. The incidence of cancer at these various sites is shown in Figure 63.25. It can be seen that just under 60 per cent of all the malignancies occurring in the oesophagus and stomach occur in proximity to the oesophagogastric junction. Adenocarcinoma at this site has doubled in incidence in the UK over the last 30 years. This high prevalence of proximal gastric cancer is not seen in Japan, where distal cancer still predominates, as it does in most of the rest of the world.

### Pathology

The most useful classification of gastric cancer is the Lauren classification. In this system there are principally two forms of gastric cancer: intestinal gastric cancer and diffuse gastric cancer. In intestinal gastric cancer, the tumour resembles a carcinoma elsewhere in the tubular gastrointestinal tract and forms polypoid tumours or ulcers. It probably arises in areas of intestinal metaplasia. In contrast, diffuse gastric cancer infiltrates deeply into the stomach without forming obvious mass lesions, but spreads widely in the gastric wall. Not surprisingly, this has a much worse prognosis. A small proportion of gastric cancers are of mixed morphology.

---

**P Correa**, a pathologist of New Orleans, LA, USA, produced a cogent hypothesis to explain the development of the intestinal type of gastric cancer.
Gastric cancer can be divided into early gastric cancer and advanced gastric cancer. Early gastric cancer is defined as cancer limited to the mucosa and submucosa with or without lymph node involvement (T1, any N). The classification is shown in Figures 63.26 and 63.27. This can be either protruding, superficial or excavated in the Japanese classification. This type of cancer is eminently curable, and even early gastric cancers associated with lymph node involvement have five-year survival rates in the region of 90 per cent. In Japan, approximately one-third of gastric cancers diagnosed are in this stage. However, in the UK it is uncommon to detect gastric cancers at this stage. A number of reasons probably still account for this. First, because gastric cancer is less common in the UK, dyspeptic patients are not always referred for endoscopy at an appropriate stage. Second, endoscopists are unfamiliar with the appearances of early gastric cancer and in all probability many such cases are missed.

Advanced gastric cancer involves the muscularis. Its macroscopic appearances have been classified by Bormann into four types (Figures 63.28 and 63.29). Types III and IV are commonly incurable.

The molecular pathology of gastric cancer
Although the molecular pathology of gastric cancer is less well worked out than colorectal cancer, several genetic events...
have been established, some of which have clinical relevance. Mutation or loss of heterozygosity in the APC gene or in β-catenin, an associated gene, is found in approximately 50 and 30 per cent, respectively, of cases of intestinal type cancer. APC mutations are found less frequently in diffuse gastric cancer and not at all in patients with β-catenin mutations. In contrast, another related molecule, E-cadherin, is mutated in 50 per cent of cases of diffuse cancer. In some families, inherited diffuse gastric cancer has been shown to be related to a germline mutation in E-cadherin.

Errors in DNA replication manifesting as microsatellite instability (MSI) have been demonstrated in approximately 15 per cent of cases, with little distinction between the intestinal or diffuse types. This genetic phenotype is associated with the inherited cancer syndrome hereditary non-polyposis colorectal cancer syndrome (HNPCC) or the Lynch syndrome. However, most cases of MSI are a result of an acquired mutation in the tumour itself. These findings serve to illustrate that there are important differences between the two types of cancer at a molecular level.

Inactivation of p53, a tumour-suppressor gene, is found in around 30 per cent of both intestinal and diffuse gastric cancer.

Several growth factor receptors are overexpressed/amplified in gastric cancer; these include c-Met, k-Sam and c-ErbB2. Similarly, several growth factors may be overexpressed, including transforming growth factor α, the epidermal growth factor and vascular endothelial growth factor (VEGF).

Lastly, loss of heterozygosity at the bcl-2 gene, an inhibitor of apoptosis, is associated with intestinal-type cancer.

These genetic changes may be involved in the familial predisposition to gastric cancer. Well-known syndromes such as HNPCC have gastric cancer as part of their spectrum.

**Staging**

The International Union Against Cancer (UICC) staging system is shown in Table 63.5. Important changes have been made in the seventh edition of the TNM staging system that are worthy of discussion. In an attempt to reflect the current evidence base and to improve outcome prediction for individual patients all gastric tumours whose epicentre is within 5 cm of the gastro-oesophageal junction and extend into the oesophagus are now classified according to the oesophageal system. Tumours whose epicentre is within 5 cm of the gastro-oesophageal junction but do not extend into the oesophagus, and all other gastric cancers are staged using the revised gastric staging system. In addition, any tumour that perforates the serosa is now classified as T4 disease.

**Spread of carcinoma of the stomach**

No better example of the various modes by which carcinoma spreads can be given than the case of stomach cancer. It is important to note that distant spread is unusual before the disease spreads locally, and distant metastases are uncommon in the absence of lymph node metastases. The intestinal and diffuse types of gastric cancer spread differently. The diffuse type spreads via the submucosal and subserosal lymphatic plexus and it penetrates the gastric wall at an early stage.

**Direct spread**

The tumour penetrates the muscularis, serosa and ultimately adjacent organs such as the pancreas, colon and liver.

**Lymphatic spread**

This is by both permeation and emboli to the affected tiers (see below) of nodes. This may be extensive, the tumour even appearing in the suprachlavicular nodes (Troisier’s sign). Unlike malignancies such as breast cancer, nodal involvement does not imply systemic dissemination.
Figure 63.28 Bormann classification of advanced gastric cancer.

Figure 63.29 Advanced gastric cancer. (a) Type I; (b) type II; (c) type III; (d) type IV (linitus plastica) (courtesy of Dr GNJ Tytgat, Amsterdam, The Netherlands).
Blood-borne metastases

These occur first to the liver and subsequently to other organs, including lung and bone. This is uncommon in the absence of nodal disease.

Transperitoneal spread

This is a common mode of spread once the tumour has reached the serosa of the stomach and indicates incurability. Tumours can manifest anywhere in the peritoneal cavity and commonly give rise to ascites. Advanced peritoneal disease may be palpated either abdominally or rectally as a tumour ‘shelf’. The ovaries may sometimes be the sole site of transcoelomic spread (Krukenberg’s tumours). Tumour may spread via the abdominal cavity to the umbilicus (Sister Joseph’s nodule). Transperitoneal spread of gastric cancer can be detected most effectively by laparoscopy and cytology.

Lymphatic drainage of the stomach

Understanding the lymphatic drainage of the stomach is the key to comprehending the radical surgery of gastric cancer. The lymphatics of the antrum drain into the right gastric lymph node superiorly, and right gastroepiploic and subpyloric lymph nodes inferiorly. The lymphatics of the pylorus drain into the right gastric suprapyloric nodes superiority and the subpyloric lymph nodes situated around the gastroduodenal artery inferiorly. The efferent lymphatics from suprapyloric lymph nodes converge on the para-aortic nodes around the coeliac axis, whereas the efferent lymphatics from the subpyloric lymph nodes pass up to the main superior mesenteric lymph nodes situated around the origin of the superior mesenteric artery. The lymphatic vessels related to the cardiac orifice of the stomach communicate freely with those of the oesophagus.

The prognosis of operable cases of carcinoma of the stomach depends on whether or not there is histological evidence of regional lymph node involvement. Retrograde (downwards) spread may occur if the upper lymphatics are blocked. In Japan, the lymph node dissection is highly advanced and the Japanese Research Society for Gastric Cancer has assigned a number to each lymph node station to aid the pathological staging (Figure 63.30). Many centres in the West now perform surgery that involves a radical lymphadenectomy but, in other centres, both the staging and surgery are less developed.

Operability

It is important that patients with incurable disease are not subjected to radical surgery that cannot help them, hence the value of CT/PET and preoperative laparoscopy. Unequivocal evidence of incurability is haematogenous metastases, involvement of the distant peritoneum, N4 nodal disease and disease beyond the N4 nodes, and fixation to structures that cannot be removed. It is important to note that involvement of another organ per se does not imply incurability, provided that it can be removed. Controversies with respect to operability include N3 nodal involvement and involvement of the adjacent peritoneum, performed in Japan but seldom elsewhere. Curative resection should be considered on the remaining patients.

Figure 63.30 Lymphatic drainage of the stomach and nodal stations by the Japanese classification. (a) The anterior view of the stomach. (b) The posterior view.

Most operable patients should have neoadjuvant chemotherapy as described below as this improves survival.

Total gastrectomy

This is best performed through a long upper midline incision. The stomach is removed en bloc, including the tissues of the entire greater omentum and lesser omentum (Figure 63.31). In commencing the operation, the transverse colon is completely separated from the greater omentum. The dissection may then be commenced proximally or, more usually, distally. The subpyloric nodes are dissected and the first part of the duodenum is divided, usually with a surgical stapler. The hepatic nodes are dissected down to clear the hepatic artery; this dissection also includes the suprapyloric nodes. The right gastric artery is taken on the hepatic artery. The lymph node dissection is continued to the origin of the left gastric artery, which is divided flush with its origin. The dissection is continued along the splenic artery, taking all of the nodes at the superior aspect of the pancreas and accessible nodes in the splenic hilum. Separation of the stomach from the spleen, if this organ is not going to be removed, is carried out and this then allows access to the nodal tissues.
around the upper stomach and oesophago gastric junction. The oesophagus can then be divided at an appropriate point using a combination of stay sutures and a soft non-crushing clamp, usually of the right-angled variety. It is important that the resection margins are well clear of the tumour (>5 cm). Involvement of either proximal or distal resection margin carries an appalling prognosis and, if in doubt, frozen section should be performed. There is some controversy regarding the management of the spleen and distal pancreas in this procedure and this is discussed below.

Gastrointestinal continuity is reconstituted by means of a Roux loop. Other methods of reconstruction should be discouraged because of poor functional results. The alimentary limb of the Roux loop should be at least 50 cm long to avoid bile reflux oesophagitis. The simplest means of effecting the oesophagojejunostomy is to place a purse string in the cut end of the oesophagus and, using a circular stapler introduced through the blind end of the Roux loop, staple the end of the oesophagus onto the side of the Roux loop. The blind open end of the Roux loop may then be closed either with sutures or, alternatively, with a linear stapler. The anastomosis can also be fashioned end to end. The Roux loop may be placed in either an antecolic or retrocolic position. The jejunoojejunostomy is undertaken at a convenient point in the usual fashion (end to side, Figure 63.32).

There remains some controversy about the extent of the lymphadenectomy required for the optimal treatment of curable gastric cancer. In Japan, at least a D2 gastrectomy (removal of the second-tier of nodes) is performed on all operable gastric cancer and some centres are practising more radical surgery (D3 and even D4 resections). Certainly, the results of surgical treatment stage for stage in Japan are much better than commonly reported in the West, and the Japanese contention is that the difference is principally related to the staging and the quality of the surgery. It is observed that the physical proportions of the average Japanese
patient favour the performance of more radical procedures compared with the average patient in the West. However, radical lymphadenectomies above D2 have not been subjected to any randomised controlled trials. In the UK and Europe, randomised trials have been set up to compare D1 and D2 gastrectomy, but the results are difficult to interpret. One of the problems relates to standardisation of the operation. Overall, it seems that the oncological outcome may be better following a D2 gastrectomy, but this operation is associated with higher levels of morbidity and perioperative mortality. It is clear that most of this morbidity and mortality relates to the removal of the spleen with or without the distal pancreas. The traditional radical gastrectomy removes the spleen and distal pancreas en bloc with the stomach and, although this is indeed an adequate means of performing clearance of the lymph nodes around the splenic artery, there now seems little doubt that adding this substantially increases the complication rate. The Japanese D2 gastrectomy will commonly preserve spleen and pancreas and this practice has been widely adopted by specialist centres in the West.

The differentiation between a D1 and a D2 operation depends upon the tiers of nodes removed. Different tiers need to be removed depending on the positions of primary tumour and this is outlined in Table 63.6. In general, a D1 resection involves the removal of the perigastric nodes and a D2 resection involves the clearance of the major arterial trunks. In practice, the majority of specialist centres will perform a radical total gastrectomy, conserving the spleen and pancreas, with D2 lymphadenectomy sparing station 10 lymph nodes.

**Table 63.6** The lymph node stations (see Figure 63.30) that need to be removed in a D1 (N1 nodes removed) or a D2 (N2 nodes removed) resection.

The nodes in stations 12–18 are not routinely removed in a D1 or D2 gastrectomy.

**Subtotal gastrectomy**

For tumours distally placed in the stomach, it appears unnecessary to remove the whole stomach. However, the operation is very similar to that of a total gastrectomy except that the proximal stomach is preserved, the blood supply being derived from the short gastric arteries. Following the resection, the simplest form of reconstruction is to close the stomach from the lesser curve, near the oesophagogastric junction, with either sutures or staples and then perform an anastomosis of the greater curve to the jejunum. Although this can be performed as in a Billroth II/Polya-type gastrectomy, this reconstruction may result in quite marked enterogastric reflux and bile reflux oesophagitis, and the preferred reconstruction is to perform the reconstruction using a Roux loop.

**Palliative surgery**

In patients suffering from significant symptoms of either obstruction or bleeding, palliative resection is appropriate. A palliative gastrectomy need not be radical and it is sufficient to remove the tumour and reconstruct the gastrointestinal tract. Sometimes it is impossible to resect an obstructing tumour in the distal stomach and other palliative procedures need to be considered, although the prognosis in such patients, even in the short term, is poor. A high gastroenterostomy is a poor operation that very frequently does not allow the stomach to empty adequately, but may produce the additional problem of bile reflux. A Roux loop with a wide anastomosis between the stom-
ach and jejunum may be a better option, although even this may not allow the stomach to empty particularly well. Gastric exclusion and oesophagojejunostomy is practised by some surgeons. For inoperable tumours situated in the cardia, either palliative intubation, stenting or another form of recanalisation can be used (Chapter 62). Recanalisation appears to offer better functional results.

Postoperative complications of gastrectomy

Radical gastrectomy is complex major surgery and predictably there is a large number of potential complications of the operation. Leakage of the oesophagojejunostomy should be uncommon in experienced hands. When it occurs it can often be managed conservatively as the Roux-en-Y reconstruction means that it is mainly saliva and ingested food that leaks. Some patients may establish a fistula from the wound or drain site and others may need radiological or surgically placed drains. It is unclear whether a nasoenteric tube should be used routinely. Many surgeons use such tubes routinely, but this is not supported by any evidence base. It is common practice to perform a water-soluble contrast swallow at 5–7 days after the operation to determine whether the anastomosis is intact, and finding a small radiological leak is not uncommon. It is unusual to detect a major leak in the absence of clinical signs. Physiological scoring systems to predict those patients likely to experience significant complications offer potential in this area.

As with any gastrectomy, leakage from the duodenal stump can occur. This is usually due to a degree of distal obstruction and care must be taken when performing the Roux-en-Y anastomosis that there is no kinking. Paraduodenal collections can be drained radiologically, which will often convert the collection into an external fistula. Biliary peritonitis requires a laparotomy and peritoneal toilet, and in this circumstance it is best to leave a Foley catheter in the duodenum to establish a controlled duodenal fistula. If it is established that there is no distal obstruction, or if any such obstruction is managed, then with time the fistula will close.

The presence of septic collections along with a very radical vascular dissection may lead to catastrophic secondary haemorrhage from the exposed or divided blood vessels. This situation may be very difficult to manage, whether or not reoperation or interventional radiology is employed.

Long-term complications of surgery

It is surprising that, considering the radical nature of the total gastrectomy, many patients, particularly the younger ones, have good functional results. However, most patients will have a reduced capacity, particularly in the short term. They need to be given detailed nutritional advice, the substance of which is to eat small meals and often, while the jejunum or small gastric remnant adapts. In fact, there is very little functional difference between patients who have a total gastrectomy and those who have a subtotal gastrectomy. Various attempts have been made to try and improve the short-term functional results by forming a jejunal pouch and attaching this to the oesophagus. Most surgeons do not perform this as in the long term there seems little functional advantage. It is surprising that these patients only infrequently suffer from the complications of gastric surgery, such as dumping and diarrhoea. Nutritional deficiencies may occur and the patient should be monitored with this in mind.

The loss of the parietal mass leads to vitamin B12 deficiency and replacement should be given routinely.

Outlook after surgical treatment

The outlook after surgical treatment varies considerably between the West and Japan. In Japan, approximately 75 per cent of patients will have a curative resection and, of these, the overall five-year survival rate will be in the region of 50–70 per cent. In contrast, in the West most series show that only 25–50 per cent of patients undergoing surgery will have a curative operation and the five-year survival rate in such patients is only about 25–30 per cent, although in some series it approaches Japanese levels. A combination of differences in staging and a higher standard of surgery in Japan probably accounts for the differences. Staging is clearly crucial when survival figures are being compared. The more thorough the staging, the higher the stage is likely to be and, therefore, stage for stage the outcome seems better in patients who are adequately staged pathologically. This phenomenon is termed ‘stage migration’.

Other treatment modalities

Because of the failure of radical surgery to cure advanced gastric cancer, there has been an interest in the use of radiotherapy and chemotherapy.

Radiotherapy

The routine use of radiotherapy is controversial as the results of clinical trials are inconclusive. There are a number of radiosensitive tissues in the region of the gastric bed, which limits the dose that can be given. Radiotherapy has a role in the palliative treatment of painful bony metastases.

Chemotherapy

Gastric cancer may respond well to combination cytotoxic chemotherapy and neoadjuvant chemotherapy improves the outcome following surgery. Most patients therefore should have prior chemotherapy. There are a number of well-investigated regimes, but the best results are currently obtained using a combination of epirubicin, cis-platinum and infusional 5-FU or an oral analogue such as capecitabine. The same regimen is used as first line for patients with inoperable disease although oxaliplatin is being substituted for cis-platinum as it has fewer side effects. Second-line treatment using combinations which include taxotere are increasingly being used. Chemotherapy for advanced disease is palliative. Newer biological agents such as trastuzumab (Herceptin®) offer potential advantages to survival in the minority of patients (<20 per cent) with HER2-positive gastric cancer. However, the absolute survival advantages are small (approximately four months) and the cost of treatment is high. Nevertheless, trastuzumab has been approved for use in metastatic HER2-positive gastric cancer in the UK and European Union.

Pattern of relapse following surgical treatment

As might be expected, the most common site of relapse following radical gastrectomy is the gastric bed, representing inadequate extirpation of the primary tumour. Widespread nodal intraperitoneal metastases, distant nodal metastases and liver metastases are all common. Dissemination to the lung and bones usually only occurs after liver metastases are already established.

Frederic Eugene Basil Foley, 1891–1966, urologist, Ankar Hospital, St Paul, MN, USA.
GASTROINTESTINAL STROMAL TUMOURS

Gastrointestinal stromal tumours (GIST) may arise in any part of the gastrointestinal tract but 50 per cent will be found in the stomach. Previously named leiomyoma and leiomyosarcoma, the term GIST is now used, recognising their particular distinct phenotype. They are tumours of mesenchymal origin and are observed equally commonly in males and females. The tumours are universally associated with a mutation in the tyrosine kinase c-kit oncogene. These tumours are sensitive to the tyrosine kinase antagonist imatinib, and an 80 per cent objective response rate can be observed. Tumours with mutations in exon 11 of c-kit are particularly sensitive to this drug. The biological behaviour of these tumours is unpredictable but size and mitotic index are the best predictors of metastasis. Peritoneal and liver metastases are most common but spread to lymph nodes extremely rare.

The incidence of the condition is unclear as small stromal tumours of the stomach are probably quite common and remain unnoticed. Clinically obvious tumours are considerably less common than gastric cancer. GIST comprise 1–3 per cent of all gastrointestinal neoplasia.

The only ways that many stromal tumours are recognised are either that the mucosa overlying the tumour ulcerates (see Figure 63.24), leading to bleeding, or that they are noticed incidentally at endoscopy. Because the mucosa overlying the tumour is normal, endoscopic biopsy can be uninformative unless the tumour has ulcerated. Targeted biopsy by endoscopic ultrasound is more helpful. Larger tumours present with non-specific gastric symptoms and, in many instances, they may be thought to be gastric cancer initially (Figure 63.33).

As the biological behaviour is difficult to predict, the best guide is to consider the size of the tumour. Tumours over 5 cm in diameter should be considered to have metastatic potential. If easily resectable, surgery is the primary mode of treatment. Smaller tumours can be treated by wedge excision although the appropriate management of asymptomatic diminutive tumours found incidentally at endoscopy is unclear. Larger tumours may require a gastrectomy or duodenectomy (see Chapter 68) but lymphadenectomy is not required. Larger tumours which require multivisceral resection may be better treated with three to six months of imatinib prior to operation as this will usually radically reduce the size and vascularity of the tumours. Adjuvant imatinib for large resected tumours of high malignant potential should probably be continued indefinitely.

The prognosis of advanced metastatic GIST has been dramatically improved with imatinib chemotherapy but resection of metastases, especially from the liver, still has an important role.

GASTRIC LYMPHOMA

Gastric lymphoma is an interesting disease and some aspects of the management are controversial. It is first important to distinguish primary gastric lymphoma from involvement of the stomach in a generalised lymphomatous process. This latter situation is more common than the former. Unlike gastric carcinoma, the incidence of lymphoma seems to be increasing. Primary gastric lymphoma accounts for approximately 5 per cent of all gastric neoplasms.

Gastric lymphoma is the most common in the sixth decade and the presentation is no different from gastric cancer, the common symptoms being pain, weight loss and bleeding. Acute presentations of gastric lymphoma, such as haematemesis, perforation or obstruction, are not common. Primary gastric lymphomas are B cell derived, the tumour arising from the mucosa-associated lymphoid tissue (MALT). Primary gastric lymphoma remains in the stomach for a prolonged period before involving the lymph nodes. At an early stage, the disease takes the form of a diffuse mucosal thickening, which may ulcerate. Diagnosis is made as a result of the endoscopic biopsy and seldom on the basis of the endoscopic features alone, which are not specific.

Following diagnosis, adequate staging is necessary, primarily to establish whether the lesion is a primary gastric lymphoma or part of a more generalised process. CT scans of the chest and abdomen and bone marrow aspirate are required, as well as a full blood count.

Although the treatment of primary gastric lymphoma is somewhat controversial, it seems most appropriate to use surgery alone for the localised disease process. No benefit has been shown from adjuvant chemotherapy, although some oncologists contend that primary gastric lymphoma can be treated by chemotherapy alone. Chemotherapy alone is appropriate for patients with systemic disease.

Some of the more controversial aspects of gastric lymphoma concern the role ofHelicobacter pylori. Lymphocytes are not found to any degree in normal gastric mucosa, but are found in association with Helicobacter infection. It has also been shown that early gastric lymphomas may regress and disappear when the Helicobacter infection is treated.

Gastric involvement with the diffuse lymphoma

These patients are treated with chemotherapy, sometimes with dramatic and rapid responses. Surgeons are frequently asked to deal with the complications of gastric involvement. The two common complications are bleeding and perforation. Both may occur at presentation, but more usually may follow the

Figure 63.33 Computed tomography of the upper abdomen showing a 3.5 cm gastrointestinal stromal tumour arising from the gastric wall.

Peter Gersohn Issaacman, Emeritus Professor of Pathology and Consultant Histopathologist, University College, London, UK.
Duodenal obstruction

chemotherapy when there is rapid regression and necrosis of the tumour. These operations can be technically very challenging and normally require gastrectomy.

**DUODENAL TUMOURS**

**Benign duodenal tumours**

Duodenal villous adenomas occur principally in the periampullary region. Although generally uncommon, they are often found in patients with familial adenomatous polyposis. The appearances are similar to those adenomas arising in the colon and, as they have malignant potential, they should be locally excised with histologically clear margins (Summary 63.7).

**Summary box 63.7**

**Duodenal tumours**

- Duodenal villous adenomas are commonly found around the ampulla of Vater and are premalignant.
- Duodenal carcinoma is uncommon, but the most common site for adenocarcinoma is in the small intestine.
- Both adenoma and carcinoma occur commonly in patients with familial polyposis and screening these patients is advised.
- Pancreatic cancer is the most common cause of duodenal obstruction.

**Duodenal adenocarcinoma**

Although uncommon, this is the most common site for adenocarcinoma arising in the small bowel. Most tumours originate in the periampullary region and commonly arise in pre-existing villous adenomas. Patients present with anaemia due to ulceration of the tumour or obstruction as the polyloid neoplasm begins to obstruct the duodenum. Direct involvement in the ampulla leads to obstructive jaundice. Histologically, the lesion is a typical adenocarcinoma and the metastases are commonly to regional lymph nodes and the liver. At presentation, about 70 per cent of the patients have resectable disease and for those who survive operation the five-year survival rate is in the region of 20 per cent, this approximately equating to cure. Poor prognostic features in the resected specimen include regional lymph node metastases, transmural involvement and perineural invasion. Curative surgical treatment will normally involve a pancreaticoduodenectomy (Whipple’s procedure). Patients with familial polyposis, which is due to a mutation in the APC gene on chromosome 5, are predisposed to periampullary cancer, which is one of the most common causes of death in patients who have had their colon removed. Other duodenal malignancies include GISTs (see above) and neuroendocrine tumours.

**Neuroendocrine tumours**

A number of neuroendocrine neoplasms occurs in the duodenum. It is a common site for primary gastrinoma (Zollinger–Ellison syndrome). Non-functioning neuroendocrine tumours (usually called carcinoid tumours) also occur but uncommonly in comparison to the ileum.

**Zollinger–Ellison syndrome**

This syndrome is mentioned here because the gastrin-producing endocrine tumour is often found in the duodenal loop, although it also occurs in the pancreas, especially the head. It is a cause of persistent peptic ulceration. Before the development of potent gastric antisecretory agents, the condition was recognised by the sometimes fulminating peptic ulceration which did not respond to gastric surgery short of total gastrectomy. It was also recognisable from gastric secretory studies in which the patient had a very high basal acid output but no marked response to pentagastrin, as the parietal cell mass was already nearly maximally stimulated by pathological levels of gastrin. The advent of proton pump inhibitors such as omeprazole has rendered this extreme endocrine condition fully controllable, but also less easily recognised.

Gastrinomas may be either sporadic or associated with the autosomal dominantly inherited multiple endocrine neoplasia (MEN) type I (in which a parathyroid adenoma is almost invariable). The tumours are most commonly found in the ‘gastrinoma triangle’ (Passaro) defined by the junction of the cystic duct and common bile duct superiorly, the junction of the second and third parts of the duodenum inferiorly, and the junction of the neck and body of the pancreas medially (essentially the superior mesenteric artery). Many are found in the duodenal loop, presumably arising in the G cells found in Brunner’s glands. It is extremely important that the duodenal wall is very carefully inspected endoscopically and also at operation. Very often all that can be detected is a small nodule that projects into the medial wall of the duodenum.

Even malignant sporadic gastrinomas may have a very indolent course. The palliative resection of liver metastases may be beneficial and liver transplantation is practised in some centres, as for other gut endocrine tumours, with reasonable long-term results. However, the minority of tumours found to the left of the superior mesenteric artery (outside the ‘triangle’) seems to have a worse prognosis, more having liver metastases at presentation. In MEN type I, the tumours may be multiple and the condition is incurable. Even in this situation, as with sporadic gastrinoma, surgical treatment should be employed to remove any obvious tumours and associated lymphatic metastases, as the palliation achieved may be good.

**DUODENAL OBSTRUCTION**

Duodenal obstruction in the adult is usually due to malignancy, and cancer of the pancreas is the most common cause. About one-fifth of patients with pancreatic cancer treated with endoscopic stenting will develop obstruction. Treatment is usually by gastroenterostomy but duodenal stenting is increasingly being used. In patients having a surgical biliary bypass for pancreatic cancer, gastric drainage may be necessary.

A variety of other malignancies can cause duodenal obstruction, including metastases from colorectal and gastric cancer. Primary duodenal cancer is much less common as a cause of obstruction than these other malignancies.

Annular pancreas may rarely cause duodenal obstruction. Obstruction usually follows an attack of pancreatitis and, on occasions, the obstruction may be mistaken for malignancy.

Arteromesenteric compression is an ill-defined condition
in which it is proposed that the fourth part of the duodenum is compressed between the superior mesenteric artery and the vertebral column; when it is convincingly demonstrated and causing weight loss, duodenojejunostomy may be performed.

**OTHER GASTRIC CONDITIONS**

**Acute gastric dilatation**

This condition usually occurs in association with pyloroduodenal disorders or postsurgery without nasogastric suction. The stomach, which may also be atonic, dilates enormously. Often the patient is also dehydrated and has electrolyte disturbances. Failure to treat this condition can result in a sudden massive vomit with aspiration into the lungs. The treatment is nasogastric suction, with a large-bore tube, fluid replacement and treatment of the underlying condition.

**Trichobezoar and phytobezoar**

Trichobezoar (hair balls) (Figure 63.34) are unusual and are virtually exclusively found in female psychiatric patients, often young. It is caused by the pathological ingestion of hair, which remains undigested in the stomach. The hair ball can lead to ulceration and gastrointestinal bleeding, perforation or obstruction. The diagnosis is made easily at endoscopy or, indeed, from a plain radiograph. Treatment consists of removal of the bezoar, which may require open surgical treatment. Phytobezoars are made of vegetable matter and found principally in patients who have gastric stasis. Often this follows gastric surgery.

**Foreign bodies in the stomach**

A variety of ingested foreign bodies reach the stomach, and very often these can be seen on a plain radiograph. If possible, they should be removed endoscopically but, if not, most can be left to pass normally. Even objects such as needles, with which there is understandable anxiety, will seldom cause harm. In general, an object which leaves the stomach will pass spontaneously. In contrast, attempted removal at laparotomy can be very difficult as the object may be much more difficult to find than might be expected. Most adults who swallow foreign bodies have ill-defined psychiatric problems and may appear to relish the attention associated with serial laparotomies. The treatment should therefore be expectant and intervention reserved for patients with symptoms in whom the foreign body is failing to progress.

**Volvulus of the stomach**

Rotation of the stomach usually occurs around the axis and between its two fixed points, i.e. the cardia and the pylorus. In theory, rotation can occur in the horizontal (organoaxial) or vertical (mesenteroaxial) direction but, commonly, it is the former which occurs. This condition is usually associated with a large diaphragmatic defect around the oesophagus (paraoesophageal herniation) (Figure 63.35). What commonly happens is that the transverse colon moves upwards to lie under the left diaphragm, thus taking the stomach with it, and the stomach and colon may both enter the chest through the eventration of the diaphragm. The condition is commonly chronic, the patient presenting with difficulty in eating. An acute presentation with ischaemia may occur. Endoscopically, it can be
extremely difficult to sort out the anatomy, and this is one situation in which the contrast radiograph is superior.

**Treatment**
If the problem is causing symptoms then surgical treatment is the only satisfactory approach. Traditionally, open surgery has been employed but this problem is suitable for laparoscopic treatment if appropriate skill is available. If there is a hernia, the sac and its contents (usually the stomach) should be reduced. The defect in the diaphragm should be closed, if necessary, with a mesh. It is advisable to separate the stomach from the transverse colon and then perform an anterior gastropexy to fix the stomach to the anterior abdominal wall. The results from this treatment are good.

**FURTHER READING**
introduction
Surgical management for obesity has been available for decades. The first recorded proper bariatric operation, the jejunoileal bypass (JIB), was described in 1954. The JIB was the most popular procedure in the 1960s but fell into disrepute because of various complications, some of which were lethal. To avoid these complications Edward Mason devised the vertical banded gastroplasty which after various iterations stood the test of time until he devised the gastric bypass which then became the gold standard in the United States. To improve on the older JIB operation, Nicola Scopinaro from Italy modified the procedure as a bilipancreatic diversion (BPD) which was further modified by Marceau with a duodenal switch. In the 1980s, gastric bands were introduced to the market, at first as non-adjustable then as adjustable bands.

The laparoscopic era heralded a paradigm shift in bariatric surgery such that all procedures are now able to be carried out laparoscopically. Open surgery has all but disappeared except for some complex revisional procedures. Furthermore, the growth in recent decades of obesity surgery has led to a much more professional approach to the subject with the establishment of a multidisciplinary team (MDT) for patient selection and follow up, emphasis on quality improvement and accreditation of surgeons and units as well as a constant search for more effective and safer surgical methods of treatment. There is now universal agreement that obesity surgery is better termed metabolic surgery because of its profound effects on the various hormones which affect insulin sensitivity.

causes of obesity and epidemiology
Obesity is a multifactorial metabolic disorder which essentially manifests itself as a surplus of unexpended energy stored as fat. The contributing factors include genetic predisposition, eating disorders, psychological issues, poor diet, lack of exercise and comorbid conditions predisposing to obesity. The outcome of excess fat storage is often the development of a metabolic syndrome which drives the excess incidence of associated comorbidities. Table 64.1 shows the comorbidities associated with morbid obesity all of which can be improved by weight loss.

Morbid obesity is defined as a body mass index (BMI) equal to or greater than 40 kg/m² (Table 64.2). A patient with a BMI of 40 kg/m² is around 80 per cent above their ideal body weight. A 40-year-old women with a BMI of 40 kg/m² has an excess mortality of 8–12 years and will die younger than her peer group with a normal BMI. As BMI increases further so does the incidence
The international trend is for obesity incidence to increase such that the definition of a normal BMI of 20–25 kg/m² has been called into question. The comorbidities caused by obesity have become one of the world’s greatest health-care problems as we do not seem to be able to stop the increase in obesity levels despite educating the public.

Non-surgical treatment for morbid obesity usually involves the patient trying various diets and attempts at exercising more regularly as well as other lifestyle changes. This can be aided by slimming clubs, professional dietitian advice, personal exercise trainers and some pharmacological agents. Sadly, for morbidly obese patients, these have a 97 per cent long-term failure rate which is the main driver for surgical means to deal with the disorder. Even after initially successful bariatric surgery there is always a trend for gradual weight regain over the long term. This requires the bariatric patient to continue to address diet and exercise requirements. It must always be emphasised to patients that bariatric surgery does not cure the obesity problem but is an adjunct to help them to manage the problem more readily.

### RELEVANT ANATOMY AND PHYSIOLOGY

Most bariatric procedures are aimed at the stomach in an attempt to restrict the amount the patient can eat. Some of these procedures also add an element of gastric and small intestinal bypass to produce a degree of malabsorption. Experimentally there are also approaches trying neuromodulation of the vagus or gastric muscle in order to create increased satiety.

The stomach receives food and starts the digestive process by adding acid and pepsin during the tituration process. The fundic area of the stomach also produces grehlin which is the only known hormone that stimulates appetite. During a meal levels of grehlin drop while between meals grehlin levels rise to stimulate the need to eat again. In addition, the stomach during filling undergoes adaptive relaxation mediated by the vagus so that it will accommodate food at a constant pressure. The jejunum and ileum also produce peptide hormones such as glucagon-like peptide-1 (GLP-1), peptide-YY (PYY) and cholecystokinin (CCK) which also have a role in stimulating the release of insulin and reducing appetite.

### RATIONALE FOR OBESITY SURGERY

Obesity is dangerous to health due to the excess incidence of comorbidities that obese patients often develop, especially the metabolic syndrome. Many studies have suggested that if weight loss is induced surgically this leads to improvement in various comorbidities which translates into increased life expectancy. The best study so far is the well-known Swedish Obese Subjects study, which started in 1987, where the investigators matched over 2000 surgically treated patients with 2000 medically treated patients and followed these cohorts up for 15 years. Essentially this research has demonstrated that surgically induced weight loss increases life expectancy, and ameliorates diabetes, hypertension, hyperlipidaemia, obstructive sleep apnoea and atherosclerosis rates. In addition, these workers also have demonstrated that bariatric surgery leads to an improved quality of life and the patient being more likely to be employed as well as costing the health service less money. There is also some evidence from these workers as well as others that bariatric surgery reduces the incidence of some cancers.

One of the biggest issues with bariatric surgery is who will pay for it. Rationing is inevitable in countries with a socialised health-care system, which nowadays is our biggest challenge. Who takes priority – a 55-year-old man with multiple comorbidities who is costing the health service a considerable amount of money or a 25-year-old man who is morbidly obese but as yet has not developed any comorbidities? No one has a clear answer to this ethical dilemma although ideally they should both be offered surgery.

### PATIENT SELECTION AND PREPARATION FOR SURGERY

The criteria for patient selection are universally agreed (Table 64.3) although the evidence base for them has never been clearly delineated. Indeed, many bariatric surgeons think they are too conservative and need to be revised in light of new knowledge. There will always be some exceptions to the guidelines but for most part they should be followed. There is also an increasing trend for bariatric surgery to be carried out in younger patients, especially those in the paediatric age group where it is becoming clear that delaying surgery to adulthood is detrimental to their health.

All surgical candidates should be seen by the bariatric MDT (Table 64.4). All patients need some dietetic assessment which may help to choose the correct operation for them. In addition, they must be seen by a physician with an interest in obesity to screen for endocrine disorders and to establish the degree of metabolic syndrome present. All patients should also

BARIATRIC SURGERY

The choosing of the best surgical procedure for an individual patient is not an exact science. What is clear is that there is no perfect operation free of side effects or complications. Some procedures are more effective than others albeit at the cost of higher perioperative rates of morbidity and mortality. It is unclear what the end point of bariatric surgery should be: is it maximum weight loss regardless of risk or just enough weight loss to alleviate comorbidities at minimum risk? Intuitively, it should be maximum weight loss with least risk and side effects, which requires a very detailed discussion of the options available with each individual patient.

As with other high-risk surgical procedures there is a volume—outcome effect thus it behoves any commissioner of bariatric services to fund only established high-volume centres in order to reduce complications and improve outcomes.

CURRENT SURGICAL OPTIONS

The surgical options have varying degrees of gastric restriction from pure (banding) to least (standard biliopancreatic diversion (BPD)). Varying degrees of malabsorption also pertain from none (banding) to severe (BPD). All procedures are usually carried out laparoscopically and increasingly through fewer access ports as instrumentation and techniques improve. With appropriate training some procedures can be carried out through a single umbilical incision although the future role of this approach is as yet unclear. Furthermore, some surgeons are now experienced at carrying out some procedures transvaginally leaving no abdominal scars at all!

Gastric banding

Around half of all surgical procedures in many countries are gastric bands which involves putting an adjustable band around the upper stomach leaving a small pouch just below the cardia (Figure 64.1). The degree of restriction can be controlled by the amount of fluid injected into the subcutaneous port. This operation is especially popular in Australia where excellent results are obtained. The perception that the band is reversible is important to some patients (although in reality it is a disadvantage). Gastric banding is certainly the least risky procedure (0.1 per cent perioperative mortality) as it does not involve cutting any stomach or bowel and is a relatively easy operation to perform in most patients who have a BMI <50 kg/m².

Most patients can expect to lose around 45–50 per cent of their excess weight, especially if the quality of follow up is intensive. However, there is a wide variation in results with

have a psychological screen to determine whether there are unresolved issues to be dealt with either pre- or postoperatively.

The risks of bariatric surgery need particular attention when counselling patients as the global risk of perioperative death is around 1 per cent although it is much lower than this for some procedures, especially in fitter patients. Involvement of the family or carers in decision-making is also crucial (Summary box 64.2).

Preoperatively patients are generally put on a low carbohydrate diet for a minimum of 2 weeks to shrink the liver to allow for adequate working space to carry out the surgery. A preoperative baseline metabolic screen (Table 64.5) is also desirable to determine the levels of vitamins, minerals and micronutrients which are essential for health. It is well recognised that many bariatric patients preoperatively suffer from vitamin and micronutrient deficiencies, usually due to their poor diet.

Gastric banding

Around half of all surgical procedures in many countries are gastric bands which involves putting an adjustable band around the upper stomach leaving a small pouch just below the cardia (Figure 64.1). The degree of restriction can be controlled by the amount of fluid injected into the subcutaneous port. This operation is especially popular in Australia where excellent results are obtained. The perception that the band is reversible is important to some patients (although in reality it is a disadvantage). Gastric banding is certainly the least risky procedure (0.1 per cent perioperative mortality) as it does not involve cutting any stomach or bowel and is a relatively easy operation to perform in most patients who have a BMI <50 kg/m².

Most patients can expect to lose around 45–50 per cent of their excess weight, especially if the quality of follow up is intensive. However, there is a wide variation in results with
some patients obtaining poor weight loss eventually requiring a revisional procedure. Furthermore, bands can fail due to prolapse of the stomach through the band or the band can slip up or down from its initial position. Bands can also erode into the stomach. Although the incidence of these complications is relatively low (<5 per cent) up to 30 per cent of patients are deemed long-term failures due to insufficient weight loss. It may be that these patients have been poorly selected in the first place or the quality of their follow up has not been very good.

One disadvantage of the gastric band is the need for continual band adjustments in the early postoperative period and occasional long-term adjustments. It is generally considered a labour-intensive procedure which requires a lot of patient compliance to get good results. Another disadvantage of the gastric band is that when a revisional procedure is indicated it is a much higher-risk procedure due to adhesions and gastric wall thickening.

However, gastric banding has a place in properly selected patients who have the correct attitude and understanding of the postoperative requirements. In selected patients a band can even be inserted as a day-case procedure. It should generally be avoided in binge eating patients and those whose eating habits involve excessive sweets and chocolate.

**Sleeve gastrectomy**

This relatively new operation requires less postoperative monitoring as it does not require any adjustments although it is a riskier procedure than gastric banding (0.2 per cent operative mortality). The long staple line can leak despite various manoeuvres to avoid leakage, such as applying reinforcing material and/or gluing. Another attraction of this procedure is that as it removes most of the grehlin-secreting area of the stomach it may have a beneficial effect on reducing appetite (Figure 64.2).

Around 65 per cent excess weight loss can be expected at two years which is as good as a gastric bypass without any malabsorption issues. However, there is a tendency for the sleeve to expand over time. A resleeving procedure is well described or alternatively it is relatively straightforward to convert the procedure to a gastric bypass or a BPD with a duodenal switch. Indeed, many bariatric surgeons believe that in patients with a BMI >50 kg/m² who want a gastric bypass, it is safer to do a sleeve gastrectomy first and convert only those patients who regain weight to a gastric bypass. The exact percentage of how many patients might require a second procedure is not yet clear but is probably around 10–20 per cent depending on patient selection. Thus, the concept of bariatric surgery as a staged procedure has been mooted with the first stage being a sleeve gastrectomy and the second a gastric bypass or BPD with a duodenal switch. The second stage in most cases will not be needed.

The true place for sleeve gastrectomy as a primary bariatric procedure is still unclear and more long-term data are needed. Despite this, the frequency of this procedure is accelerating at a remarkable rate largely because of the relative technical ease of doing the procedure, the lack of potential malabsorption problems and the option of doing a relatively safe second-stage procedure if needed.

**Roux-en-Y gastric bypass**

The gastric bypass is a very effective weight loss procedure but is performed with a myriad of technical variations making comparisons difficult. However, overall it produces 65–75 per cent excess weight loss albeit at a higher risk of around 0.5 per cent perioperative mortality.

Gastric bypass is a very effective operation for alleviating and even curing type II diabetes – the result being almost immediate and independent of weight loss. There are two major theories as to how this happens (Table 64.6), given that other bariatric procedures such as banding and sleeve gastrectomy are dependent on weight loss to resolve the diabetes. Over 80 per cent of patients will have their diabetes permanently resolved (Table 64.7).

There are many variations in the actual gastric bypass technique, e.g. antecolic versus retrocolic Roux limb placement, varying alimentary and biliary limb lengths, additional banding of the gastrojejunal anastomosis to prevent dilatation, varying methods of doing the gastrojejunal anastomosis and varying methods of closing potential hernia spaces (Figure 64.3). There is a need to consolidate knowledge about the outcomes of these variations in order to standardise the procedure.

Although weight loss is generally very good the downside of this procedure is the need for careful postoperative metabolic
follow up to avoid deficiency syndromes. Additional multivitamins, iron and calcium are needed for all patients as well as vitamin B12 administration. Some surgeons also recommend periodic bone densitometry measurements to avoid premature osteoporosis.

**Biliopancreatic diversion – with or without a duodenal switch**

This procedure, which produces the most malabsorption of all operations, is the most effective with 75–85 per cent excess weight loss but at the expense of the highest perioperative mortality of 1–2 per cent. Additionally as time goes by, if the patient does not adhere to their vitamin and micronutrient supplementation regime they are at severe risk of many deficiency syndromes. Furthermore, due to the extreme malabsorption these operations produce there is a need for a high protein intake of around 90 g/day which many patients find difficult. If this is not achieved then protein calorie malnutrition can be a problem. In correctly selected patients however, the BPD can be very effective, especially in those patients with a very high BMI. A BPD also has the same rapid effect as a gastric bypass for alleviating diabetes independent of weight loss (Tables 64.6 and 64.7).

The duodenal switch variation of the BPD was designed to reduce the need for taking vitamin B12 and reduce the incidence of anastomotic strictures at the gastrojejunal anastomosis. In the standard BPD, approximately two-thirds of the distal stomach is removed while in the duodenal switch variation there is a vertical sleeve gastrectomy. In the duodenal switch variation, the anastomosis is made to the first part of the duodenum rather than the stomach as in the standard BPD. The limb lengths also vary, as shown in Figure 64.4. In reality, there is very little difference between these two procedures in terms of weight loss and long-term complications despite some assertions to the contrary (Summary box 64.3).

### RESULTS

When discussing results of bariatric surgery there is an immediate problem in defining success. Traditionally it has been considered as losing at least 50 per cent of the excess weight in the first 12–24 months. The excess weight of a patient is their current weight minus their ideal body weight (at BMI 25 kg/m²). For a given procedure that removes say 50 per cent of excess weight, the higher the initial BMI of the patient the more weight is removed but the patient may still be considerably overweight after surgery compared to a lower BMI patient. Furthermore, many comorbidities are improved with only 10–20 per cent of excess weight loss thus the end point of removing as much weight as possible may not always be necessary from a health and longevity point of view. Other outcomes such as improved quality of life may also be as important. In general terms, however, most surgeons strive for an effective operation which is usually perceived as reducing as much weight as possible for the given risk of the procedure. In addition, it should also resolve or ameliorate any of the comorbidities which are linked to obesity (Table 64.1). Table 64.7 shows the usual outcomes for bariatric procedures.

While there is a spectrum of weight loss results between the various procedures there is also a variation in weight loss for each individual procedure which is usually a function of patient selection and postoperative follow up. For example, restrictive procedures are notorious for good early results but as time goes by the patient learns to cheat more effectively, eats more soft calories and becomes complacent about exercise. This results in weight regain which is always difficult to manage and in some cases will result in revisional surgery which is always more risky than a primary procedure. In addition, patients will often ‘move
the goal posts’ wanting a better result than the surgery promises. Thus, a clear understanding of the end point of surgery must be agreed before embarking on any procedure, i.e. amount of weight loss or resolution of comorbidities or, usually, a combination of both. If this is written down and agreed preoperatively this avoids misunderstandings postoperatively.

It behoves the surgeon to get the operation right the first time for an individual patient after a thorough understanding of what risks they are prepared to take for a particular outcome. This will vary from patient to patient. Those patients who are very risk averse, often young with young children, will understandably often want an operation with the least postoperative mortality even though it may not result in as much weight loss as another more risky procedure. Conversely, a patient without children who is older and much heavier may be keen to undergo a more risky procedure to maximise their weight loss. It is a matter of considerable judgement on both the patient and surgeon’s part to decide what is the most suitable procedure for a given patient. Discussion at a bariatric MDT is always desirable in order that every member of the bariatric team has a chance to express their views about the suitability of any particular procedure for the patient in question.

**COMPLICATIONS**

Carrying out surgery in obese patients generally is more risky than surgery in lean patients no matter what type of surgery is contemplated. Obese patients are more likely to suffer from cardiorespiratory comorbidities which increase surgical complications. Furthermore, they are often hypercoagulable with an increased risk of deep-vein thrombosis and pulmonary embolism. Most of the general risks of surgery, such as bleeding and infection, are also more likely to occur. The specific risks in relation to the actual surgical procedure will vary from procedure to procedure and are listed in Table 64.8.

Perioperative mortality should be minimal but is higher in those patients with the most severe comorbidities. Severe unstable cardiovascular disease is an absolute contraindication to bariatric surgery. Super-obese (BMI >50 kg/m²) males also have a higher risk of perioperative mortality as well as patients with a past history of pulmonary embolism. For the latter a prophylactic

---

**Figure 64.3** Gastric bypass.

**Figure 64.4** (a) Standard biliopancreatic diversion (BPD); (b) BPD with duodenal switch variation.
of effectiveness. The bariatric surgeon of the future will be doing different procedures from those of today, more likely with an array of procedures according to patient needs. The diabetic patient with a BMI between 30 and 34 kg/m² is likely to be a candidate for some form of metabolic surgery when the results from studies in these patients become available. Some of the surgical modalities used may be neuromodulation using gastric-implanted electrodes, vagal blocking using electrodes around the abdominal vagus, endoscopically placed intraluminal sleeves, endoscopic gastric restriction procedures as well as improvements in the current operations, especially involving less abdominal wall trauma by using single incision and transvaginal approaches. Careful evaluation will determine their place in the armamentarium for managing obesity and related metabolic conditions (Summary box 64.5).

**SUMMARY**

Bariatric surgery is the only effective long-term treatment for morbid obesity. Evidence for its initial and medium-term success is overwhelming. Extension of the principles of surgery for obesity to other metabolic conditions, especially type II diabetes mellitus, will increase its usage. Newer techniques for performing this type of surgery promise to offer less complications, less invasive surgery and better outcomes.

INTRODUCTION

The liver is the largest organ in the body, weighing 1.5 kg in the average 70-kg man. The liver parenchyma is entirely covered by a thin capsule and by visceral peritoneum on all but the posterior surface of the liver, termed the 'bare area'. The liver is divided into a large right lobe, which constitutes three-quarters of the liver parenchyma, and a smaller left lobe.

ANATOMY OF THE LIVER

Ligaments and peritoneal reflections

The liver is fixed in the right upper quadrant by peritoneal reflections that form ligaments. On the superior surface of the left lobe is the left triangular ligament. Dividing the anterior and posterior folds of this ligament allows the left lobe to be mobilised from the diaphragm and the left lateral wall of the inferior vena cava (IVC) to be exposed. The right triangular ligament fixes the entire right lobe of the liver to the undersurface of the right hemidiaphragm. Division of this ligament allows the liver to be mobilised from under the diaphragm and rotated to the left. Another major supporting structure is the falciform ligament (remnant of the umbilical vein), which runs from the umbilicus to the liver between the right and left lobes, passing into the interlobar fissure. Division of the superior leaves of the falciform ligament allows exposure of the suprahepatic IVC, lying within a thin sheath of fibrous tissue. The final peritoneal reflection is between the stomach and the liver. This lesser omentum is often thin and fragile, but contains the hilar structures in its free edge.

Liver blood supply

The blood supply to the liver is unique, 80 per cent being derived from the portal vein and 20 per cent from the hepatic artery. The arterial blood supply in most individuals is derived from the coeliac trunk of the aorta, where the hepatic artery arises along with the splenic artery. After supplying the gastroduodenal artery, it branches at a very variable level to produce the right and left hepatic arteries. The right artery supplies the majority of the liver parenchyma and is therefore the larger of the two arteries. There are many anatomical variations, knowledge of which is essential for safe surgery on the liver. The blood supply to the right lobe of the liver may be partly or completely supplied by a right hepatic artery arising from the superior mesenteric artery. This vessel passes posterior to the uncinate process and head of the pancreas, and runs to the liver on the posterior wall of the bile duct. Similarly, the arterial blood supply to the left lobe of the liver may be derived from the coeliac trunk via its left gastric branch. This vessel runs between the lesser curve of the stomach and the left lobe of the liver in the lesser omentum (Figure 65.1).

Structures in the hilum of the liver

The porta hepatis, a transverse fissure on the visceral surface of the liver, is the hilum of the liver. The hepatic artery, portal vein and bile duct are present within the free edge of the lesser omentum or the ‘hepatoduodenal ligament’ and together with nerves and lymphatics enter the liver at the porta hepatis. To expose these structures requires division of the overlying peritoneum followed by the division of small vessels and the lymphatic plexus. The usual anatomical relationship of these structures is for the bile duct to be within the free edge, the hepatic artery to be above and medial, and the portal vein to lie posteriorly. Within this ligament, the common hepatic duct is joined by the cystic duct at a varying level to form the common bile duct. The common hepatic artery branches at a variable level within the ligament to form two, or often three, main arterial branches to the liver. The right hepatic artery crosses the bile duct either anteriorly or posteriorly before giving rise to the cystic artery (see Figure 67.1 in Chapter 67). Multiple small hepatic arterial branches provide blood to the bile duct, principally from the right hepatic artery. The portal vein arises from the confluence of the splenic vein and the superior mesenteric vein behind the neck of the pancreas. It has some important tributaries, including the left gastric vein which joins just above the pancreas.

10/09/2012   11:51

Division of structures at the hilum

At the hilum, the major structures are divided into right and left branches. The right and left hepatic ducts arise from the hepatic parenchyma and join to form the common hepatic duct. The left duct has a longer extrahepatic course of approximately 2 cm. Once within the liver parenchyma, the duct accompanies the branches of the hepatic artery and portal vein within a fibrous sheath. The portal vein often gives off two large branches to the right lobe, which are usually outside the liver for a short length, before giving a left portal vein branch that runs behind the left hepatic duct.

Venous drainage of the liver

The venous drainage of the liver is via the hepatic veins into the IVC. The vena cava lies within a groove in the posterior wall of the liver. Above the liver, it immediately penetrates the diaphragm to join the right atrium, whereas below the liver parenchyma, there is a short length of vessel before the insertion of the renal veins. The inferior hepatic veins are short vessels that pass directly between the liver parenchyma and the anterior wall of the IVC. The major venous drainage is through three large veins that join the IVC immediately below the diaphragm. Outside the liver, these vessels are surrounded by a thin fibrous layer. The right hepatic vein can be exposed fully outside the liver, but the middle and left veins usually join within the liver parenchyma. The right kidney and adrenal gland lie immediately adjacent to the retrohepatic IVC. The right adrenal vein drains into the IVC at this level, usually via one main branch. The IVC can be mobilised fully from the retroperitoneal tissues and, in the healthy state, there are no large vessels in this tissue plane.

SEGMENTAL ANATOMY OF THE LIVER

Understanding the internal anatomy of the liver has greatly facilitated safe liver surgery. Couinaud, a French anatomist, described the liver as being divided into eight segments (Figure 65.2). Each of these segments can be considered as a functional

Figure 65.1 Hepatic angiography/conventional arterial anatomy. Arterial (a) and venous (b) phase of a selective hepatic angiogram. The hepatic artery usually arises from the coeliac trunk, along with the splenic artery, and gives rise to the gastroduodenal artery before dividing into the right and left hepatic arteries. The portal vein forms from the superior mesenteric and splenic veins, and divides into right and left branches in the hilum of the liver.

Figure 65.2 (a) The ‘surgical’ labels of the liver compared with the usual anatomical division into right and left lobes by the falciform ligament. (b) Segments of the liver (after Couinaud). IVC, inferior vena cava; LHV, left hepatic vein; LT, ligamentum teres; MHV, middle hepatic vein; RHV, right hepatic vein.
unit, with a branch of the hepatic artery, portal vein and bile duct, and drained by a branch of the hepatic vein. The overall anatomy of the liver is divided into a functional right and left ‘unit’ along the line between the gall bladder fossa and the middle hepatic vein (Cantlie’s line). Liver segments (V–VIII), to the right of this line, are supplied by the right hepatic artery and the right branch of the portal vein, and drains bile via the right hepatic duct. To the left of this line (segments I–IV), functionally, is the left liver, which is supplied by the left branch of the hepatic artery and the left portal vein branch, and drains bile via the left hepatic duct (Summary box 65.1).

Summary box 65.1
Liver anatomy

- There are two anatomical lobes with separate blood supply, bile duct and venous drainage
- Dual blood supply (20 per cent hepatic artery and 80 per cent portal vein)
- The liver regenerates fully after partial resection
- Resection is based on anatomical lines to preserve maximal functioning liver

The hepatic lobules
The functional units within the liver segments are the liver lobules. These comprise plates of liver cells separated by the hepatic sinusoids, large, thin-walled venous channels that carry blood to the central vein, a tributary of the hepatic vein, from the portal tracts, which contain branches of the hepatic artery and portal vein. During passage through the sinusoids, the many functions of the liver take place, including bile formation, which is channelled in an opposite direction to the blood flow to drain via the bile duct tributaries within the portal tracts.

Embryology
The liver is a foregut structure and forms as a small endodermal bud early in gestation. The cell population is bipotential, and cells may develop into hepatocytes or intrahepatic ductal cells. The liver endothelium is derived from the vitelline and umbilical veins, which merge with the endodermal bud to form the liver sinusoids. The supporting connective tissue, haemopoietic cells, and Kupffer cells are derived from the mesoderm of the septum transversum which is a mass of mesenchymal connective tissue.

ACUTE AND CHRONIC LIVER DISEASE

Liver function and tests
Adequate liver function is essential to survival; humans will survive for only 24–48 hours in the anhepatic state despite full supportive therapy. The liver is central to many key metabolic pathways (Summary box 65.2).

An awareness of the currently available liver function tests and their significance is essential (Table 65.1).

Bilirubin is synthesised in the liver and excreted in bile. Increased levels may be associated with increased haemoglobin breakdown, hepatocellular dysfunction resulting in impaired bilirubin transport and excretion, or biliary obstruction. In patients with known parenchymal liver disease, progressive elevation of bilirubin in the absence of a secondary complication suggests deterioration in liver function. The serum alkaline phosphatase is particularly elevated with cholestatic liver disease or biliary obstruction. The transaminase levels (aspartate transaminase (AST) and alanine transaminase (ALT)) reflect acute hepatocellular damage, as does the gamma-glutamyl transpeptidase (GGT) level, which may be used to detect the liver injury associated with acute alcohol ingestion. The synthetic functions of the liver are reflected in the ability to synthesise proteins (albumin level) and clotting factors (prothrombin time). The standard method of monitoring liver function in patients with chronic liver disease is serial measurement of bilirubin, albumin and prothrombin time.

Clinical signs of impaired liver function
These signs depend on the severity of dysfunction and whether it is acute or chronic.

Acute liver failure
Causes of acute liver failure
In the early stages, there may be no objective signs, but with severe dysfunction the onset of clinical jaundice may be associated with neurological signs of liver failure (hepatic encephalopathy), consisting of a liver flap, drowsiness, confusion and, eventually, coma (Summary box 65.3).

Treatment of acute liver failure
The overall mortality from acute liver failure is approximately 50 per cent, even with the best supportive therapy (Summary box 65.4).

Summary box 65.2
Main functions of the liver

- Maintaining core body temperature
- pH balance and correction of lactic acidosis
- Synthesis of clotting factors
- Glucose metabolism, glycolysis and gluconeogenesis
- Urea formation from protein catabolism
- Bilirubin formation from haemoglobin degradation
- Drug and hormone metabolism and excretion
- Removal of gut endotoxins and foreign antigens

Table 65.1 Routinely available tests of liver function.

Summary box 65.3
Liver anatomy

- There are two anatomical lobes with separate blood supply, bile duct and venous drainage
- Dual blood supply (20 per cent hepatic artery and 80 per cent portal vein)
- The liver regenerates fully after partial resection
- Resection is based on anatomical lines to preserve maximal functioning liver

**Criteria for orthotopic liver transplantation in acute liver failure**

- Paracetamol induced
  - pH < 7.30 (irrespective of grade of encephalopathy)
  - or prothrombin time (PT) > 100 s + serum creatinine > 300 μmol/L + grade 3 or 4 encephalopathy.
- Non-paracetamol induced (irrespective of encephalopathy)
  - PT > 100 s
  - or any three of the following:
    - Age < 10 years or > 40 years
    - Aetiology non-A, non-B, halothane or idiosyncratic drug reaction
    - More than 7 days’ jaundice before encephalopathy
    - PT > 50 s
    - Bilirubin > 300 μmol/L

**Chronic liver disease**

Lethargy and weakness are common features irrespective of the underlying cause. This often precedes clinical jaundice, which indicates the liver’s inability to metabolise bilirubin. The serum bilirubin level reflects the severity of the underlying liver disease. Progressive deterioration in liver function is associated with a hyperdynamic circulation involving a high cardiac output, large pulse volume, low blood pressure and flushed warm extremities. Fever is a common feature, which may be related to underlying inflammation and cytokine release from the diseased liver or may be due to bacterial infection, to which patients with chronic liver disease are predisposed. Skin changes may be evident, including spider naevi*, cutaneous vascular abnormalities that blanch on pressure, palmar erythema and white nails (leuconychia). Endocrine abnormalities are responsible for hypogonadism and gynaecomastia. The mental derangement associated with chronic liver disease is termed ‘hepatic encephalopathy’. This is associated with memory impairment, confusion, personality changes, altered sleep patterns and slow, slurred speech. The most useful clinical sign is the flapping tremor demonstrated by asking the patient to extend his or her arms and hyperextend the wrist joint. Abdominal distension due to ascites is a common late feature. This may be suggested clinically by the demonstration of a fluid thrill or shifting dullness. Protein catabolism produces loss of muscle bulk and wasting, and a coagulation defect is suggested by the presence of skin bruising. A patient with the typical features of end-stage chronic liver disease is shown in Figure 65.3 (Summary box 65.6).

**Classifying the severity of chronic liver disease**

Two prognostic models commonly used to assess the severity of chronic liver disease and perioperative risk are the Child–Turcotte–Pugh (CTP) Classification and the Model for End-Stage Liver Disease (MELD) score. The CTP classification has been modified from the original Child classification which was developed to predict mortality following shunt surgery in cirrhotic patients. The CTP classification is included in Table 65.2. The MELD score was originally developed to predict short-term
prognosis in patients undergoing transjugular intrahepatic portosystemic shunt insertion, but has now been adopted to prioritise patients awaiting liver transplantation. In the MELD model, the survival probability of patients with end-stage liver disease is computed based on the patient’s international normalised ratio (INR), serum bilirubin and serum creatinine.

**Table 65.2** Child–Turcotte–Pugh (CTP) classification of hepatocellular function in cirrhosis.

**IMAGING THE LIVER**

The major advances that have taken place over recent years in surgical approaches to the liver and the enormous improvement in the safety of liver surgery are a result of the careful individualised planning of surgery achieved through improvements in preoperative imaging. The ideal choice of imaging modality is determined by the likely liver pathology and the locally available equipment and radiological expertise (Table 65.3).

**Ultrasound**

This is the first-line test owing to its safety and wide availability. It is entirely operator dependent. It is useful for determining bile duct dilatation, the presence of gallstones (Figure 65.4) and the presence of liver tumours. Ultrasound can reliably differentiate between cystic and solid masses. Doppler ultrasound allows flow in the hepatic artery, portal vein and hepatic veins to be assessed. In some countries, it is used as a screening test for the development of primary liver cancers in a high-risk population. Ultrasound is useful in guiding the percutaneous biopsy of a liver lesion, and aspiration of liver abscesses.

**Computed tomography**

Modern computed tomography (CT) technology has increased the accuracy of diagnosis and staging of liver lesions, and contrast-enhanced computed tomography is currently the most widely used and best validated modality for liver imaging. This provides fine detail of liver lesions down to less than 1 cm in diameter and gives information on their nature (Figure 65.5). Oral contrast enhancement allows visualisation of the stomach and duodenum in relation to the liver hilum. The early arterial phase of the intravenous contrast vascular enhancement is particularly useful for detecting small primary liver cancers, owing to their preferential arterial blood supply. The venous phase...
maps the branches of the portal vein within the liver and the drainage via the hepatic veins. Inflammatory liver lesions often exhibit rim enhancement with intravenous contrast, whereas the common haemangioma characteristically shows late venous enhancement. The density of any liver lesion can be measured, which can be useful in establishing the presence of a cystic lesion. CT has high accuracy in determining the stage, and high sensitivity and specificity in determining resectability of liver tumours. Local and distant metastases can also be detected, although peritoneal metastases are often missed on CT.

**Magnetic resonance imaging**

Magnetic resonance imaging (MRI) (Figure 65.6) would appear to be as effective an imaging modality as CT in the majority of patients with liver disease. It does, however, offer several advantages. First, the use of iodine-containing intravenous contrast agents is precluded in many patients because of a history of allergy. These patients should be offered MRI rather than contrast CT. Second, magnetic resonance cholangiopancreatography (MRCP) provides excellent quality, non-invasive imaging of the biliary tract, the accuracy of which is comparable to direct cholangiography by endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC). Complementary to CT, MRI and MRCP are the best imaging modalities for suspected hilar cholangiocarcinoma. It is useful for diagnostic questions when ERCP has failed or is impossible due to previous surgery. Magnetic resonance angiography (MRA) similarly provides high-quality images of the hepatic artery and portal vein, without the need for arterial cannulation. It is used as an alternative to selective hepatic angiography for diagnosis. It is particularly useful in patients with chronic liver disease and coagulopathy in whom the patency of the portal vein and its branches is in question.

**Endoscopic retrograde cholangiopancreatography**

ERCP (Figure 65.7a) is performed in patients with obstructive jaundice when an endoscopic intervention is anticipated based on imaging (endoscopic removal of common bile duct...
Eugen (János) Alexander Pólya, 1876–1944, surgeon, St Stephen’s Hospital, Budapest, Hungary.

(CBD) stones, biliary drainage in a septic patient or insertion of a biliary tract stent). A preoperative check of coagulation is essential, along with prophylactic antibiotics and an explanation of the main complications, which include pancreatitis, cholangitis and bleeding or perforation of the duodenum related to sphincterotomy.

**Percutaneous transhepatic cholangiography**

PTC is indicated where endoscopic cholangiography has failed or is impossible, e.g. in patients with previous pancreat-oduodenectomy or Pólya gastrectomy. It is often required in patients with hilar bile duct tumours to guide external drainage of the obstructed bile ducts to relieve jaundice, evaluate resectability and to direct stent insertion (Figure 65.7b).

**Angiography**

Selective visceral angiography (see Figure 65.1) can provide accurate assessment of vascular involvement by tumour, but the technique is invasive. CT and MRA have evolved and their diagnostic accuracy is comparable to conventional angiography which is nowadays mostly employed for therapeutic intervention only. Therapeutic interventions include the occlusion of arteriovenous malformations, the embolisation of bleeding sites in the liver and the treatment of liver tumours (transarterial embolisation, TAE).

**Nuclear medicine scanning**

Radioisotope scanning can provide important diagnostic information. HIDA is a technetium-99m (99mTc)-labelled radiouclide that is administered intravenously, removed from the circulation by the liver, processed by hepatocytes and excreted in the bile. Imaging under a gamma camera allows its uptake and excretion to be monitored in real time. This is a useful non-invasive test when there is suspicion of bile leak.

18F-2-fluoro-2-deoxy-D-glucose positron emission tomography (FDG–PET) depends on the avid uptake of glucose by cancerous tissue in comparison with benign or inflammatory tissue. Deoxyglucose is labelled with the positron emitter fluorine-18 (18FDG), and this is administered to the patient prior to imaging by positron emission tomography (PET). A three-dimensional image of the whole body is obtained, highlighting areas of increased glucose metabolism (Figure 65.8). PET or

**Figure 65.7** (a) Endoscopic retrograde cholangiopancreatography demonstrating the biliary tract with multiple stones in the distal common bile duct. (b) Percutaneous transhepatic cholangiography. Some contrast has extravasated at the site of hepatic puncture of the percutaneously placed needle, but the biliary tract is clearly demonstrated and shows the multiple strictures typical of primary sclerosing cholangitis.

**Figure 65.8** Whole-body positron emission tomography in a patient with colorectal metastases showing widespread areas of 18F-2-fluoro-2-deoxy-D-glucose uptake, indicating the sites of metastatic disease.
integrated PET-CT can be useful in the diagnosis of regional lymph node metastases and distant metastases particularly when CT and MRI findings are equivocal.

**Laparoscopy**

Laparoscopy is useful for the staging of hepatopancreatobiliary cancers particularly primary liver and biliary tract cancers. Lesions overlooked by conventional imaging are mainly peri toneal metastases and superficial liver tumours. These lesions can be detected at laparoscopy, thus avoiding an unnecessary laparotomy. A liver biopsy to confirm or exclude chronic liver disease can also be performed during laparoscopy.

**LIVER TRAUMA**

**General**

The liver is the second most common organ injured in abdominal trauma. Liver trauma can be divided into blunt and penetrating injuries. Blunt injury produces contusion, laceration and avulsion injuries to the liver, often in association with splenic, mesenteric or renal injury. Penetrating injuries, such as stab and gunshot wounds, are often associated with chest or pericardial involvement (Summary box 65.7). Blunt injuries are more common and have a higher mortality than penetrating injuries.

**Diagnosis of liver injury**

The liver is an extremely well-vascularised organ, and blood loss is therefore the major early complication of liver injuries. Clinical suspicion of a possible liver injury is essential, as a laparotomy by an inexperienced surgeon with inadequate preparation preoperatively is doomed to failure. All lower chest and upper abdominal stab wounds should be suspect, especially if considerable blood volume replacement has been required. Similarly, severe crushing injuries to the lower chest or upper abdomen often combine rib fractures, haemothorax and damage to the spleen and/or liver. Focused assessment sonography in trauma (FAST) performed in the emergency room by an experienced operator can reliably diagnose free intraperitoneal fluid. Patients with free intraperitoneal fluid on FAST and haemodynamic instability, and patients with a penetrating wound will require a laparotomy and/or thoracotomy once active resuscitation is under way. Owing to the opportunity for massive ongoing blood loss and the rapid development of a coagulopathy, the patient should be directly transferred to the operating theatre while blood products are obtained and volume replacement is taking place. Patients who are haemodynamically stable should have a contrast-enhanced CT scan of the chest and abdomen as the next step. This will demonstrate evidence of parenchymal damage to the liver or spleen, as well as associated traumatic injuries to their feeding vessels. Free fluid can also be clearly established. The chest scan will help to exclude injuries to the great vessels and demonstrate damage to the lung parenchyma. Additional investigations that may be of value include diagnostic peritoneal lavage, which can confirm the presence of haemoperitoneum, but this is rarely performed nowadays due to increased use of FAST and CT.

**Initial management of liver injuries**

**Penetrating**

The initial management is maintenance of airway patency, breathing and circulation (ABC) following the principles of advanced trauma life support (ATLS). Peripheral venous access is gained with two large-bore cannulae and blood sent for cross-match of ten units of blood, full blood count, urea and electrolytes, liver function tests, clotting screen, glucose and amylase. Initial volume replacement should be with colloid or O-negative blood if necessary. Arterial blood gases should be obtained and the patient intubated and ventilated if the gas exchange is inadequate. Intercostal chest drains should be inserted if associated pneumothorax or haemothorax is suspected. Once initial resuscitation has commenced, the patient should be transferred to the operating theatre, with further resuscitation performed on the operating table. The necessity for fresh-frozen plasma and cryoprecipitate should be discussed with the blood transfusion service immediately the patient arrives, as these patients rapidly develop irreversible coagulopathies due to a lack of fibrinogen and clotting factors. Standard coagulation profiles are inadequate to evaluate this acute loss of clotting factors, and factors should be given empirically, aided by the results of thromboelastography (TEG), if available (Figure 65.9). A contrast CT prior to laparotomy should be considered if the patient is haemodynamically stable.

**Blunt trauma**

With blunt injuries, the initial plan for resuscitation and management is as outlined above for penetrating injuries. Patients who are haemodynamically unstable will require an immediate laparotomy. For the patient who is haemodynamically stable, imaging by CT should be performed to further evaluate the nature of the injury. Most patients with blunt liver injury who are haemodynamically stable can be managed conservatively. The indication for discontinuing conservative treatment for blunt liver trauma would be development of haemodynamic instability, evidence of ongoing blood loss despite correction of any underlying coagulopathy and the development of signs of generalised peritonitis. Interventional radiology has an
important role in management of liver trauma and embolisation to control hepatic artery bleeding is safe and effective in a stable patient with no evidence of hollow viscus perforation.

The surgical approach to liver trauma

Good access is vital. A ‘rooftop’ incision with midline extension to the xiphisternum and retraction of the costal margins gives excellent access to the liver and spleen. If the laparotomy has been started through a midline incision, a transverse lateral extension to the right can be added to improve access to the liver. Compression of the liver with packs and correction of coagulopathy, if present, will control most of the active bleeding. If bleeding persists, further control can be achieved by vascular inflow occlusion by placing an atraumatic clamp across the foramen of Winslow (the Pringle manoeuvre). A stab incision in the liver can be sutured with a fine absorbable monofilament suture. Lacerations to the hepatic artery should be identified and repaired with 5/0 Prolene. Inflow occlusion facilitates suturing of lacerations and vessels.

If bleeding persists despite inflow occlusion, consider major hepatic vein or IVC injuries, and also look for aberrant arteries. Injuries should be repaired with 6/0 Prolene. If unavoidable, the hepatic vein or IVC may require resection. Late vascular complications of the liver may require resection. Late vascular complications include hepatic artery aneurysm and arteriovenous or arterio-biliary fistulae (Figure 65.10). These are best treated nonsurgically by a specialist hepatobilical interventional radiologist. The feeding vessel can be embolised transarterially.

Hepatic failure may occur following extensive liver trauma. This will usually reverse with conservative supportive treatment if the blood supply and biliary drainage of the liver are intact (Summary box 65.8).

Abscesses may form as a result of secondary infection of an area of parenchymal ischaemia, especially after penetrating trauma. Treatment is with systemic antibiotics and aspiration under ultrasound guidance once the necrotic tissue has liquefied. Bile collections require aspiration under ultrasound guidance or percutaneous transhepatic drainage or endoprosthesis insertion. If this fails to control the fistula, the affected portion of the liver may require resection. Late vascular complications include hepatic artery aneurysm and arteriovenous or arterio-biliary fistulae (Figure 65.10). These are best treated nonsurgically by a specialist hepatobilical interventional radiologist. The feeding vessel can be embolised transarterially.

A subcapsular or intrahepatic haematoma requires no specific intervention and should be allowed to resolve spontaneously. Abscesses may form as a result of secondary infection of an area of parenchymal ischaemia, especially after penetrating trauma. Treatment is with systemic antibiotics and aspiration under ultrasound guidance once the necrotic tissue has liquefied. Bile collections require aspiration under ultrasound guidance or percutaneous transhepatic drainage or endoprosthesis insertion. If this fails to control the fistula, the affected portion of the liver may require resection. Late vascular complications include hepatic artery aneurysm and arteriovenous or arterio-biliary fistulae (Figure 65.10). These are best treated nonsurgically by a specialist hepatobilical interventional radiologist. The feeding vessel can be embolised transarterially.

Hepatic failure may occur following extensive liver trauma. This will usually reverse with conservative supportive treatment if the blood supply and biliary drainage of the liver are intact (Summary box 65.8).
veno-occlusive disease or occlusion of the main hepatic veins (Budd–Chiari syndrome (BCS)). As portal hypertension per se produces no symptoms, it is usually diagnosed following presentation with decompensated chronic liver disease and encephalopathy, ascites or variceal bleeding.

Management of bleeding varices

General resuscitation

Varices usually present with the acute onset of a large-volume haematemesis, the lower oesophagus being the most common site for variceal bleeding. The diagnosis may be suspected if the patient is known to have liver cirrhosis, but it needs to be confirmed following initial resuscitation of the patient. Variceal haemorrhage is a medical emergency. Patients with massive haemorrhage should be admitted to the intensive treatment unit (ITU). Venous access should be obtained through two large bore peripheral cannulae. Colloids should be administered while adequate blood is obtained (initially ten units). Liver function tests will reveal underlying liver disease, and a coagulation profile will reveal any underlying coagulopathy. Blood volume should be replaced with colloids, plasma expanders and blood transfusions. Hypervolaemia should be avoided since this may increase portal pressure and exacerbate the bleeding. Vitamin K is administered (10 mg intravenously (i.v.)), but correction of a coagulopathy will require the administration of fresh-frozen plasma (FFP). An associated thrombocytopenia is usually secondary to hypersplenism due to cirrhosis and is treated if the platelet count falls below 50 × 10^9/L. Treatment with a splanchic vasoconstrictor should be started. Administration of a prophylactic antibiotic is recommended to prevent or treat associated bacterial infection. As soon as the patient is haemodynamically stabilised an upper gastrointestinal endoscopy should be performed to establish the diagnosis because 50 per cent of patients with portal hypertension will have a non-variceal source of bleeding. Variceal bleeding is often associated with hepatic encephalopathy and, in these circumstances and when bleeding is severe, endotracheal intubation will be required for endoscopy. Bronchial aspiration is a frequent complication of variceal bleeding (Summary box 65.9).

Long-term outcome of liver trauma

The capacity of the liver to recover from extensive trauma is remarkable, and parenchymal regeneration occurs rapidly. Late complications are rare, but the development of biliary tract strictures many years after recovery from liver trauma has been reported. The treatment depends on the mode of presentation and the extent and site of stricturing. A segmental or lobar stricture, associated with atrophy of the corresponding area of liver parenchyma and compensatory hypertrophy of the other liver lobe, may be treated expectantly. A dominant extrahepatic bile duct stricture associated with obstructive jaundice may be treated initially with endobiliary balloon dilatation or stenting, but will usually require surgical correction using a Roux-en-Y hepatodesochojejunostomy.

PORTAL HYPERTENSION

An elevation in portal pressure is most commonly found in the presence of liver cirrhosis, although it may be present in patients with extrahepatic portal vein occlusion, extrahepatic
of air and retracted to the gastric fundus, where the varices at the oesophagogastric junction are tamponaded by the subsequent inflation of the oesophageal balloon to a pressure of 40 mmHg. The two remaining channels allow gastric and oesophageal aspiration. An x-ray is used to confirm the position of the tube. The balloons should be temporarily deflated after 12 hours to prevent pressure necrosis of the oesophagus. Aspiration pneumonia and oesophageal ulceration are other complications. Balloon tamponade is very effective in stopping bleeding and once the patient is stabilised, a more definitive treatment can be carried out.

**Drug treatment for variceal bleeding**

Splanchnic vasoconstrictors reduce portal flow and pressure and should be started early in the treatment of variceal haemorrhage. Vasopressin is a potent vasoconstrictor and has been the most extensively used drug for the initial control of variceal haemorrhage, but it can cause myocardial ischaemia, arrhythmias, mesenteric and limb ischaemia. Terlipressin, somatostatin and octreotide are safer than vasopressin and equally effective.

**Endoscopic treatment of varices**

Treatment with a vasoconstrictor (see above) combined with endoscopic therapy is the standard medical treatment for acute variceal bleeding. The two most commonly used endoscopic techniques are endoscopic band ligation which involves placing a constricting rubber band at the base of the varix, and endoscopic sclerotherapy which involves injection of a sclerosant, such as polidocanol (1–3 per cent) or ethanolamine (5 per cent), into or around the varix. Although both are effective in controlling the bleed, banding is significantly better in preventing rebleeding and is the preferred option. The majority of variceal bleeds will respond to a single course.

**Transjugular intrahepatic portosystemic stent shunts**

The emergency management of variceal haemorrhage has been revolutionised by the introduction of transjugular intrahepatic portosystemic stent shunts (TIPSS) in 1988. Over a short period, it has become the main treatment of variceal haemorrhage that has not responded to drug treatment and endoscopic therapy. The shunts are inserted under local anaesthetic, analgesia and sedation using fluoroscopic guidance and ultrasonography. Via the internal jugular vein and SVC, a guidewire is inserted into a hepatic vein and through the hepatic parenchyma into a branch of the portal vein. The track through the parenchyma is then dilated with a balloon catheter to allow insertion of a metallic stent, which is expanded once a satisfactory position is achieved (Figure 65.12) to form a channel between systemic and portal venous systems. A satisfactory drop in portal venous pressure is usually associated with good control of the variceal haemorrhage. The main early complication of this technique is perforation of the liver capsule, which can be associated with fatal intraperitoneal haemorrhage. TIPSS occlusion may result in further variceal haemorrhage and occurs more commonly in patients with well-compensated liver disease and good synthetic function. Post-shunt encephalopathy is the confusional state caused by the portal blood bypassing the detoxification of the liver. It occurs in about 40 per cent of patients, a similar incidence to that found after surgical shunts. If severe, the lumen of the TIPSS can be reduced by insertion of a smaller stent. The
main contraindication to TIPSS is portal vein occlusion. The main long-term complication of TIPSS is stenosis of the shunt, which is common (approximately 50 per cent at one year) and may present as further variceal haemorrhage.

Surgical shunts for variceal haemorrhage
The increasing availability of liver transplantation and TIPSS has greatly reduced the indications for surgical shunts. It is rarely considered for the acute management of variceal haemorrhage, as the morbidity and mortality in these circumstances are high. The main current indication for a surgical shunt is a patient with Child’s grade A cirrhosis, in whom the initial bleed has been controlled by sclerotherapy. Long-term β-blocker therapy and chronic sclerotherapy or banding are the main alternatives.

Surgical shunts are an effective method of preventing rebleeding from oesophageal or gastric varices, as they reduce the pressure in the portal circulation by diverting the blood into the low-pressure systemic circulation. Shunts may be divided into selective (e.g. splenorenal) and non-selective (e.g. portocaval), the former attempting to preserve blood flow to the liver while decompressing the left side of the portal circulation responsible for giving rise to the oesophageal and gastric varices. Selective shunts may be associated with a lower incidence of portal systemic encephalopathy (PSE), a confusional state commonly found in patients with chronic liver disease who have undergone radiological or surgical portosystemic shunts. The different types of surgical shunt are shown in Figure 65.13. There is no evidence that prophylactic shunting is beneficial in patients with varices that have not bled.

Oesophageal stapled transection
This technique for the management of bleeding oesophageal varices uses the circular stapling device for stapling and resecting a doughnut ring of the lower oesophagus. As with surgical shunts in the acute situation, it was associated with a high perioperative mortality and has been largely abandoned in centres where TIPSS is available.

Management of recurrent variceal bleeds secondary to splenic or portal vein thrombosis
Treatment is by splenectomy and gastro-oesophageal devascularisation, in which the blood supply to the greater and lesser curve of the stomach and lower oesophagus is divided. Splenic vein thrombosis may be seen secondary to chronic pancreatitis, and portal vein thrombosis is a common late complication of liver cirrhosis.

Variceal bleeding and orthotopic liver transplantation
Liver transplantation is the only therapy which will treat portal hypertension and the underlying liver disease. The management of variceal bleeding should always take into account the possibility of liver transplantation when this is available. Previous surgical shunts greatly increase the morbidity associated with orthotopic liver transplantation. TIPSS would be the preferred management for bleeds resistant to sclerotherapy, as long as placement is optimal.

Ascites
The accumulation of free peritoneal fluid is a common feature of advanced liver disease independent of the aetiology. The fluid accumulation is usually associated with abdominal discomfort and a dragging sensation. Development is usually insidious. The aetiology of the ascites must be established (Summary box 65.10).

Imaging by CT will confirm the ascites and demonstrate the irregular and shrunken nature of a cirrhotic liver and associated splenomegaly. Intravenous contrast enhancement will allow abdominal varices to be demonstrated and assess patency of the portal vein, as portal vein thrombosis is a common predisposing
factor to the development of ascites in chronic liver disease. In patients without evidence of liver disease, malignancy is a common cause, and the primary site may also be established on CT. Aspiration of the peritoneal fluid allows the measurement of protein content to determine whether the fluid is an exudate or transudate, and an amylase estimation to exclude pancreatic ascites. Cytology will determine the presence of cancerous cells, and both microscopy and culture will exclude primary bacterial peritonitis and tuberculous peritonitis.

**Treatment of ascites in chronic liver disease**

The initial treatment is to restrict additional salt intake and commence diuretics using either spironolactone or furosemide. This should be combined with advice on avoiding any precipitating factors for impaired liver function, such as alcohol intake in patients with alcoholic cirrhosis. Patients on diuretics should be monitored for the development of hyponatraemia and hypokalaemia (Summary box 65.11).

**Summary box 65.10**

**Determining the cause of ascites**

- Imaging (ultrasound or CT)
  - Irregular cirrhotic liver
  - Portal vein patency
  - Splenomegaly of cirrhosis
- Aspiration
  - Culture and microscopy
  - Protein content
  - Cytology
  - Amylase level

**Summary box 65.11**

**Treatment of ascites in chronic liver disease**

- Salt restriction
- Diuretics
- Abdominal paracentesis
- Peritoneovenous shunting
- Transjugular intrahepatic portosystemic stent shunts (TIPSS)
- Liver transplantation

Abdominal paracentesis

Patients who fail to respond to diuretic treatment may require repeated percutaneous aspiration of large volume of the ascites (abdominal paracentesis), combined with volume replacement using salt-poor or standard human albumin solution, dependent on the serum sodium level. Paracentesis provides only short-term symptomatic relief.

Peritoneovenous shunting

The LeVeen shunt is designed for the relief of ascites due to chronic liver disease. One end of the silastic tube is inserted into the ascites within the peritoneal cavity and the other end is tunnelled subcutaneously to the neck, where it is inserted under direct vision into the internal jugular vein and fed into the SVC. Owing to a one-way valve within the tubing, peritoneal fluid is drawn from the abdomen and drained to the circulation due to the lower pressure in the SVC in comparison with the abdomen during the respiratory cycle. Complications include occlusion, displacement, infection and disseminated intravascular coagulation. In an attempt to prevent the high occlusion rate, a further development was the insertion of a chamber placed over the costal margin to allow digital pressure and evacuation of any debris within the peritoneovenous shunt (Denver shunt). Peritovenous shunts are rarely performed nowadays.

**TIPSS for ascites**

The use of TIPSS for ascites is for symptomatic relief. In patients with intractable ascites, TIPSS is a good alternative to repeated paracentesis, but post-stent encephalopathy is common (about 40 per cent), and the majority of stents will stenose on follow up (approximately 50 per cent by one year).

**Liver transplantation for ascites**

Diuretic-resistant ascites is an indication for liver transplantation if associated with deterioration in liver function (rising bilirubin, dropping albumin, prolonged prothrombin time). The patient’s age, underlying aetiology of liver disease and associated medical problems will be the major factors determining suitability for liver transplantation. In those considered inappropriate for liver transplantation, management is aimed at symptomatic control of ascites.

**CHRONIC LIVER CONDITIONS**

There are several chronic liver conditions, which, although rare, are important to recognise because they require a specific plan for investigation and treatment, and may present mimicking a more common clinical condition (Table 65.4).

**Table 65.4 Important chronic liver conditions.**

LFTs, liver function tests.

**Budd–Chiari syndrome**

This is a condition principally affecting young females, in which the venous drainage of the liver is occluded by hepatic venous thrombosis or obstruction from a venous web. As a result of venous outflow obstruction, the liver becomes acutely congested, with the development of impaired liver function and, subsequently, portal hypertension, ascites and oesophageal varices. In an acute thrombosis, the patient may rapidly progress...
to fulminant liver failure but, in the majority of cases, abdominal discomfort and ascites are the main presenting features. If chronic, the liver progresses to established cirrhosis. The cause of the venous thrombosis needs to be established, and an underlying myeloproliferative disorder or procoagulant state is commonly found, such as anti-thrombin 3, protein C or protein S deficiency. The diagnosis is commonly suspected in a patient presenting with ascites, in whom a CT scan shows a large congested liver (early stage, Figure 65.14) or a small cirrhotic liver in which there is gross enlargement of segment I (the caudate lobe). This feature results from preservation and hypertrophy of the segment with direct venous drainage to the IVC in the face of atrophy of the rest of the liver due to venous obstruction (Figure 65.15). IVC compression or occlusion from the segment I hypertrophy is also a common feature, as is thrombosis of the portal vein. Confirmation of the suspected diagnosis is by hepatic venography via a transjugular approach, which demonstrates occlusion of the hepatic veins and may allow a transjugular biopsy.

Treatment of BCS must be tailored to the individual patient and, in particular, to the stage of disease at presentation. Patients presenting in fulminant liver failure should be considered for liver transplantation, as should those with established cirrhosis and the complications of portal hypertension. Those in whom cirrhosis is not established may be considered for portosystemic shunting by TIPSS, portocaval shunt or mesoatrial shunting. IVC compression may be relieved by the insertion of a retrohepatic expandable metallic stent. If the BCS is treated satisfactorily, the prognosis of this patient group is largely dependent on the underlying aetiology and whether this is amenable to treatment. Patients are usually left on lifelong anticoagulation with warfarin.

**Primary sclerosing cholangitis**

This condition often presents in young adults with mild nonspecific symptoms, and biliary disease is suggested by the finding of abnormal liver function tests. Rarely, the first presentation is with jaundice due to biliary obstruction. The disease process results in progressive fibrous stricturing and obliteration of both the intrahepatic and the extrahepatic bile ducts. Although the aetiology is unknown, a genetic predisposition is likely owing to its association with ulcerative colitis (UC). In patients with primary sclerosing cholangitis (PSC) and UC, the condition usually progresses even if the diseased colon is removed. The diagnosis is principally based on the findings at cholangiography, in which irregular, narrowed bile ducts are demonstrated in both the intrahepatic and the extrahepatic biliary tree (Figure 65.16). If the radiological appearances are equivocal, a liver biopsy is required to demonstrate the fibrous obliteration of the biliary tracts. There is no specific treatment that can reverse the ductal changes, and the patients usually slowly progress to progressive cholestasis and death from liver failure. There is a strong predisposition to cholangiocarcinoma (CCA), and this should be considered in any patient with PSC in whom a new or dominant stricture is demonstrated on cholangiography.

Diagnosis of CCA in PSC is greatly facilitated by biliary brush cytology, as imaging rarely shows evidence of a mass lesion even in patients with advanced CCA. Further, imaging cannot reliably differentiate between inflammatory and malignant biliary strictures. Serum CA 19-9 level may be increased but the sensitivity of CA 19-9 in detecting CCA in PSC is approximately 60 per cent. Patients with good liver function, no dominant strictures and negative biliary cytology may simply be monitored for disease progression. The only useful treatment modality is liver transplantation, which is associated with excellent results if carried out before bile duct cancer has developed. Temporary relief of obstructive jaundice due to a dominant bile duct stricture can be achieved by biliary stenting, although there is considerable risk of cholangitis from the introduction of bacteria to the biliary tract.

**Primary biliary cirrhosis**

As with PSC, the presentation of patients with primary biliary cirrhosis (PBC) is often hidden, with general malaise, lethargy and pruritus prior to the development of clinical jaundice or the finding of abnormal liver function tests. The condition is largely confined to females. Diagnosis is suggested by the finding...
Liver infections

undergoing abdominal ultrasound. Radiological findings to
may be treated by resection of the affected part, although
treatment may be required. Large cysts may be associated with symptoms of abdominal discomfort possibly related to stretching of the overlying liver capsule. Acute pain associated with haemorrhage in the cyst, or may present as right upper quadrant abdominal mass. Aspiration of the cyst contents under radiological guidance provides a sample for culture, microscopy and cytology, and allows the symptomatic response to cyst drainage to be assessed. Aspiration alone is usually associated with cyst and symptom recurrence, in which case more definitive treatment is required. Laparoscopic deroofing is the treatment of choice for large symptomatic cysts and is associated with good long-term symptomatic relief.

Polycystic liver disease
This is a congenital abnormality associated with cyst formation within the liver and often other abdominal organs, principally the pancreas and kidney. Those associated with renal cysts may have autosomal dominant inheritance. The cysts are often asymptomatic and incidental findings on ultrasound. They usually have no effect on organ function and require no specific treatment. Massive polycystic disease of the liver is rare, but can give rise to discomfort or pain. This often responds to treatment with simple analgesics. Severe pain often indicates haemorrhage into a cyst, which may be confirmed by ultrasound or CT scan. Cyst discomfort that is not adequately controlled by oral analgesics may be treated by open or laparoscopic fenestration of the liver cysts, although the results are less favourable than with simple cysts. Ultimately, massive polycystic liver disease may require liver transplantation.

LIVER INFECTIONS

Viral hepatitis
Viral hepatitis is a major world health problem. In addition to the well-recognised acute and chronic liver diseases produced by hepatitis A, B and C, other hepatitis viruses have been isolated, including hepatitis D, which is usually detected only in patients with hepatitis B virus (HBV) infection, and hepatitis E, which produces a self-limiting hepatitis due to faeco-oral spread similar to hepatitis A (Table 65.5).

Hepatitis A presents with anorexia, weakness and general malaise for several weeks prior to the development of clinical jaundice, often accompanied by tenderness on palpation of an enlarged liver. The condition is spread by the faeco-oral route and often spreads rapidly in closed communities. Liver function tests will be compatible with an acute hepatitis, with elevation of bilirubin and transaminases. Diagnosis is confirmed by the antibody titre to hepatitis A. The condition is virtually always self-limiting, although rarely the viral hepatitis can lead to fulminant liver failure. Once the clinical condition resolves, the liver tends to recover fully, with no functional deficit and no long-term sequelae.

Hepatitis B is a more serious condition in most respects than hepatitis A. Although it can also produce an acute self-resolving hepatitis, the virus is often not cleared and produces chronic hepatitis B causing long-term liver damage, with the

development of liver cirrhosis and hepatocellular carcinoma. Therefore, patients may present acutely with malaise, anorexia, abdominal pain and clinical jaundice due to active hepatitis, or at a late stage owing to the complications of cirrhosis, most commonly ascites or variceal bleeding. Treatment for acute hepatitis is antivirals and supportive. In patients with cirrhosis, treatment is initially dictated by the specific complication at presentation (see above under Treatment of ascites in chronic liver disease). In established cirrhosis, liver transplantation may be considered if viral eradication or suppression can be achieved with anti-viral agents (e.g. lamivudine). Without viral suppression, death from reinfection of the transplanted liver is common. The hepatitis virus greatly increases the risk of primary liver cancer, which usually appears at the stage when the liver parenchyma has become cirrhotic. The assessment and management of HBV cirrhosis with hepatocellular carcinoma (HCC) is discussed below under Liver tumours.

Hepatitis C has become one of the most common causes of chronic liver disease worldwide and, in many countries, a large percentage of the population has been exposed; 1 per cent of potential blood donors worldwide are hepatitis C virus (HCV) positive. Transmission is often related back to blood transfusion, and routine screening of blood for HCV has only recently been introduced in many countries. Chronic HCV infection is an important health problem because currently there is no vaccine available to prevent the disease and current anti-viral treatment has limitations. As with hepatitis B, it may present as an acute hepatitis or progress to chronic hepatitis which may lead to development of liver cirrhosis and hepatocellular carcinoma. Chronic hepatitis C infection can remain hidden until the development of cirrhosis and the complications of portal hypertension or until development of hepatocellular carcinoma. Acute hepatitis C progresses to chronic infection and cirrhosis in about 20 per cent of cases. Decompensation of cirrhosis suggested by deterioration in liver function, encephalopathy, ascites or bleeding in a patient with known HCV cirrhosis necessitates an urgent assessment for liver transplantation, if available. Reinfection of the graft with HCV after liver transplantation occurs in almost all patients.

**Ascending cholangitis**

Ascending bacterial infection of the biliary tract is usually associated with obstruction and presents with clinical jaundice, rigors and a tender hepatomegaly. The diagnosis is confirmed by the finding of dilated bile ducts on ultrasound, an obstructive picture of liver function tests and the isolation of an organism from the blood on culture. The condition is a medical emergency, and delay in appropriate treatment results in organ failure secondary to sepsicaemia. Once the diagnosis has been confirmed, the patient should be commenced on a first-line broad-spectrum antibiotic and rehydrated, and arrangements should be made for urgent endoscopic or percutaneous transhepatic drainage of the biliary tree. Biliary stone disease is a common predisposing factor, and the causative ductal stones may be removed at the time of endoscopic cholangiography by endoscopic sphincterotomy.

**Pyogenic liver abscess**

The aetiology of a pyogenic liver abscess is unexplained in the majority of patients. It has an increased incidence in the elderly, diabetics and the immunosuppressed, who usually present with anorexia, fevers and malaise, accompanied by right upper quadrant discomfort. The diagnosis is suggested by the finding of a multiloculated cystic mass on ultrasound or CT scan (Figure 65.17) and is confirmed by aspiration for culture and sensitivity. The most common organisms are *Streptococcus milleri* and *Escherichia coli*, but other enteric organisms such as *S. faecalis*, *Klebsiella* and *Proteus vulgaris* also occur, and mixed growths are common. Opportunistic pathogens include *staphylococci*. Treatment is with antibiotics and ultrasound-guided aspiration. First-line antibiotics to be used are a penicillin, an aminoglycoside and metronidazole or a cephalosporin and metronidazole. Often, repeated aspirations may be necessary. Percutaneous drainage without ultrasound guidance should be avoided as an empyema may follow drainage through the pleural space. A source for the liver abscess should be sought, particularly from the colon. Atypical clinical or radiological findings should raise the possibility of a necrotic neoplasm.

![Figure 65.17 Liver abscess. Computed tomography scan showing an air-fluid level and rim enhancement with intravenous contrast typical of a liver abscess. In the adjacent liver is a calcified hydatid cyst.](image)
Amoebic liver abscess

Entamoeba histolytica is endemic in many parts of the world. It exists in vegetative form outside the body and is spread by the faeco-oral route. The most common presentation is with dysentery, but it may also present with an amoebic abscess, the common sites being paracaecal and in the liver. The amoebic cyst is ingested and develops into the trophozoite form in the colon, and then passes through the bowel wall and to the liver via the portal blood. Diagnosis is by isolation of the parasite from the liver lesion or the stool and confirming its nature by microscopy. Often patients with clinical signs of an amoebic abscess will be treated empirically with metronidazole (400–800 mg, three times a day, for 7–10 days) and investigated further only if they do not respond. Resolution of the abscess can be monitored using ultrasound.

Hydatid liver disease

This is a very common condition in countries around the Mediterranean. The causative tapeworm, Echinococcus granulosus, is present in the dog intestine, and ova are ingested by humans and pass in the portal blood to the liver. Liver abscesses are often large by the time of presentation with upper abdominal discomfort or may present after minor abdominal trauma as an acute abdomen due to rupture of the cyst into the peritoneal cavity. Diagnosis is suggested by the finding of a multiloculated cyst on ultrasound and is further supported by the finding of a floating membrane within the cysts on CT scan (Figure 65.18). Active cysts contain a large number of smaller daughter cysts (Figure 65.19), and rupture can result in these implanting and growing within the peritoneal cavity. Liver cysts can also rupture through the diaphragm producing an empyema, into the biliary tract producing obstructive jaundice, or into the stomach. Clinical and radiological diagnosis can be supported by serology for antibodies to hydatid antigen in the form of an enzyme-linked immunosorbent assay (ELISA). Treatment is indicated to prevent progressive enlargement and rupture of the cysts. In the first instance, a course of albendazole or mebendazole may be tried. There are many reports that percutaneous treatment of hydatid cysts is safe and effective. Percutaneous treatment constitutes an initial course of albendazole followed by puncture of the cyst under image guidance, aspiration of the cyst contents, instillation of hypertonic saline in the cyst cavity and re-aspiration (PAIR). PAIR should only be attempted if there is no communication with the biliary tree. Failure to respond to medical treatment or percutaneous treatment usually requires surgical intervention. The surgical options range from liver resection or local excision of the cysts to de-roofing with evacuation of the contents. Contamination of the peritoneal cavity at the time of surgery with active hydatid daughter cysts should be avoided by continuing drug therapy with albendazole and adding peroperative praziquantel. This should be combined with packing of the peritoneal cavity with 20 per cent hypertonic saline-soaked packs and instilling 20 per cent hypertonic saline into the cyst before it is opened. A biliary communication should be actively sought and sutured. The residual cavity may become infected, and this may be reduced, as may bile leakage, by packing the space with pedicled greater omentum (an omentoplasty). Calcified cysts may well be dead. If doubt exists as to whether a suspected cyst is active, it can be followed on ultrasound, as active cysts gradually become larger and more superficial in the liver. Rupture of daughter hydatids into the biliary tract may result in obstructive jaundice or acute cholangitis. This may be treated by endoscopic clearance of the daughter cysts prior to cyst removal from the liver.

Liver tumours

Surgical approaches to resection of liver tumours

Adequate exposure of the liver is an absolute prerequisite to safe liver surgery. A transverse abdominal incision in the right upper quadrant with a vertical midline extension to the xiphoid provides excellent access to the liver if adequate retraction of the costal margin is employed using a costal margin retractor. If necessary, the incision can be extended across the midline transversely in the left upper quadrant. Thoracoabdominal incisions are no longer required. The procedure for complete mobilisation of the liver is described, although this will not be necessary in all cases. There are many variations in surgical technique.
Mobilisation of the liver

The falciform ligament is first divided and followed along the anterior surface of the liver towards the suprarehepatic IVC. The left triangular ligament is divided, facilitated by placing an abdominal pack in front of the oesophagogastric junction. The right triangular ligament is then divided by retraction of the diaphragm away from the right lobe parenchyma. On exposure of the bare area of the liver, the IVC can be seen as it passes behind the liver, and this can be slung above the renal veins below the liver and at the level of the main hepatic veins. Mobilisation of the liver is completed by division of the lesser omentum. Removing the liver from the IVC is achieved by lifting the liver anteriorly to expose the multiple small veins (inferior hepatic veins) passing between the liver parenchyma and the IVC. These should be suture ligated to ensure haemostasis. This proceeds from above the renal veins until the main hepatic veins are reached below the diaphragm.

Dissection of the hilum

The peritoneum overlying the hilar triad is divided. The CBD is then exposed on the free edge of the lesser omentum, mobilisation being facilitated by ligation and division of the cystic duct and artery followed by removal of the gall bladder. Slinging the CBD with an elastic sling allows exposure of the common hepatic artery and dissection of the main right and left branches. These again may be slung to allow the remaining lymphatic tissue surrounding the portal vein to be ligated and divided. The possibility of an aberrant right hepatic artery lying posterior to the bile duct or an accessory left hepatic artery from the left gastric artery in the lesser omentum should be considered and carefully excluded. Dissection of the hilar bile ducts requires careful retraction on segment IV of the liver, and division of the small vessels and bile duct branches passing between segment IV and the confluence of the right and left hepatic ducts.

Division of the parenchyma

Once the liver has been adequately mobilised and the hilar vessels have been exposed, the main inflow vessels and bile duct to the liver lobe to be resected can be divided. The arterial branch should be transfixed with 4/0 Prolene, the bile duct transfixed with 4/0 PDS and the portal vein branch with a 4/0 Prolene suture. Division of the inflow vessels produces a line of demarcation commencing by diathermy of the liver capsule. The ultrasound dissector (Cavitron ultrasonic surgical aspirator (CUSA)) is the most common method used for division of the parenchyma. This allows the parenchyma to be divided, leaving the vessels and bile duct branches to be diathermed or ligated depending on their size. Dissection continues on an even plane until the hepatic vein branches are approached from within the liver parenchyma, when they are ligated or stapled, and then divided (Figure 65.20).

Segmental and local resections

These are considered in patients whose liver tumours can be excised with an adequate margin (generally considered to be 1 cm) without a formal right or left lobe liver resection. The segments that can be removed individually are those shown in Figure 65.2. Each carries its own blood supply, venous drainage and bile drainage. The extent of mobilisation of the liver required (described above under Mobilisation of the liver) depends on the segment to be resected. Hilar dissection may not be necessary. Segmental resections are used particularly in patients with HCC and underlying liver disease (e.g. HBV or HCV) to minimise the risk of postoperative liver failure (Figure 65.21). Local resections are principally used for patients with multiple liver metastases when removal of the tumour mass with a minimum margin of 1 cm of normal liver parenchyma is required.

Laparoscopic liver resections

With advances in minimal access surgery, the application of laparoscopic surgery in performing liver resections has evolved considerably. However, success in laparoscopic liver resections requires expertise both in advanced laparoscopic techniques and in liver surgery. Wedge resections of superficial and peripherally located tumours, and left lateral liver resections are commonly performed in most centres. Major right and left heptectomies are also being performed in selected centres.

Blood loss and transfusion

The reduction of blood loss during liver surgery has been one of the major achievements in the last decade, and resection without blood transfusion is often possible. Better understanding of the segmental anatomy of the liver, better patient selection for surgery, reducing central venous pressure (<10 mmHg) during parenchymal transection have all helped to reduce the need for blood transfusions. Intraoperative cell saver, used in non-cancer cases and during liver transplantation, has reduced the need for autologous blood transfusions. Devices such as the ultrasound dissector have helped, but clamp crushing (Kelly clysis) is equally effective in achieving parenchymal transection with minimal blood loss. Better control of the coagulation cascade has been achieved using TEG (see Figure 65.9), and the antifibrinolytic drug aprotinin has significantly reduced bleeding in patients with liver disease and an underlying coagulopathy. Oozing from the resected surface can be reduced by the topical application of fibrin glue or fibrin-impregnated collagen fleece.
The main alternative is use of the argon-beam coagulator. Temporary clamping of the portal vein and hepatic artery in the hepatoduodenal ligament (Pringle manoeuvre) can prevent excessive blood loss during parenchymal transection. The optimal duration of the Pringle manoeuvre is unknown, but it can be applied intermittently, e.g. cycles of 15 minutes inflow occlusion followed by 5 minutes of reperfusion, until parenchymal transection is complete.

**Benign liver tumours**

**Haemangiomas**

These are the most common liver lesions, and the reported incidence has increased with the widespread availability of diagnostic ultrasound. They consist of an abnormal plexus of vessels, and their nature is usually apparent on ultrasound. If diagnostic uncertainty exists, CT scanning with delayed contrast enhancement shows the characteristic appearance of slow contrast enhancement due to small vessel uptake in the haemangioma. Often, haemangiomas are multiple. Lesions found incidentally require confirmation of their nature and no further treatment. The management of ‘giant’ haemangiomas is more controversial. Occasional reports of rupture of haemangiomas have led some to consider resection for the large lesions, especially if they appear to be symptomatic. They have little if any malignant potential, and this is no indication for surgery. Percutaneous biopsy of these lesions should be avoided as they are vascular lesions and may bleed profusely into the peritoneal cavity.

**Hepatic adenoma**

Hepatic adenomas (Figure 65.22) are rare benign liver tumours. They occur mostly in women of child-bearing age. Imaging by CT or MRI demonstrates a well-circumscribed and vascular solid tumour. They usually develop in an otherwise normal liver. Unfortunately, there are no characteristic radiological features to differentiate these lesions from HCC. Arterial phase CT demonstrates a well-developed peripheral arterialisation of the tumour. Biopsy may be necessary for confirmation and characterisation of the nature of these lesions. These tumours may bleed and are thought to have malignant potential, and resection is therefore the treatment of choice. An association with sex hormones (including the oral contraceptive pill) is well recognised, and regression of symptomatic adenomas on withdrawal of hormone stimulation is well documented.

**Focal nodular hyperplasia**

This is an unusual benign condition of unknown aetiology in which there is a focal overgrowth of functioning liver tissue supported by fibrous stroma. Patients are usually middle-aged

![Figure 65.21 Segmental resection. Removal of a primary liver tumour by resection of liver segment VI (a and b) in a patient with well-compensated liver cirrhosis.](image)

![Figure 65.22 Hepatic adenoma. Magnetic resonance imaging scan of a giant hepatic adenoma. These lesions are thought to be premalignant, they may haemorrhage and, in some cases, their growth is sex hormone sensitive. Withdrawal of hormone preparations may allow spontaneous regression.](image)
females, and there is no association with underlying liver disease. Ultrasound shows a solid tumour mass but does not help in discrimination. Contrast CT or/and MRI may show central scarring and evidence of a well-vascularised lesion. Again, these appearances are not specific for focal nodular hyperplasia (FNH). FNH contain both hepatocytes and Kupffer cells. MRI using liver-specific contrast agents, such as gadobenate dimeglumine, which is taken up by hepatocytes and excreted in bile or superparamagnetic iron oxide which is taken up by Kupffer cells, may be useful in determining the hepatocellular origin of FNH and allowing differentiation of FNH from metastatic cancer. Similarly, a sulphur colloid liver scan may be useful, since Kupffer cells take up the colloid. FNH do not have any malignant potential and, once the diagnosis is confirmed, they do not require any treatment.

Surgery for liver metastases

**Outcome**

The role of surgery in the treatment of colorectal liver metastases is now well established, based on prospective data on resected patients compared with unresected patients with a similar stage of disease. The role of resection of liver metastases from other primary sites has not been well defined. The resectability rate for liver metastases from colorectal cancer is 20–30 per cent. The expected patient survival rate for resection of colorectal metastases is approximately 35 per cent at five years, with few cancer-related deaths beyond this period. Solitary, multiple unilobar and multiple bilobar liver metastases are all considered for resection, although cure rates will vary significantly (Summary box 65.12).

**Staging**

This involves defining the extent of the liver involvement with metastases and excluding extrahepatic disease. A standard work up would involve oral and intravenous contrast CT scans of the liver and abdomen, chest CT scan and colonoscopy to look for locally recurrent or synchronous colonic cancers. MRI and PET scanning are useful in the clarification of equivocal lesions. This information should be taken in parallel with a general medical evaluation before deciding on the suitability for surgery of an individual patient. The typical appearance of colorectal liver metastases on contrast CT is shown in Figure 65.23. These patients usually have normal liver parenchyma and therefore tolerate a 60–70 per cent resection of liver parenchyma without risk of postoperative liver failure (Summary box 65.13). Tumour markers are useful but have low specificity. Histological confirmation prior to undertaking surgery is not necessary and percutaneous biopsy of resectable lesions should be avoided as there is good evidence that malignant cells can seed along the biopsy track.

**Surgical approach**

The basic surgical approach to liver resection is outlined above. A search for local recurrent disease, peritoneal deposits and
regional lymph node involvement should be made at the start of the laparotomy. Planar imaging often overlooks peritoneal or superficial liver metastatic deposits. Coeliac node involvement in patients with liver metastases considerably reduces the overall survival whether or not the liver and nodal disease is resected. Intraoperative ultrasound with bimanual palpation of the liver is valuable in assessing the number of lesions and resectability.

**Downstaging therapies**

There have been major advances in the management of patients with colorectal liver metastases who, until recently, would have been considered ‘unresectable’ due to the size or distribution of their metastases. Chemotherapy with 5-fluorouracil (5FU) and folinic acid produces a response rate of approximately 30 per cent but, when combined with oxaliplatin, the response rate increases to 50–60 per cent, often with a dramatic size reduction of the lesions. The combination of chemotherapy with monoclonal antibodies (mAbs) that recognize vascular endothelial growth factor (VEGF) receptor or the epidermal growth factor receptor (EGFR) may provide additional benefit. Long-term follow-up of patients downstaged with chemotherapy, who have proceeded to resection of their cancers, have shown five-year survival rates of 30–40 per cent.

Patients with bilobar metastases with a lesion centrally within the right lobe and a second lesion peripherally in the left lobe may have resection of their metastases in two stages to allow for regeneration of the liver parenchyma between the procedures. Good long-term survival has been reported for this group of patients.

Portal vein embolisation is a third development to affect patients previously deemed unresectable. Patients who require a right or extended right hepatectomy and in whom the left lobe volumes are congenitally small (<30 per cent of functioning parenchyma) have an increased risk of post-resection liver failure. This can be reduced by preoperative (3–6 weeks) percutaneous embolisation of the right portal vein branch, which produces atrophy of the affected lobe and hypertrophy of the contralateral lobe.

In patients who cannot be rendered resectable, systemic chemotherapy has been shown to produce survival and quality of life benefit. Many techniques are now available that produce local ablation of the tumours, including cryotherapy, interstitial laser hyperthermia, radiofrequency ablation (RFA), microwave therapy, focused ultrasound and electrolytic therapy. These techniques may produce survival benefit along with chemotherapy in the palliative setting, but there is little objective evidence of long-term survival, and they should therefore be restricted to patients who cannot be offered surgical resection (Summary box 65.14).

### Summary box 65.14

**Strategies for ‘unresectable’ colorectal liver metastases**

- Neoadjuvant chemotherapy
- Anti-VEGF or EGFR monoclonal antibody therapy
- Two-stage liver resection
- Portal vein embolisation
- Ablation techniques

Approximately 15–20 per cent of patients with colorectal cancer present with synchronous liver metastases. However, the timing of resection of the liver metastases in these patients is controversial. For most patients, a staged approach consisting of resection of the colorectal primary followed by liver resection at a later date is the standard treatment. In selected patients in whom the colorectal primary is small and asymptomatic, the liver resection may be performed first to prevent progression of the liver metastases. In patients requiring minor liver resection for small metastases, simultaneous liver and colorectal resections is safe and effective. Similarly, a right-sided colonic resection which is usually straightforward can be combined with liver resection safely. Combining major liver resection with major colorectal resection is controversial.

**Hepatocellular carcinoma**

Primary liver cancer (HCC) is one of the world’s most common cancers, and its incidence is expected to rise rapidly over the next decade due to the association with chronic liver disease, particularly HBV and HCV. Many patients known to have chronic liver disease are now being screened for the development of HCC by serial ultrasound scans of the liver or serum measurements of alpha-fetoprotein (AFP). Patients often present in middle age, either because of the symptoms of chronic liver disease (malaise, weakness, jaundice, ascites, variceal bleed, encephalopathy) or with the anorexia and weight loss of an advanced cancer. The surgical treatment options include resection of the tumour and liver transplantation. Which option is most appropriate for an individual patient depends on the stage of the underlying liver disease, the size and site of the tumour, the availability of organ transplantation and the management of the immunosuppressed patient.

**Staging and clinical assessment of HCC**

In addition to a general assessment of the patient’s fitness for surgery, crucial information is the severity of the underlying liver disease, based on CTP classification (see Table 65.2) or MELD score, and the size, number and site of the tumour. As chronic liver disease predisposes to these tumours, they are often multifocal by the time of diagnosis. Extensive liver resections in patients with advanced cirrhosis are associated with a high mortality due to liver failure and sepsis. In contrast, extensive resections for HCC in a non-cirrhotic liver are associated with a low risk of liver failure, and resection rather than transplantation would be the treatment option of choice. Tumours often metastasise to the lung and bone and, therefore, a chest CT scan and a bone scan are useful staging investigations. Evidence of intraperitoneal disease is difficult to determine by CT scan, and laparoscopy may be useful for this purpose. The intrahepatic distribution of HCC is equally difficult to determine within the cirrhotic liver. Ultrasound, early arterial phase-enhanced spiral CT scan and contrast MRI are the most useful investigations that are currently available. Wedged hepatic venous pressure (WHVP) measurements are useful in cirrhotic patients. An elevated WHVP suggests portal hypertension and is an independent predictor of poor outcome after liver resection in cirrhotic patients. Indocyanine green (ICG) clearance test is useful to assess liver function preoperatively in cirrhotic patients. Intravenously injected ICG is exclusively eliminated by hepatocytes and excreted into bile and does not enter enterohepatic circulation. The plasma clearance of ICG has been used as an...
indicator of hepatic blood flow and hepatic function. Generally, cirrhotic patients who are CTP class A and have a high ICG clearance are suitable for major liver resections.

**Surgical approach to HCC**

The surgical approach should remove the known cancer with a 1- to 2-cm margin of unaffected liver tissue. In patients with associated chronic liver disease, the volume of liver resected should be minimised to reduce the incidence of postoperative liver failure. Local or segmental resections are preferred to major resections (see Figure 65.21). In carefully selected patients, liver transplantation is an effective treatment. Patients with cirrhosis who have a single HCC less than 5 cm in diameter or multiple HCCs each less than 3 cm, and with no evidence of vascular invasion or extrahepatic spread are ideal candidates for liver transplantation.

**Non-surgical therapy for hepatocellular carcinoma**

The majority of patients diagnosed with HCC will not be amenable to surgical resection because of the advanced stage of the cancer or the severity of the underlying liver disease. Those patients awaiting liver transplantation may develop progressive disease before a suitable donor liver is found, because of the long waiting list for transplantation. Patients with unresectable disease can be offered local ablative treatments, such as transarterial embolisation (TAE), transarterial chemoembolisation (TACE), percutaneous ethanol ablation (PEA) or RFA (Figure 65.24). These local ablative treatments may also be used as bridging procedures to liver transplantation.

**Follow up and adjuvant treatment**

There is little evidence that adjuvant chemotherapy will improve the prognosis of patients following resection of HCC, but trials with the multikinase inhibitor Sorafenib are ongoing. Chemotherapy may damage the function of the liver in those with underlying chronic liver disease. AFP is a clinically useful tumour marker for follow up, although its low sensitivity would suggest that imaging should also be used.

**Cholangiocarcinoma**

**Presentation, pathology and natural history**

Bile duct cancers typically present with painless obstructive jaundice. Elderly patients are frequently affected, but patients with PSC may develop these tumours at a much earlier age. These tumours are typically slow growing and often arise at the confluence of the right and left hepatic ducts (Klatskin tumours), eventually invading the liver parenchyma. Cancers at this site are usually fibrous and produce tight duct strictures. Distal bile duct cholangiocarcinomas are more frequently polypoidal and obstruct the lumen of the duct. Investigation, staging and management of bile duct and gall bladder malignancies are discussed in Chapter 67.

**FURTHER READING**

The spleen

LEARNING OBJECTIVES

To understand:
- The function of the spleen
- The common pathologies involving the spleen
- The principles and potential complications of splenectomy
- The potential advantages of laparoscopic splenectomy
- The benefits of splenic conservation
- The importance of prophylaxis against infection following splenectomy

EMBRYOLOGY, ANATOMY AND PHYSIOLOGY

Embryology

Fetal splenic tissue develops from condensations of mesoderm in the dorsal mesogastrium. This peritoneal fold attaches the dorsal body wall to the fusiform swelling in the foregut that develops into the stomach. This condensation divides the mesogastrium into two parts, one between the fetal splenic tissue and the stomach to form the gastrosplenic ligament and the other between it and the left kidney to form the lienorenal ligament.

Anatomy

The weight of the normal adult spleen is 75–250 g. It lies in the left hypochondrium between the gastric fundus and the left hemidiaphragm, with its long axis lying along the tenth rib. The hilum sits in the angle between the stomach and the kidney and is in contact with the tail of the pancreas. The concave visceral surface lies in contact with these structures, and the lower pole extends no further than the mid-axillary line. There is a notch on the inferolateral border, and this may be palpated when the spleen is enlarged. The tortuous splenic artery arises from the coeliac axis and runs along the upper border of the body and tail of the pancreas, to which it gives small branches. The short gastric and left gastroepiploic branches pass between the layers of the gastrosplenic ligament. The main splenic artery generally divides into superior and inferior branches, which, in turn, subdivide into several segmental branches.

The splenic vein is formed from several tributaries that drain the hilum. The vein runs behind the pancreas, receiving several small tributaries from the pancreas before joining the superior mesenteric vein at the neck of the pancreas to form the portal vein.

The splenic pulp is invested by an external serous and internal fibroelastic coat which is reflected inwards at the hilum onto the vessels to form vascular sheaths. The lymphatic drainage comprises efferent vessels in the white pulp that run with the arterioles and emerge from nodes at the hilum. These nodes and lymphatics drain via retropancreatic nodes to the coeliac nodes. Sympathetic nerve fibres run from the coeliac plexus and innervate splenic arterial branches.

Physiology

The splenic parenchyma consists of white and red pulp that is surrounded by serosa and a collagenous capsule with smooth muscle fibres. These penetrate the parenchyma as trabeculae of dense connective tissue fibres rich in collagen and elastic tissue. These, with the reticular framework, support the cells of the spleen and surround the vessels in the splenic pulp. The white pulp comprises a central trabecular artery surrounded by nodules with germinal centres and periarterial lymphatic sheaths that provide a framework filled with lymphocytes and macrophages. Arteries from the central artery and the peripheral ‘penicillar’ arteries pass into the marginal zone that lies at the edge of the white pulp. Plasma-rich blood that has passed through the central lymphatic nodules is filtered as it passes through the sinuses within the marginal zone, and particles are phagocytosed. Immunoglobulins produced in the lymphatic nodules enter the circulation through the sinuses in the marginal zone, beyond which lies the red pulp, which consists of cords and sinuses. Cell-concentrated blood passes in the trabecular artery through the centre of the white pulp to the red pulp cords. Red cells must elongate and become thinner to pass from the cords to the sinuses, a process that removes abnormally shaped cells from the circulation (Figure 66.1). As 90 per cent of the blood passing through the spleen moves through an open circulation in which blood flows from arteries to cords, and thence sinuses, splenic pulp pressure reflects the pressure throughout the portal system. The remaining 10 per cent of the blood flow through the spleen bypasses the cords and sinuses by direct arteriovenous communications. The overall flow rate of blood is about 300 mL/min.
FUNCTIONS OF THE SPLEEN

Although the spleen was previously thought to be dispensable, increasing knowledge of its function has led to a conservative approach in the management of conditions involving the spleen. It is now recognised that an incidental splenectomy during the course of another operative procedure increases the risk of complication and death. The surgeon should therefore normally endeavour to preserve the spleen to maintain the following functions:

- **Immune function.** The spleen processes foreign antigens and is the major site of specific immunoglobulin M (IgM) production. The non-specific opsonins, properdin and tuftsin, are synthesised. These antibodies are of B- and T-cell origin and bind to the specific receptors on the surface of macrophages and leukocytes, stimulating their phagocytic, bactericidal and tumoricidal activity.

- **Filter function.** Macrophages in the reticulum capture cellular and non-cellular material from the blood and plasma. This will include the removal of effete platelets and red blood cells. This process takes place in the sinuses and the splenic cords by the action of the endothelial macrophages. Iron is removed from the degraded haemoglobin during red cell breakdown and is returned to the plasma. Removed non-cellular material may include bacteria and, in particular, pneumococci.

- **Pitting.** Particulate inclusions from red cells are removed, and the repaired red cells are returned to the circulation. These include Howell–Jolly and Heinz bodies, which represent nuclear remnants and precipitated haemoglobin or globin subunits, respectively.

- **Reservoir function.** This function in humans is less marked than in other species, but the spleen does contain approximately 8 per cent of the red cell mass. An enlarged spleen may contain a much larger proportion of the blood volume.

- **Cytopoiesis.** From the fourth month of intrauterine life, some degree of haemopoiesis occurs in the fetal spleen. Stimulation of the white pulp may occur following antigenic challenge, resulting in the proliferation of T and B cells and macrophages. This may also occur in myeloproliferative disorders, thalassaemias and chronic haemolytic anaemias (Summary box 66.1).

**INVESTIGATION OF THE SPLEEN**

Conditions that result in splenomegaly can be diagnosed on the basis of the history and examination findings and from laboratory examination. In haemolytic anaemia, a full blood count, reticulocyte count and tests for haemolysis will determine the cause of the anaemia. Splenomegaly associated with portal hypertension caused by cirrhosis is diagnosed on the history, physical signs of liver dysfunction, abnormal tests of liver function and endoscopic evidence of oesophageal varices. Sinistral or segmental portal hypertension may result from isolated occlusion of the splenic vein by pancreatic inflammation or tumour. As many conditions that cause splenomegaly are associated with lymphadenopathy, investigation should be directed at those disease processes known to be associated with both physical signs. Lymph node biopsy may be required.
Radiological imaging

Plain radiology is rarely used in investigation, but the incidental finding of calcification of the splenic artery or spleen may raise the possible diagnosis of a splenic artery aneurysm, an old infarct, a benign cyst or hydatid disease. Multiple areas of calcification may suggest splenic tuberculosis. Ultrasonography can determine the size and consistency of the spleen, and whether a cyst is present. However, computed tomography (CT) with contrast enhancement is more commonly undertaken to better characterise the nature of the suspected splenic pathology and to exclude other intra-abdominal pathology. Magnetic resonance imaging (MRI) may be similarly useful. Radioisotope scanning is used occasionally to provide information about the spleen. The use of technetium-99m ($^{99m}$Tc)-labelled colloid is normally restricted to determining whether the spleen is a significant site of destruction of red blood cells.

CONGENITAL ABNORMALITIES OF THE SPLEEN

Splenic agenesis is rare, but is present in 10 per cent of children with congenital heart disease. Polysplenia is a rare condition resulting from failure of splenic fusion.

Splenunculi are single or multiple accessory spleens that are found in approximately 10–30 per cent of the population. They are located near the hilum of the spleen in 50 per cent of cases and are related to the splenic vessels or behind the tail of the pancreas in 30 per cent. The remainder are located in the mesocolon or the splenic ligaments. Their significance lies in the fact that failure to identify and remove these at the time of splenectomy may give rise to persistent disease.

Hamartomas are rarely found in life and vary in size from 1 cm in diameter to masses large enough to produce an abdominal swelling. One form is mainly lymphoid and resembles the white pulp, whereas the other resembles the red pulp.

Non-parasitic splenic cysts are rare. Splenic cysts are classified as primary cysts (true) or pseudocysts (secondary) on the basis of the presence or absence of lining epithelium. True cysts form from embryonal rests and include dermoid and mesenchymal inclusion cysts (Figure 66.2). True cysts of the spleen are very rare and are frequently classified as cystic hemangiomas, cystic lymphangiomata and epidermoid and dermoid cysts. Epidermoid cysts are thought to be of congenital origin and represent 10 per cent of the splenic cysts. They are lined by flattened squamous epithelium and are more frequent in children and young patients. Splenectomy or partial splenectomy is usually considered for cysts larger than 5 cm in diameter. These should be differentiated from false or secondary cysts that may result from trauma and contain serous or hemorrhagic fluid. The walls of such degenerative cysts may be calcified and therefore resemble the radiological appearances of a hydatid cyst. The spleen is also a common site for pseudocyst development following a severe attack of pancreatitis (Figure 66.3). Pseudocysts can easily be diagnosed on scanning, and intervention is normally required for symptomatic lesions that persist following a period of observation.

SPLENIC ARTERY ANEURYSM, INFARCT AND RUPTURE

Splenic artery aneurysm

Aneurysms involving the splenic artery are estimated to occur at 0.04–1 per cent of post-mortem examinations. They are twice as common in the female and are usually situated in the main arterial trunk. Although these are generally single, more than one aneurysm is found in a quarter of cases. These may be a consequence of intra-abdominal sepsis and pancreatic necrosis in particular. They are more likely to be associated with arteriosclerosis in elderly patients.

The aneurysm is symptomless unless it ruptures and is more likely to be detected on a plain abdominal x-ray or scan. It is unlikely to be palpable, although a bruit may be present. Rupture is unsuspected in the majority of cases and, as it will generally rupture into the peritoneal cavity, the symptoms mimic those of splenic rupture. Almost half the cases of rupture occur in patients younger than 45 years of age, and a quarter are in pregnant women, usually in the third trimester of pregnancy or at labour. Aneurysmal rupture carries a high mortality rate and...
this increases disproportionately in pregnant women with almost inevitable fetal death.

The treatment of choice previously consisted of splenectomy and removal of the diseased artery. Some surgeons advocate ligation of the proximal and distal ends of the sac to allow thrombosis of the aneurysm and partial or complete splenectomy if necessary. The procedure has been performed laparoscopically with success. Embolisation or endovascular stenting following selective splenic artery angiography can be considered. In the younger patient with an asymptomatic splenic artery aneurysm, surgery or interventional radiology is indicated depending on local expertise after CT, MRI or selective coeliac angiography has confirmed the diagnosis (Figure 66.4). In the elderly patient with a calcified aneurysm, there is less risk of rupture, and observation may be preferred. In patients with pancreatic necrosis, the treatment will include drainage of the septic focus.

**Splenic infarction**

This condition commonly occurs in patients with a massively enlarged spleen from myeloproliferative syndrome, portal hypertension or vascular occlusion produced by pancreatic disease, splenic vein thrombosis or sickle cell disease. The infarct may be asymptomatic or give rise to left upper quadrant and left shoulder tip pain. A contrast-enhanced CT will show the characteristic perfusion defect in the enlarged spleen (Figure 66.5). Treatment is conservative and splenectomy should be considered only when a septic infarct causes an abscess.

**Splenic rupture**

Splenic rupture (see Chapter 28, Torso trauma) should be considered in any case of blunt abdominal trauma, particularly when the injury occurs to the left upper quadrant of the abdomen. Iatrogenic injury to the spleen remains a frequent complication of any surgical procedure, particularly those in the left upper quadrant when adhesions are present.

**Rupture of a malarial spleen**

In tropical countries, rupture of a spleen enlarged due to malaria is not uncommon (see below under Tropical splenomegaly). Delayed presentation following a 'trivial' injury is not infrequent. In such patients, splenectomy should be considered before a perisplenic haematoma ruptures, a complication that is associated with a worse prognosis.

Surgery in such patients is challenging, and early ligation of the splenic vessels along the superior border of the pancreatic body should be considered before disturbing the haematoma.

**Splenomegaly and Hypersplenism**

**Splenomegaly** is a common feature of many disease processes (Table 66.1). It should be borne in mind, however, that many conditions affecting the spleen, such as idiopathic thrombocytopenic purpura, may be associated with enlargement, but the gland is seldom palpable. Few conditions that cause splenomegaly will require splenectomy as part of treatment. **Hypersplenism** is an indefinite clinical syndrome that is characterised by splenic enlargement, any combination of anaemia, leukopenia or thrombocytopenia, compensatory bone marrow hyperplasia and improvement after splenectomy. Careful clinical judgement is required to balance the long- and short-term risks of splenectomy against continued conservative management.

**Splenic abscess**

Splenic abscess may arise from an infected splenic embolus or in association with typhoid and paratyphoid fever, osteomyelitis, otitis media and puerperal sepsis. In general surgical practice, it may be associated with pancreatic necrosis or other intra-abdominal infection (Figure 66.6). An abscess may rupture and form a left subphrenic abscess or result in diffuse peritonitis. Treatment involves that of the underlying cause and percutaneous drainage of the splenic abscess under radiological guidance is normally required.

**Tuberculosis**

The diagnosis of tuberculosis should be considered in young adults with splenomegaly presenting with asthenia, loss of weight and fever. Tuberculosis of the spleen may produce portal hypertension or, rarely, cold abscess. Treatment with anti-tuberculous drugs will normally produce improvement. Splenectomy is not normally required and is made difficult by the inflammatory adhesions.
Adolph Weil, 1848–1916, physician, Dorpat (now Tartu), Estonia described leptospirosis icterohaemorrhagica in 1886.

Sir George Frederic Still, 1868–1941, Professor of Diseases of Children, King’s College Hospital, London, UK, described chronic articulr rheumatism in children in 1896.

Tropical splenomegaly

Massive splenic enlargement frequently occurs in the tropics from malaria, kala-azar and schistosomiasis. Occasionally, splenomegaly cannot be fully attributed to these diseases. It may result from occult infection or be related to malnutrition. The massive splenomegaly observed in this condition may require removal in those patients disabled by anaemia or local symptoms. Life-long anti-malarial therapy is indicated in malaria-endemic areas.

Schistosomiasis

This condition is prevalent in Africa, Asia and South America. It is caused by infection with Schistosoma mansoni in 75 per cent of cases and by Schistosoma haematobium in the remainder. The splenic enlargement may result from portal hypertension associated with hepatic fibrosis, but can also result from hyperplasia induced by the phagocytosis of disintegrated worms, ova and toxin. Splenomegaly can occur at any age. The diagnosis is based on examination of the urine and faeces for ova, abnormal liver function tests and the presence of hypochromic anaemia.

Successful medical treatment of established cases does not result in regression of splenomegaly, and removal of the painful and bulky spleen is indicated where there is no evidence

Clinical features

The adult form normally affects females between the ages of 15 and 50 years, although it can be associated with other conditions, including systemic lupus erythematosus, chronic lymphatic leukaemia and Hodgkin’s disease. The childhood form is distributed equally between males and females and commonly presents before the age of five years. Purpuric patches (ecchymoses) occur on the skin and mucous membranes. Following trauma or pressure, examination often reveals numbers of petechial haemorrhages in the skin. There is a tendency to spontaneous bleeding from mucous membranes (e.g. epistaxis); in women, menorrhagia and the prolonged bleeding of minor wounds are common. Haemorrhage from the urinary and gastrointestinal tracts and haemarthrosis are rare. Although intracranial haemorrhage is also uncommon, it is the most frequent cause of death. The diagnosis is made based upon the presence of cutaneous ecchymoses and a positive tourniquet test. The spleen is palpable in fewer than 10 per cent of patients, and the presence of gross splenic enlargement should raise the suspicion of an alternative diagnosis.

Investigations

Coagulation studies are normal, and a bleeding time is not helpful in diagnosis. Platelet count in the peripheral blood film is reduced (usually <60 × 10^9/L). Bone marrow aspiration reveals a plentiful supply of platelet-producing megakaryocytes.

Treatment

The course of the disease differs in children and adults. The disease regresses spontaneously in 75 per cent of paediatric cases following the initial attack. Short courses of corticosteroids in both adult and child are usually followed by recovery. Prolonged steroid therapy should not be continued if this does not produce remission. Splenectomy is usually recommended if a patient has two relapses on steroid therapy or if the platelet count remains low. Generally, this is indicated where the ITP has persisted for more than 6–9 months.

Up to two-thirds of patients will be cured by surgical intervention, and 15 per cent will be improved, but no benefit will be derived in the remainder. The response to steroids predicts a good response to splenectomy. In the acute setting, if severe bleeding has not been controlled by steroid therapy, fresh blood transfusion or transfusion with platelet concentrates before operation is necessary, although these are generally withheld until the splenic vessels have been controlled at operation.

Haemolytic anaemias

There are four causes of haemolytic anaemia that are generally amenable to splenectomy.

Hereditary spherocytosis

Hereditary spherocytosis is an autosomal dominant hereditary disorder characterised by the presence of spherocytic red cells, caused by various molecular defects in the genes that code for alpha- and beta-spectrin, ankyrin, band 3 protein, protein 4.2 and other erythrocyte membrane proteins. These proteins are necessary to maintain the normal biconcave shape of the erythrocyte. Spherocytosis arises essentially from an increase in permeability of the red cell membranes to sodium. As this ion leaks into the cell, the osmotic pressure rises, resulting in swelling and increased fragility of the spherocyte. As the sodium pump has to work harder to rid the cells of sodium, there is greater loss of membrane phospholipid, resulting in an increased fragility of the membrane, and the energy and oxygen requirements increase. A large number of red cells are destroyed in the spleen, where there is a relative deficiency of both glucose and oxygen.

The clinical presentation is generally in childhood, but may be delayed until later life. Mild intermittent jaundice is associated with mild anaemia, splenomegaly and gallstones. Circulating bilirubin is not conjugated with glucuronic acid, and is not therefore excreted in the urine as it is bound to albumin. Excretion of the resulting bilirubin complex by the liver favours the formation of pigment gallstones. Once the disease manifests itself, spontaneous remissions are uncommon; the patient is...
often pale and jaundiced at presentation and, in established cases, lassitude and undue fatigue are present.

In some families, the disease is characterised by a severe crisis of red blood cell destruction, during which the erythrocyte count may fall from \(4.5 \times 10^6\) to \(1.5 \times 10^6\)/mL within a week. Such crises are characterised by the onset of pyrexia, abdominal pain, nausea, vomiting and extreme pallor followed by increased jaundice. These episodes may be precipitated by acute infection. Any child with gallstone disease should be investigated for hereditary spherocytosis and a family history sought.

Examination reveals splenomegaly, and the liver may also be palpable. Chronic leg ulcers may arise in adults with the disease.

Haematological investigations include the fragility test. Erythrocytes begin to haemolys e in 0.47 per cent saline solution but, in this condition, haemolysis may occur in 0.6 per cent or even stronger solutions. Immature red blood cells (reticulocytes), which differ from adult cells by possessing a reticulum, are discharged into the circulation by the bone marrow to compensate for the loss of erythrocytes by haemolysis.

Faecal urobilinogen is increased as this route excretes most of the urobilinogen.

Radioactive chromium \(^{51}\text{Cr}\) labelling of the patient's own red cells will demonstrate the severity of red cell destruction. Daily scanning over the spleen will show the degree of red cell sequestration by the spleen. The presence of high levels of splenic radioactivity generally predicts a good response to splenectomy, but this test is used less commonly.

All patients with hereditary spherocytosis should be treated by splenectomy but, in juvenile cases, this is generally delayed until six years of age to minimise the risk of post-splenectomy infection, but before gallstones have had time to form. Ultrasoundography should be performed preoperatively to determine the presence or absence of gallstones.

**Acquired autoimmune haemolytic anaemia**

This condition is divided into immune and non-immune-mediated forms. It may arise following exposure to agents such as chemicals, infection or drugs, e.g. alpha-methylidopa, or be associated with another disease (e.g. systemic lupus erythematosus). In most instances, the cause is unknown, and red cell survival is reduced because of an immune reaction triggered by immunoglobulin or complement on the red cell surface. This results in an immune-mediated destruction of the red cell, which porphyrinuria occurs. Abdominal crises, characterised by the administration of barbiturates. The patient is anaemic and may suffer from photosensitivity; in advanced forms of the disease, neurological and mental symptoms are present. The splenomegaly associated with this condition may be overlooked. The urine may be orange and develops a port-wine colour after
a few hours of exposure to the air. Splenectomy has little role to play in the management of this condition.

**Gaucher’s disease**

This lipid storage disease is characterised by storage of glucocerebroside in the reticuloendothelial system and in the spleen. Enormous splenic enlargement may be associated with yellowish-brown discolouration of the skin on the hands and face, anaemia and conjunctival thickening (pinguecula). Slavonic and Jewish races are more prone to the disease, and the detection of Gaucher cells in the bone marrow confirms the diagnosis. Splenectomy is indicated only for severe symptoms related to the splenomegaly.

**Hypersplenism due to portal hypertension**

Splenomegaly is an invariable feature of portal hypertension (Figure 66.7) and results in the thrombocytopenia and granulocytopenia observed in these patients. These may be improved if the portal hypertension is relieved by shunt surgery or liver transplantation. Splenectomy would normally be required only in those patients whose segmental portal hypertension has resulted in symptomatic oesophagogastric varices.

**Felty’s syndrome**

Patients with rheumatoid arthritis may develop leukopenia. This is referred to as Felty syndrome if it is extreme and associated with splenomegaly. There is no definite relationship between the severity of the arthritic changes and the leukopenia and splenomegaly. Splenectomy produces only a transient improvement in the blood picture, but rheumatoid arthritis may respond to steroid therapy to which it had previously become resistant.

**NEOPLASMS**

Haemangioma is the most common benign tumour of the spleen and may rarely develop into a haemangiosarcoma that is managed by splenectomy. The spleen is rarely the site of metastatic disease. Lymphoma is the most common cause of neoplastic enlargement, and splenectomy may play a part in its management. Splenectomy may be required to achieve a diagnosis in the absence of palpable lymph nodes or to relieve the symptoms of gross splenomegaly. However, the need for staging laparotomy has largely receded with the advent of CT scanning. Its use has been restricted to those patients in whom a definite histological diagnosis of intra-abdominal disease will affect management. Thus, selected patients with stage IA or IIA Hodkin's disease may be candidates for staging laparotomy or laparoscopy. In the absence of obvious liver or intra-abdominal nodal disease, splenectomy is an integral part of the staging procedure to exclude splenic involvement, which would alter the method of treatment.

Myelofibrosis results from an abnormal proliferation of mesenchymal elements in the bone marrow, spleen, liver and lymph nodes. Most patients present over the age of 50 years, and the spleen may produce pain owing to its gross enlargement (Figure 66.8) or from splenic infarcts. Splenectomy reduces the need for transfusion and may relieve the discomfort resulting from the splenomegaly.

**SPLENECTOMY**

The common indications for splenectomy are:
- trauma resulting from an accident or during a surgical procedure, as for example during mobilisation of the oesophagus, stomach, distal pancreas or splenic flexure of the colon;
- removal en bloc with the stomach as part of a radical gastrectomy or with the pancreas as part of a distal or total pancreatectomy;
- to reduce anaemia or thrombocytopenia in splenectomy, idiopathic thrombocytopenic purpura or hypersplenism;
- in association with shunt or variceal surgery for portal hypertension (Summary box 66.2).
Indications for splenectomy

- Trauma
  - Accidental
  - Operative
- Oncological
  - Part of en bloc resection
  - Diagnostic
  - Therapeutic
- Haematological
  - Spherocytosis
  - Purpura (ITP)
  - Hypersplenism
- Portal hypertension
  - Variceal surgery

Preoperative preparation

In the presence of a bleeding tendency, transfusion of blood, fresh-frozen plasma, cryoprecipitate or platelets may be required. Coagulation profiles should be as near normal as possible at operation, and platelets should be available for patients with thrombocytopenia at operation and in the early postoperative period.

Antibiotic prophylaxis appropriate to the operative procedure should be given and consideration should be given to the risk of post-splenectomy sepsis (see below under Postoperative complications).

Technique of open splenectomy

Most surgeons use a midline or transverse left subcostal incision for open splenectomy. Rarely, a thoracoabdominal incision may be necessary for a massive spleen that is adherent to the diaphragm. Passage of a nasogastric tube following induction of the anaesthetic enables the stomach to be emptied.

In elective splenectomy, the gastrosplenic ligament is opened up, and the short gastric vessels are divided. The splenic vessels at the superior border of the pancreas are suture-ligated. The posterior surface of the spleen is exposed, the posterior leaf of the lienorenal ligament divided with long curved scissors, and the spleen rotated medially along with the tail and body of the pancreas (Figure 66.9). The pancreas is separated from the hilar vessels, which are ligated and divided. Accessory splenic tissue in the splenic hilum or omentum should be excluded by a careful search at operation. There is no need to drain the wound if haemostasis is secured adequately.

The segmental vasculature of the spleen does make it possible to undertake limited resection of the parenchyma. Haemostasis can be achieved by ligation of, or application of, metal clips to intrasplenic vessels, and by careful application of topical haemostatic agents or mesh. Conservative splenic surgery is therefore possible in some cases of splenic trauma and other pathology, such as splenic cysts.

Technique of laparoscopic splenectomy

The patient is placed on the right side with the space between the left ilium and costal margin exposed. Placement of access ports is often determined by the size of the patient and the spleen. Insufflation of the abdomen can be performed once access is obtained through an incision 1 cm from the costal margin at the left mid-clavicular line. A further trocar is inserted close to the costal margin below the xiphoid. A 12-mm trocar is inserted at a similar distance from the costal margin at the posterior axillary line. The splenocolic ligament is divided to give access to the lower splenic pole. The spleen is separated from the kidney and diaphragm before the gap between the splenic hilum and the tail of the pancreas is enlarged. The spleen is elevated to expose the splenic hilum, which is secured and divided with an endoscopic vascular stapler (Figure 66.10). Two or three applications of the instrument may be required to secure the hilum and the short gastric vessels. Any remaining attachments to the diaphragm are divided before a self-retaining opening bag is introduced through the incision of the open laparoscopy after removal of the 12-mm port. The spleen is placed in the bag, the mouth of which is pulled out of the abdominal opening before the spleen is crushed and retrieved with an instrument. The operation may be undertaken as a hand-assisted procedure particularly when the spleen is grossly enlarged.

Figure 66.9 Diagrammatic view of the approach required to divide the short gastric vessels anteriorly and the lienorenal ligament posteriorly.

Figure 66.10 Photograph showing a stapling gun across the hilus of spleen for division of the splenic vessels during laparoscopic splenectomy.
Postoperative complications

Immediate complications specific to splenectomy include haemorrhage resulting from a slipped ligature. Haematemesis from gastric mucosal damage and gastric dilatation is uncommon. Left basal atelectasis is common, and a pleural effusion may be present. Adjacent structures at risk during the procedure include the stomach and pancreas. A fistula may result from damage to the greater curvature of the stomach during ligation of the short gastric vessels. Damage to the tail of the pancreas may result in pancreatitis, a localised abscess or a pancreatic fistula. Postoperative thrombocytosis may arise and, if the blood platelet count exceeds $1 \times 10^6$/mL, prophylactic aspirin is recommended to prevent axillary or other venous thrombosis.

Post-splenectomy sepsicaemia may result from Streptococcus pneumoniae, Neisseria meningitides, Haemophilus influenzae and Escherichia coli. The risk is greater in the young patient, in spleenectomised patients treated with chemotherapy and in patients who have undergone splenectomy for thalassaemia, sickle cell disease and autoimmune anaemia or thrombocytopenia.

Opportunist post-splenectomy infection (OPSI) is a major concern. Published guidelines emphasise that most infections after splenectomy could be avoided by measures that include offering patients appropriate and timely immunisation, antibiotic prophylaxis, education and prompt treatment of infection. The benefit of prophylactic antibiotics in this setting remains controversial. It is thought that children who have undergone splenectomy before the age of five years should be treated with a daily dose of penicillin until the age of ten years. Prophylaxis in older children should be continued at least until the age of 16 years, but its use is less well defined in adults. Furthermore, compliance is problematic in the long term but, as the risk of overwhelming sepsis is greatest within the first 2–3 years after splenectomy, it seems reasonable to give prophylaxis during this time. However, all patients with compromised immune function should receive prophylaxis. Satisfactory oral prophylaxis can be obtained with penicillin, erythromycin or amoxicillin, or co-amoxiclav. Suspected infection can be treated intravenously with these same antibiotics and cefotaxime, ceftriaxone or chloramphenicol in patients allergic to penicillin and cephalosporins. If elective splenectomy is planned, consideration should be given to vaccinating against pneumococci, meningococci C (both repeated every five years) and H. influenzae type B (Hib) (repeated every ten years). The latter two vaccines are commonly delivered as a combined preparation. Yearly influenza vaccination has been recommended as there is some evidence that it may reduce the risk of secondary bacterial infection. Such vaccinations should be administered at least 2 weeks before elective surgery or as soon as possible after recovery from surgery but before discharge from hospital. Pneumococcal vaccination is recommended in those patients aged over two years. Haemophilus influenzae type b vaccination is recommended irrespective of age. Asplenic patients should carry a medical alert and an up-to-date vaccination card. They require specific advice regarding travel and animal handling. Patients who have undergone splenectomy and are travelling to countries where malaria is present are strongly advised to use all physical anti-mosquito barriers, as well as anti-malarial therapy, since they are at increased risk of severe malaria. Overwhelming post-splenectomy sepsis due to Capnocytophaga canimorsus may result from dog, cat or other animal bites.

In the trauma victim, vaccination can be given in the postoperative period, and the resulting antibody levels will be protective in the majority of cases. Antibody levels are, however, less than 50 per cent of those achieved if vaccination is given in the presence of an intact spleen. Protection following vaccination is not always guaranteed (Summary box 66.3).

Summary box 66.3

**Splenectomy**
- Remember preoperative immunisation
- Prophylactic antibiotics in the long term
- OPSI is a real clinical danger
- Splenic conservation should be considered

The spleen dislikes, distrusts and devours spheroidal red cells.

Arthur Rendle Short 1880–1953
Professor of Surgery, University of Bristol, UK

Albert Ludwig Siegmund Neisser, 1835–1916, Director of the Dermatological Institute, Breslau, Germany (now Wroclaw, Poland).

Theodor Escherich, 1857–1911, Professor of Paediatrics, Austria, Vienna.
The gall bladder lies on the underside of the liver in the main liver scissura at the junction of the right and left lobes of the liver. The relationship of the gall bladder to the liver varies between being embedded within the liver substance to being suspended by a mesentry. It is a pear-shaped structure, 7.5–12 cm long, with a normal capacity of about 25–30 mL. The anatomical divisions are a fundus, a body and a neck that terminates in a narrow infundibulum. The muscle fibres in the wall of the gall bladder are arranged in a criss-cross manner, being particularly well developed in its neck. The mucous membrane contains indentations of the mucosa that sink into the muscle coat; these are the crypts of Luschka.

The cystic duct is about 3 cm in length, but the length is variable. The lumen is usually 1–3 mm in diameter. The mucosa of the cystic duct is arranged in spiral folds known as the ‘valves of Heister’ and the wall is surrounded by a sphincteric structure called the ‘sphincter of Lütkens’. The cystic duct joins the supraduodenal segment of the common hepatic duct in 80 per cent of cases; however, the anatomy may vary and the junction may be much lower in the retroduodenal or even retropancreatic part of the bile duct. Occasionally, the cystic duct may join the right hepatic duct or even a right hepatic sectorial duct (see below).

The common hepatic duct is usually less than 2.5 cm long and is formed by the union of the right and left hepatic ducts. The common bile duct is about 7.5 cm long and formed by the junction of the cystic and common hepatic ducts. It is divided into four parts:

- **Supraduodenal portion.** About 2.5 cm long, running in the free edge of the lesser omentum.
- **Retroduodenal portion.**
- **Intraduodenal portion** lies in a groove, but at times in a tunnel, on the posterior surface of the pancreas.

**Intraduodenal portion** passes obliquely through the wall of the second part of the duodenum, where it is surrounded by the sphincter of Oddi, and terminates by opening on the summit of the ampulla of Vater.

The cystic artery, a branch of the right hepatic artery, usually arises behind the common hepatic duct (Figure 67.1).

---

**LEARNING OBJECTIVES**

- To understand the anatomy and physiology of the gall bladder and bile ducts
- To be familiar with the pathophysiology and management of gallstones
- To be aware of unusual disorders of the biliary tree
- To be aware of malignant disease of the gall bladder and bile ducts

---

**SURGICAL ANATOMY AND PHYSIOLOGY**

The gall bladder and bile ducts

Occasionally, an accessory cystic artery arises from the gastroduodenal artery. In 15 per cent of cases, the right hepatic artery and/or the cystic artery cross in front of the common hepatic duct and the cystic duct.

Calot’s triangle or the hepatobiliary triangle is the space bordered by the cystic duct inferiorly, the common hepatic artery medially and the superior border of the cystic artery. This was described in 1891 by Jean-François Calot. It is an important surgical landmark and should be identified by surgeons performing a cholecystectomy to avoid damage to the extrahepatic biliary system (Figure 67.2a).

The most dangerous anomalies are where the hepatic artery takes a tortuous course on the front of the origin of the cystic duct (Figure 67.2b), or the right hepatic artery is tortuous and the cystic artery short (Figure 67.2c). The tortuosity is known as the ‘caterpillar turn’ or ‘Moynihan’s hump’. This variation is the cause of many problems during a difficult cholecystectomy with inflammation in the region of the cystic duct.

### Lymphatics

The lymphatic vessels of the gall bladder (subserosal and submucosal) drain into the cystic lymph node of Lund (the sentinel lymph node), which lies in the foramen created by the junction of the cystic and common hepatic ducts. Efferent vessels from this lymph node go to the hilum of the liver, and to the coeliac lymph nodes. The subserosal lymphatic vessels of the gall bladder also connect with the subcapsular lymph channels of the liver, and this accounts for the frequent spread of carcinoma of the gall bladder to the liver.

### Surgical physiology

Bile is produced by the liver and stored in the gall bladder from which it is released into the duodenum. As it leaves the liver, it is composed of 97 per cent water, bile salts (cholic and cheno-
deoxycholic acids, deoxycholic and lithocholic acids), phospholipids, cholesterol and bilirubin. The liver excretes bile at a rate estimated to be approximately 40 mL/hour. About 95 per cent of bile salts are reabsorbed in the terminal ileum (enterohepatic circulation).

**FUNCTIONS OF THE GALL BLADDER**

The gall bladder is a reservoir for bile. During fasting, resistance to flow through the sphincter of Oddi is high, and bile excreted by the liver is diverted to the gall bladder. After feeding, the resistance to flow through the sphincter is reduced, the gall bladder contracts and the bile enters the duodenum. These motor responses of the biliary tract are in part effected by the hormone cholecystokinin.

The second function of the gall bladder is concentration of bile by active absorption of water, sodium chloride and bicarbonate by the mucous membrane of the gall bladder. The hepatic bile which enters the gall bladder becomes concentrated 5–10 times, with a corresponding increase in the proportion of bile salts, bile pigments, cholesterol and calcium.

The third function of the gall bladder is the secretion of mucus – approximately 20 mL is produced per day. With complete obstruction of the cystic duct in an otherwise healthy gall bladder, a mucocoele may develop as a result of ongoing mucus secretion by the gall bladder mucosa.

**RADIOLOGICAL INVESTIGATION OF THE BILIARY TRACT**

**Plain x-rays**

The skillfully taken plain x-ray of the gall bladder will show radiopaque gallstones in 10 per cent of patients (Figure 67.3). Rarely, the centre of a stone may contain radiolucent gas in a triradiate or biradiate fissure and this gives rise to characteristic dark shapes on a radiograph – the ‘Mercedes–Benz’ or ‘seagull’ sign.

A plain x-ray may also show the rare cases of calcification of the gall bladder, a so-called ‘porcelain’ gall bladder (Figure 67.4). Today, this is more commonly seen on computed tomography (CT) scan (Figure 67.5). The importance of this appearance is that it is associated with carcinoma in up to 25 per cent of cases and is an indication for cholecystectomy. Gas may be seen in the wall of the gall bladder (emphysematous cholecystitis) (Figure 67.6). Gas in the biliary tree may be seen after endoscopic sphincterotomy or surgical anastomosis.
Oral cholecystography and intravenous cholangiography

Oral and intravenous cholecystography are of interest for historical purposes only, as they were relatively inaccurate and have been replaced by more accurate imaging modalities.

Ultrasonography

Transabdominal ultrasonography (Figures 67.7 and 67.8) is the initial imaging modality of choice as it is accurate, readily available, inexpensive and quick to perform. However, it is operator dependent and may be suboptimal due to excessive body fat and intraluminal bowel gas. It can demonstrate biliary calculi, the size of the gall bladder, the thickness of the gall bladder wall, the presence of inflammation around the gall bladder, the size of the common bile duct and, occasionally, the presence of stones within the biliary tree.

In the patient who presents with obstructive jaundice, ultrasonography is particularly helpful as it can identify intra- and extrahepatic biliary dilation and often the level of obstruction. In addition, the cause of the obstruction may also be identified, such as gallstones in the gall bladder, common hepatic or common bile duct stones or lesions in the wall of the common bile duct suggestive of a cholangiocarcinoma or enlargement of the pancreatic head indicative of a pancreatic carcinoma.

Endoscopic ultrasonography utilises a specially designed endoscope with an ultrasound transducer at its tip which allows the gastroenterologist to visualise the liver and biliary tree from within the stomach and duodenum (Figure 67.9). It is an accurate technique to determine the presence of stones in the common bile duct. In addition, it has been shown to be highly accurate in diagnosing and staging both pancreatic and peri-ampullary cancers.
Radioisotope scanning

Technetium-99m ($^{99m}$Tc)-labelled derivatives of iminodiacetic acid (HIDA, IODIDA) when injected intravenously are selectively taken up by the retroendothelial cells of the liver and excreted into the bile. This allows for visualisation of the biliary tree and gall bladder. In 90 per cent of normal individuals the gall bladder is visualised within 30 minutes following injection with 100 per cent being seen within 1 hour (Figure 67.10). The bowel is seen usually within 1 hour in the majority of patients. Non-visualisation of the gall bladder is suggestive of acute cholecystitis. If the patient has a contracted gall bladder as often seen in chronic cholecystitis, the gall bladder visualisation may be reduced or delayed.

Biliary scintigraphy may also be helpful in diagnosing bile leaks and iatrogenic biliary obstruction. When there is a suspicion of a bile leak following a cholecystectomy, radioisotope imaging should be one of the initial investigations performed. It can identify and quantify the leak thus helping the surgeon determine whether or not an operative or conservative approach is warranted. If available, endoscopic retrograde cholangiopancreatography (ERCP) should be considered as this is both diagnostic and potentially therapeutic. The most common bile leak following cholecystectomy is from the cystic duct. This can be treated by the gastroenterologist placing a biliary endoprosthesis (stent) in the common bile duct across the origin of the cystic duct.

Computed tomography

Unlike ultrasonography, CT is less affected by body habitus and is not operator dependent. It allows visualisation of the liver, bile ducts, gall bladder and pancreas (Figure 67.11) and is particularly useful in detecting hepatic and pancreatic lesions and is the modality of choice in the staging of cancers of the liver, gall bladder, bile ducts and pancreas. It can identify the extent of the primary tumour and defines its relationship to other organs and blood vessels (Figure 67.12). In addition, the presence of enlarged lymph nodes or metastatic disease can be seen.

Improvements in CT technology, such as multidetector scanners, which allow for three-dimensional reconstruction of the biliary tree have led to greater diagnostic accuracy and have increased the accuracy of CT in assessing benign disease.

Magnetic resonance cholangiopancreatography

Magnetic resonance cholangiopancreatography (MRCP) is an imaging technique based on the principles of nuclear magnetic resonance used to image the gall bladder and biliary system. It is non-invasive and can provide either cross-sectional or projection images (Figures 67.13 and 67.14). Excellent images can be obtained of the biliary tree demonstrating ductal obstruction, strictures or other intraductal abnormalities. Images comparable to those obtained at ERCP or percutaneous transhepatic cholangiography (PTC) can be achieved non-invasively without the potential complications of either technique.

Endoscopic retrograde cholangiopancreatography

This technique remains widely used as both a diagnostic and therapeutic modality. Using a side-viewing endoscope the ampulla of Vater can be identified and cannulated. Injection
of water-soluble contrast directly into the bile duct provides excellent images of the ductal anatomy (Figure 67.15) and can identify causes of obstruction, such as calculi (Figure 67.16) or malignant strictures (Figure 67.17). While the widespread availability of ultrasound and MRCP has reduced its diagnostic use, ERCP still has a real role in the assessment of the patient with obstructive jaundice. In this group of patients, it is especially useful in determining the cause and level of obstruction.

During ERCP, bile aspirates can be sent for cytological and microbiological examination, and endoluminal brushings can be taken from strictures for cytological studies. Therapeutic interventions, such as stone removal or stent placement to relieve the obstruction, can be performed. Thus, ERCP has evolved into a mainly therapeutic rather than a diagnostic technique.

**Percutaneous transhepatic cholangiography**

This is an invasive technique in which the bile ducts are cannulated directly. It is only undertaken once a bleeding tendency has been excluded and the patient’s prothrombin time is normal. Antibiotics should be given prior to the procedure. Usually, under fluoroscopic control, a needle (the Chiba or Okuda needle) is introduced percutaneously into the liver substance. Under radiological control (either ultrasound or CT), a bile duct is cannulated. Successful entry is confirmed by contrast injection or aspiration of bile. Water-soluble contrast medium is injected to demonstrate the biliary system. Multiple images can be taken demonstrating areas of strictures or obstruction (Figure 67.18). Bile can be sent for cytology. In addition, this technique enables placement of a catheter into the bile ducts to provide external biliary drainage or the insertion of indwelling stents. The scope of this procedure can be further extended by leaving...
the drainage catheter in situ for a number of days and then dilating the track sufficiently for a fine flexible choledochoscope to be passed into the intrahepatic biliary tree in order to diagnose strictures, take biopsies and remove stones.

In general, if a malignant stricture at the level of the confluence of the right and left hepatic ducts or higher is suspected in a jaundiced patient, a PTC is preferred to ERCP as successful drainage is more likely (Summary box 67.1).

Summary box 67.1

Investigation of the biliary tree
- Ultrasound: stones and biliary dilation
- Plain radiograph: calcification
- MRCP: anatomy and stones
- MDR-CT scan: anatomy liver, gall bladder and pancreas cancer
- Radioisotope scanning (HIDA scan): function
- ERCP: anatomy, stones and biliary strictures
- PTC: anatomy and biliary strictures
- Endoscopic ultrasound (EUS): anatomy, stones

Intraoperative imaging techniques

Peroperative cholangiography

During open or laparoscopic cholecystectomy, a catheter can be placed in the cystic duct and contrast injected directly into the biliary tree. The technique defines the anatomy and in the main is used to exclude the presence of stones within the bile ducts (Figures 67.19, 67.20 and 67.21). A single x-ray plate or image intensifier can be used to obtain and review the images intraoperatively. Irrespective of the technique used, the operating table should be tilted head down approximately 20° to facilitate

Figure 67.18 Transhepatic cholangiogram showing a stricture of the common hepatic duct (courtesy of Miss Phyllis George, FRCS, London, UK).

Figure 67.19 Preoperative cholangiography using a radiolucent table-top.

Figure 67.20 Peroperative cholangiography. Technique of introducing contrast.

Figure 67.21 Peroperative cholangiography. (a) Normal common bile duct: gentle infusion of contrast which passes without hindrance into the duodenum. (b) The common bile duct is dilated with multiple stones. Contrast is seen to reflux into the pancreatic duct. A sphincterotomy was performed.
filling of the intrahepatic ducts. In addition, care should be taken when injecting contrast not to introduce air bubbles into the system as these may give the appearance of stones and lead to a false-positive result.

**Operative biliary endoscopy (choledochoscopy)**

At operation, a flexible fiberoptic endoscope can be passed via the cystic duct into the common bile duct enabling stone identification and removal under direct vision. The technique can be combined with an x-ray image intensifier to ensure complete clearance of the biliary tree. After exploration of the bile duct, a tube can be left in the cystic duct remnant or in the common bile duct (a T-tube) and drainage of the biliary tree established. After 7–10 days, a track will be established. This track can be used for the passage of a choledochoscope to remove residual stones in the awake patient in an endoscopy suite. This technique is invaluable in the management of difficult stone disease and prevents the excessive prolongation of an operative exploration of the common bile duct.

**Laparoscopic ultrasonography**

At laparoscopy, the use of a laparoscopic ultrasound probe can be used to image the extrahepatic biliary system. It is a useful technique in biliary and pancreatic tumour staging as it can identify the primary tumour and determine its relationship to major vessels, such as the hepatic artery, superior mesenteric artery, portal vein and superior mesenteric vein.

## CONGENITAL ABNORMALITIES OF THE GALL BLADDER AND BILE DUCTS

### Embryology

The hepatic diverticulum arises from the ventral wall of the foregut and elongates into a stalk to form the choledochus. A lateral bud is given off, which is destined to become the gall bladder and cystic duct. The embryonic hepatic duct sends out many branches which join up the canaliculi between the liver cells. As is usual with embryonic tubular structures, hyperplasia obliterates the lumina of this ductal system; normally, recanalisation subsequently occurs and bile begins to flow. During early fetal life, the gall bladder is entirely intrahepatic.

### Absence of the gall bladder

Occasionally, the gall bladder is absent. Failure to visualise the gall bladder is not necessarily a pathological problem.

### The Phrygian cap

The Phrygian cap (Figure 67.22) is present in 2–6 per cent of cholecystograms and may be mistaken for a pathological deformity of the organ. ‘Phrygian cap’ refers to hats worn by the people of Phrygia, an ancient country of Asia Minor; it was rather like a liberté cap of the French Revolution.

### Floating gall bladder

The gall bladder may hang on a mesentery, which makes it liable to undergo torsion.

### Absence of the cystic duct

This is usually a pathological, as opposed to an anatomical, anomaly and indicates the recent passage of a stone or the presence of a stone at the lower end of the cystic duct, which is ulcerating into the common bile duct. The main danger at surgery is damage to the bile duct, and particular care to identify the correct anatomy is essential before division of any duct.

### Low insertion of the cystic duct

The cystic duct opens into the common bile duct near the ampulla. All variations of this anomaly can occur (Figure 67.23). At operation, they are not important. Dissection of a cystic duct which is inserted low in the bile duct should be avoided, as removal will damage the blood supply to the common bile duct and can lead to stricture formation.

### An accessory choledystohepatic duct

Ducts passing directly into the gall bladder from the liver are not uncommon. Larger ducts should be closed, but before doing so the precise anatomy should be carefully ascertained to ensure a right hepatic duct is not being ligated (Figure 67.23).

## EXTRAHEPATIC BILIARY ATRESIA

### Aetiology and physiology

Atresia is present in approximately 1 per 12 000 live births, and affects males and females equally. The extrahepatic bile
CONGENITAL DILATATION OF THE INTRAHEPATIC DUCTS (CAROLI’S DISEASE)

This rare condition is characterised by multiple irregular sacular dilatations of the intrahepatic ducts separated by segments of normal or stenotic ducts with a normal extrahepatic biliary system. The aetiology is unknown, but it is considered to be hereditary. It can be divided into a simple and periportal fibrotic type. The periportal fibrotic type presents in childhood and is associated with biliary stasis, stone formation and cholangitis, whereas the simple type presents later with episodes of...

Clinical features

About one-third of patients are jaundiced at birth. In all, however, jaundice is present by the end of the first week and deepens progressively. Liver function tests show an obstructive pattern with elevated bilirubin and alkaline phosphatase. The meconium may be a little bile stained, but later the stools are pale and the urine is dark. Prolonged steatorrhoea gives rise to osteomalacia (biliary rickets). Pruritus is severe. Clubbing and skin xanthomas, probably related to a raised serum cholesterol, may be present.

Differential diagnosis

This includes any form of jaundice in a neonate giving a cholestatic picture. Examples are alpha-antitrypsin deficiency, cholestasis associated with intravenous feeding, choledochal cyst and inspissated bile syndrome. Neonatal hepatitis is the most difficult to differentiate. Both extrahepatic biliary atresia and neonatal hepatitis are associated with giant cell transformation of the hepatocytes. Liver biopsy and radionuclide excretion scans are essential.

Treatment

Patent segments of proximal bile duct are found in 10 per cent of type I lesions. A direct Roux-en-Y hepaticojejunostomy will achieve bile flow in 75 per cent, but progressive fibrosis results in disappointing long-term results. A simple biliary-enteric anastomosis is not possible in the majority of cases in which the proximal hepatic ducts are either very small (type II) or atretic (type III). These are treated by the Kasai procedure, in which radical excision of all bile duct tissue up to the liver capsule is performed. A Roux-en-Y loop of jejunum is anastomosed to the exposed area of liver capsule above the bifurcation of the portal vein creating a portoenterostomy. The chances of achieving effective bile drainage after portoenterostomy are maximal when the operation is performed before the age of 8 weeks, and approximately 90 per cent of children whose bilirubin falls to within the normal range can be expected to survive for ten years or more. Early referral for surgery is critical.

Postoperative complications include bacterial cholangitis, which occurs in 40 per cent of patients. Repeated attacks lead to hepatic fibrosis and 50 per cent of long-term survivors develop portal hypertension, with one-third having variceal bleeding.

Liver transplantation should be considered in children in whom a portoenterostomy is unsuccessful. Results are improving with 70–80 per cent alive two to five years following transplant.
abdominal pain and biliary sepsis. Associated conditions include congenital hepatic fibrosis, polycystic liver and, rarely, cholangiocarcinoma. The mainstays of treatment are antibiotics for the cholangitis and the removal of calculi. As the condition can be limited to one lobe of the liver, lobectomy may be indicated.

**Choledochal cyst**

Cystic disease of the biliary system is rare. Choledochal cysts are congenital dilations of the intra- and/or extrahepatic biliary system. The pathogenesis is unclear. Anomalous junctions of the biliary pancreatic junction are frequently observed, but whether or not these play a role in the pathogenesis of the condition is unclear. Todani and colleagues proposed a classification of cystic disease of the biliary tract (Figure 67.25). Type I cysts are the most common and account for approximately 75 per cent of patients.

Patients may present at any age with jaundice, fever, abdominal pain and a right upper quadrant mass on examination, however, 60 per cent of cases are diagnosed before the age of ten years. Pancreatitis is not an infrequent presentation in adults. Patients with choledochal cysts have an increased risk of developing cholangiocarcinoma with the risk varying directly with the age at diagnosis.

Ultrasonography will confirm the presence of an abnormal cyst and magnetic resonance imaging (MRI/MRCP) will reveal the anatomy, in particular the relationship between the lower end of the bile duct and the pancreatic duct. CT is also useful for delineating the extent of the intra- or extrahepatic dilatation.

Radical excision of the cyst is the treatment of choice with reconstruction of the biliary tract using a Roux-en-Y loop of jejunum. Complete resection of the cyst is important because of the association with the development of cholangiocarcinoma. Resection and Roux-en-Y reconstruction is also associated with a reduced incidence of stricture formation and recurrent cholangitis.

**TRAUMA**

Injuries to the gall bladder and extrahepatic biliary tree are rare. They occur as a result of blunt or penetrating abdominal trauma. Operative trauma is perhaps more frequent than external trauma. The physical signs are those of an acute abdomen. Management depends on the location and extent of the biliary and associated injury. In the stable patient, a transsected bile duct is best repaired by a Roux-en-Y choledochojejunostomy. Injuries to the gall bladder can be dealt with by cholecystectomy.

**TORSION OF THE GALL BLADDER**

This is very rare and requires a long mesentery, which often occurs in an older patient with a large mucocoele of the gall bladder. The patient presents with extreme pain and an acute abdomen. Immediate exploration is indicated, with cholecystectomy as the only treatment.

**GALLSTONES (CHOLELITHIASIS)**

Gallstones are the most common biliary pathology. It is estimated that gallstones affect 10–15 per cent of the population in western societies. They are asymptomatic in the majority of cases (>80 per cent). In the UK, the prevalence of gallstones at the time of death is estimated to be 17 per cent and may be increasing. Approximately, 1–2 per cent of asymptomatic patients will develop symptoms requiring surgery per year, making cholecystectomy one of the most common operations performed by general surgeons.

**Causal factors in gallstone formation**

Gallstones can be divided into three main types: cholesterol, pigment (brown/black) or mixed stones. In the United States and Europe, 80 per cent are cholesterol or mixed stones, whereas in Asia, 80 per cent are pigment stones. Cholesterol or mixed stones contain 51–99 per cent pure cholesterol plus an admixture of calcium salts, bile acids, bile pigments and phospholipids.

Cholesterol, which is insoluble in water, is secreted from the canalicular membrane in phospholipid vesicles. Whether cholesterol remains in solution depends on the concentration of phospholipids and bile acids in bile, and the type of phospholipid and bile acid. Micelles formed by the phospholipid hold cholesterol in a stable thermodynamic state. When bile is supersaturated with cholesterol or bile acid concentrations are low, unstable unilamellar phospholipid vesicles form, from which cholesterol crystals may nucleate, and stones may form. The process of gallstone formation is complex (Figure 67.26), and many areas remain unclear. Obesity, high-caloric diets and certain medications (e.g. oral contraceptives) can increase secretion of cholesterol and supersaturate the bile increasing the lithogenicity of bile. Resection of the terminal ileum, which diminishes the enterohepatic circulation, will deplete the bile acid pool and result in cholesterol supersaturation. Nucleation of cholesterol monohydrate crystals from multilamellar vesicles is a crucial step in gallstone formation. Abnormal emptying of the gall bladder function may aid the aggregation of nucleated cholesterol crystals; hence, removing gallstones without removing the gall bladder inevitably leads to gallstone recurrence.

Pigment stone is the name used for stones containing less...
than 30 per cent cholesterol. There are two types – black and brown. Black stones are largely composed of an insoluble bilirubin pigment polymer mixed with calcium phosphate and calcium bicarbonate. Overall, 20–30 per cent of stones are black. The incidence rises with age. Black stones are associated with haemolysis, usually hereditary, spherocytosis or sickle cell disease. For reasons that are unclear, patients with cirrhosis have a higher instance of pigmented stones.

Brown pigment stones contain calcium bilirubinate, calcium palmitate and calcium stearate, as well as cholesterol. Brown stones are rare in the gall bladder. They form in the bile ducts and are related to bile stasis and infected bile. Stone formation is related to the deconjugation of bilirubin deglucuronide by bacterial β-glucuronidase. Insoluble unconjugated bilirubinate precipitates. Brown pigment stones are also associated with the presence of foreign bodies within the bile ducts, such as endoprosthesis (stents), or parasites, such as Clonorchis sinensis and Ascaris lumbricoides.

**Clinical presentation**

Gallstones may remain asymptomatic, being detected incidentally as imaging is performed for other symptoms. If symptoms occur, patients typically complain of right upper quadrant or epigastric pain, which may radiate to the back. This may be described as colicky, but more often is dull and constant. Other symptoms include dyspepsia, flatulence, food intolerance, particularly to fats, and some alteration in bowel frequency. Biliary colic is typically present in 10–25 per cent of patients. This is described as a severe right upper quadrant pain which ebbs and flows associated with nausea and vomiting. Pain may radiate to the chest. The pain is usually severe and may last for minutes or even several hours. Frequently, the pain starts during the night and wakes the patient. Minor episodes of the same discomfort may occur intermittently during the day. Dyspeptic symptoms may coexist and be worse after such an attack. As the pain resolves, the patient improves and is able to eat and drink again, often only to suffer further episodes. It is of interest that a patient may have several episodes of this nature over a period of a few weeks and then no more trouble for some months. Jaundice may result if the stone migrates from the gall bladder and obstructs the common bile duct. Rarely, a gallstone can lead to bowel obstruction (gallstone ileus) (Summary box 67.2).

**Summary box 67.2**

**Effects and complications of gallstones**

- Biliary colic
- Acute cholecystitis
- Chronic cholecystitis
- Empyema of the gall bladder
- Mucocele
- Perforation
- Biliary obstruction
- Acute cholangitis
- Acute pancreatitis
- Intestinal obstruction (gallstone ileus)

When the symptoms do not resolve, but progress to continued pain with fever and leukocytosis, the diagnosis of acute cholecystitis should be considered. The differential diagnosis is given in Summary box 67.3.

**Summary box 67.3**

**Differential diagnosis of acute cholecystitis**

- Common
  - Appendicitis
  - Perforated peptic ulcer
  - Acute pancreatitis
- Rare
  - Acute pyelonephritis
  - Myocardial infarction
  - Pneumonia – right lower lobe

**Diagnosis**

A diagnosis of gallstone disease is based on the history and physical examination with confirmatory radiological studies, such as transabdominal ultrasonography and radionuclide scans (see above under Radiological investigation of the biliary tract). In the acute phase, the patient may have right upper quadrant tenderness that is exacerbated during inspiration by the examiner’s right subcostal palpation (Murphy’s sign). A positive Murphy’s sign suggests acute inflammation and may be associated with a leukocytosis and moderately elevated liver function tests. A mass may be palpable as the omentum walls off an inflamed gall bladder. Fortunately in the majority of cases, the process is limited by the stone slipping back into the body of the gall bladder and the contents of the gall bladder escaping by way of the cystic duct. This achieves adequate drainage of the gall bladder and enables the inflammation to resolve.

If resolution does not occur, an empyema of the gall bladder may result. The wall may become necrotic and perforate, with development of localised peritonitis. The abscess may then perforate into the peritoneal cavity with a septic peritonitis –
however, this is uncommon, because the inflamed gall bladder is usually localized by omentum which contains the perforation.

A palpable, non-tender gall bladder (Courvoisier’s sign) portends a more sinister diagnosis. This usually results from a distal common duct obstruction secondary to a peripancreatic malignancy. Rarely, a non-tender, palpable gall bladder results from complete obstruction of the cystic duct with reabsorption of the intraluminal bile salts and secretion of uninfected mucus secreted by the gall bladder epithelium leading to a mucocoele of the gall bladder.

**Treatment**

Most consider that it is safe to observe patients with asymptomatic gallstones, with cholecystectomy reserved for patients who develop symptoms or complications. However, prophylactic cholecystectomy may be considered for diabetic patients, those with congenital haemolytic anaemia and those patients who are undergoing bariatric surgery for morbid obesity as it has been found in these groups that the risk of developing symptoms is increased. For patients with biliary colic or cholecystitis, cholecystectomy is the treatment of choice if there are no medical contraindications.

Experience shows that in more than 90 per cent of cases, the symptoms of acute cholecystitis subside with conservative measures. Non-operative treatment is based on four principles:

- **Nil per mouth (NPO) and intravenous fluid administration until the pain resolves.**
- **Administration of analgesics.**
- **Administration of antibiotics.** As the cystic duct is blocked in most instances, the concentration of antibiotic in the serum is more important than its concentration in bile. A broad-spectrum antibiotic effective against Gram-negative aerobes is most appropriate (e.g. cefazolin, cefuroxime or gentamicin).
- **Subsequent management.** When the temperature, pulse and other physical signs show that the inflammation is subsiding, oral fluids are reinstalled followed by regular diet. Ultrasonography is performed to confirm the diagnosis. If jaundice is present, an MRCP is performed to exclude cholecystolithiasis. If there is any concern regarding the diagnosis or presence of complications, such as perforation, a CT should be performed. Cholecystectomy may be performed on the next available list, or the patient may be allowed home to return later when the inflammation has completely resolved.

Conservative treatment must be abandoned if the pain and tenderness increase; depending on the status of the patient, either operative intervention and cholecystectomy should be performed or if the patient has comorbid conditions, a percutaneous cholecystostomy can be performed by a radiologist under ultrasound control. This will usually rapidly relieve symptoms, however an interval cholecystectomy will be required once the patient’s condition has stabilised.

The timing of surgery in acute cholecystitis remains controversial with many units favouring an early intervention within the first week, whereas others suggest that a delayed approach is preferable. Early cholecystectomy during acute cholecystitis appears to be safe and shortens the total hospital stay.

Provided that the operation is undertaken within 5–7 days of the onset of the attack, the surgeon is experienced and excellent operating facilities are available, good results are achieved. Nevertheless, the conversion rate in laparoscopic cholecystectomy is higher in acute than in elective surgery. If an early operation is not indicated, one should wait approximately 6 weeks for the inflammation to subside before operating.

**EMPYEMA OF THE GALL BLADDER**

Empyema may be a sequel of acute cholecystitis or the result of a mucocoele becoming infected. The gall bladder is distended with pus. The optimal treatment is drainage (cholecystostomy, see above under Gallstones (cholelithiasis)) and, later, cholecystectomy.

**Acalculous cholecystitis**

Acute and chronic inflammation of the gall bladder can occur in the absence of stones and give rise to a clinical picture similar to calculous cholecystitis. Some patients have non-specific inflammation of the gall bladder, whereas others have one of the cholecystoses (see below). Acute acalculous cholecystitis is particularly seen in critically ill patients and those recovering from major surgery, trauma and burns. The diagnosis is often missed and the mortality rate is high.

**THE CHOLECYSTOSES (CHOLESTEROSIS, POLYPOSIS, ADENOMYOMATOSIS AND CHOLECYSTITIS GLANDULARIS PROLIFERANS)**

This is a relatively uncommon group of conditions affecting the gall bladder, in which there are chronic inflammatory changes with hyperplasia of all tissue elements.

**Cholesterosis (‘strawberry gall bladder’)**

In the fresh state, the interior of the gall bladder looks something like a strawberry; the yellow specks (submucous aggregations of cholesterol crystals and cholesterol esters) correspond to the seeds (Figure 67.27). It may be associated with cholesterol stones.

![Figure 67.27 The interior of a strawberry gall bladder (cholesterosis) (courtesy of Dr Sanjay P Thakur, Patna, India).](image)
**Cholesterol polyposis of the gall bladder**
Cholecystography shows negative shadows in a functioning gall bladder, or on ultrasound there is a well-defined polyp present. These are due either to cholesterol polyposis or adenomatous change. With high resolution ultrasonography, they are seen more frequently, and surgery is advised only if there is a change in size over time or are larger than 1 cm.

**Cholecystitis glandularis proliferans (polyp, adenomyomatosis and intramural diverticulosis)**
Figure 67.28 summarises the varieties of this condition. A polyp of the mucous membrane is fleshy and granulomatous. All layers of the gall bladder wall may be thickened, but sometimes an incomplete septum forms that separates the hyperplastic from the normal. Intraparietal ‘mixed’ calculi may be present. These can be complicated by an intramural, and later extramural, abscess and potentially fistula formation. If symptomatic, the patient is treated by cholecystectomy.

**Diverticulosis of the gall bladder**
Diverticulosis of the gall bladder is usually manifest as black pigment stones impacted in the outpouchings of the lacunae of Luschka. Diverticulosis of the gall bladder may be demonstrated by cholecystography, especially when the gall bladder contracts after a fatty meal. There are small dots of contrast medium just within and outside the gall bladder (Figure 67.29). A septum may also be present to be distinguished from the Phrygian cap. The treatment is cholecystectomy.

**Typhoid infection of the gall bladder**
Salmonella typhi or S. typhimurium can infect the gall bladder. Acute cholecystitis can occur. More frequently, chronic cholecystitis occurs, the patient being a typhoid carrier excreting the bacteria in the bile. Gallstones may be present (surgeons should not give patients their stones after their operation if there is any suspicion of typhoid!). It is debatable whether the stones are secondary to the Salmonella cholecystitis or whether pre-existing stones predispose the gall bladder to chronic infection. Salmonellae can, however, frequently be cultured from these stones. Treatment with ampicillin and cholecystectomy are indicated. In cases of penicillin allergy, a quinolone antibiotic can be used.

**CHOLECYSTECTOMY**

**Preparation for operation**
After appropriate history taking and assessment of the patient’s fitness for the procedure, a full blood count and biochemical profile should be performed to exclude anaemia and to identify abnormal liver function. A blood coagulation screen should be checked if there is a history of jaundice or liver function is abnormal. Prophylactic antibiotics should be administered either with the premedication or at the time of induction of anaesthesia. A second-generation cephalosporin is appropriate. Subcutaneous heparin or anti-embolic stockings should be prescribed. The patient must sign a consent form to indicate that he or she is fully aware of the procedure being undertaken, alternative options and the risks involved and complications that may occur (Summary box 67.4).

**Laparoscopic cholecystectomy**
The preparation and indications for cholecystectomy are the same whether it is performed by laparoscopy or by open techniques. Laparoscopic cholecystectomy is the procedure of choice for the majority of patients with gall bladder disease. The key, as in open surgery, is the identification and safe dissection of Calot’s triangle (Figure 67.30).
PART 11 | ABDOMINAL

THE GALL BLADDER AND BILE DUCTS

Figure 67.30 Operative image of a laparoscopic cholecystectomy. Laparoscopic forceps (arrow) are used to dissect Calot’s triangle.

The patient is placed supine on the operating table. Following induction and maintenance of general anaesthetic, the abdomen is prepared in a standard fashion. Pneumoperitoneum is established. A number of techniques are described. The author’s preference is to use an open subumbilical cutdown with direct visualisation of the peritoneum to place the initial port. This port will function as the camera port. An angled telescope (30°) is preferred. Many surgeons use a ‘closed’ technique using a Verres needle to establish pneumoperitoneum prior to placing the initial trocar.

Additional operating ports are inserted in the subxiphoid area and in the right subcostal area. The patient is placed in a reverse Trendelburg position slightly rotated to the left. This exposes the fundus of the gall bladder which is retracted towards the diaphragm. The neck of the gall bladder is then retracted towards the right iliac fossa exposing Calot’s triangle. This area is laid widely open by dividing the peritoneum on the posterior and on the anterior aspect. The cystic duct is carefully defined, as is the cystic artery. The gall bladder is separated from the liver bed for about 2 cm to allow for confirmation of the anatomy. Unless there are specific indications (see below), a routine cholangiogram is not performed. However, if doubt exists regarding the anatomy, a cholangiogram is warranted. Once the anatomy is clearly defined and the triangle of Calot has been laid widely open, the cystic duct and artery are clipped and divided. The gall bladder is then removed from the gall bladder bed by sharp or cautery dissection and once free removed via the umbilicus.

Open cholecystectomy

For patients in whom a laparoscopic approach is not indicated or in whom conversion from a laparoscopic approach is required an open cholecystectomy is performed.

Either an upper midline or a short right upper transverse incision is made centred over the lateral border of the rectus muscle. The gall bladder is appropriately exposed and packs are placed on the hepatic flexure of the colon, the duodenum and the lesser omentum to ensure a clear view of the anatomy of the porta hepatis. These packs may be retracted using the hand of the assistant (‘It is the left hand of the assistant that does all the work’ – Moynihan), or, alternatively, a stabilised ring retractor can be used to keep the packs in position.

An artery or Duval forceps is placed on the infundibulum of the gall bladder and the peritoneum overlying Calot’s triangle is placed on a stretch. The peritoneum is then divided close to the wall of the gall bladder and the fat in the triangle of Calot carefully dissected away to expose the cystic artery and the cystic duct. The cystic duct is cleaned down to the common bile duct, whose position is clearly ascertained. The cystic artery is tied and divided. The whole of the triangle of Calot is displayed to ensure that the anatomy of the ducts is clear and the cystic duct is then divided between ligatures (Figure 67.31). The gall bladder is then dissected away from the gall bladder bed.

Some golden rules to observe in case of difficulty:

- When the anatomy of the triangle of Calot is unclear, blind dissection should stop.
- Bleeding adjacent to the triangle of Calot should be controlled by pressure and not by blind clipping or clamping.
- When there is doubt about the anatomy, a retrograde or ‘fundus-first’ cholecystectomy dissecting on the gall bladder wall down from the fundus to the cystic duct can be helpful.
- If the cystic duct is densely adherent to the common bile duct and there is the possibility of a Mirizzi syndrome (a stone ulcerating through the neck of the gall bladder into the common hepatic duct), the infundibulum of the gall bladder should be opened, the stone removed and the infundibulum oversewn. Attempts to completely dissect out the cystic duct will only lead to common hepatic or common bile duct injury.
- A cholecystostomy is rarely indicated, but, if it has to be done, as many stones as possible should be extracted and a large Foley catheter (14 F) placed in the fundus of the gall bladder with a direct track externally. By so doing, should stones be left behind in the gall bladder, these can be subsequently extracted with a cholecystoscope.

Indications for choledochotomy

In an environment in which neither the modern diagnostic armamentarium described at the beginning of this chapter nor peroperative cholangiography is available, it is well to remember the traditional indications for choledochotomy, which are:

- palpable duct stones;
- jaundice or a history of jaundice or cholangitis;
- a dilated common bile duct;
- abnormal liver function tests, in particular a raised alkaline phosphatase.

Figure 67.31 Ligatures are passed and tied around the cystic artery and cystic duct. The grey shaded area represents Calot’s triangle.
Unless the expertise is available, it is probably inadvisable to perform a cholecodochotomy laparoscopically; rather one should rely on endoscopic techniques or convert to an open operation. The incidence of symptomatic stones in the bile duct varies from 5 to 8 per cent. These can, in the main, be dealt with endoscopically without resort to opening the duct. However, current trials suggest that in experienced hands the morbidity of the two techniques is identical.

Complications of cholecystectomy
Recovery after laparoscopic cholecystectomy is associated with less pain, enhanced recovery and faster return to normal activity. The majority of patients undergoing an elective procedure can have this procedure performed as a day case, avoiding hospital admission. Any untoward symptoms in the postoperative period, such as fevers, chills or abdominal pain require immediate investigation.

The operative mortality for cholecystectomy is less than 1 per cent. Factors increasing the risk for postoperative mortality include advanced age, comorbid conditions and acute presentation. Complications can occur in 10–15 per cent of cases. Serious complications of laparoscopic cholecystectomy fall into two major areas: access complications or bile duct injuries. The latter are rare occurring in approximately 0.5 per cent of cases. In the main, biliary injury results from poor dissection and failure to adequately define the surgical anatomy. Controversy exists as to whether or not the use of operative cholangiography reduces the incidence of bile duct injury. The majority of surgeons use cholangiography only in selected cases.

Patients who develop jaundice in the postoperative period require urgent investigation. This is especially true if the jaundice is associated with infection, a condition called cholangitis.

The first step in management is to undertake an immediate ultrasound scan. This will demonstrate whether there is intra- or extrahepatic ductal dilation. The anatomy needs to be defined by either an ERCP or a MRI. The former will also allow therapeutic manoeuvres such as removal of an obstructing stone or insertion of a stent across a biliary leak. If a fluid collection is present in the subhepatic space drainage catheters may be required. These can be inserted under radiological control or if this expertise is not available at open operation. Small biliary leaks will usually resolve spontaneously, especially if there is no distal obstruction. Should the common bile duct be damaged, the patient should be referred to an appropriate expert for reconstruction of the duct.

About 15 per cent of injuries to the bile ducts are recognised at the time of operation, in the remaining 85 per cent of cases, the injury declares itself postoperatively by: (1) a profuse and persistent leakage of bile if drainage has been provided, or bile peritonitis if such drainage has not been provided; and (2) deepening obstructive jaundice. When the obstruction is incomplete, jaundice is delayed until subsequent fibrosis renders the lumen of the duct inadequate.

Any postoperative elevation in serum bilirubin or suggestion of duct damage requires investigation and the nature of the bile duct injury clarified. The surgical repair and subsequent outcome is related to the level of injury, which is determined using the Bismuth classification.

In a debilitated patient, temporary external biliary drainage may be achieved by passing a catheter percutaneously into an intrahepatic duct. Also, stents may be passed through strictures at the time of ERCP and left to drain into the duodenum. When the general condition of the patient has improved, definitive surgery can be undertaken. The principles of surgical repair are maintenance of duct length and restoration of biliary drainage. For benign stricture or duct transection, the preferred treatment is immediate Roux-en-Y cholecdochojunostomy performed by an experienced surgeon. For a stricture of recent onset through which a guidewire can be passed, balloon dilatation with insertion of a stent is an acceptable alternative provided that the services of an experienced endoscopist are available. The outcome of such surgery is good, with 90 per cent patients having no further cholangitis or stricture formation.

Late symptoms after cholecystectomy
In up to 15 per cent of patients, cholecystectomy fails to relieve the symptoms for which the operation was performed. Such patients may be considered to have a ‘post-cholecystectomy’ syndrome. However, such problems are usually related to the preoperative symptoms and are merely a continuation of those symptoms. Full investigation should be undertaken to confirm the diagnosis and exclude the presence of a stone in the bile duct, a stone in the cystic duct stump or operative damage to the biliary tree. This is best performed by MRC or ERP, the latter which has the added advantage that if a stone is in the common bile duct it can be removed.

Post-cholecystectomy choledocholithiasis
Duct stones may occur many years after a cholecystectomy or be related to the development of new pathology, such as infection of the biliary tree or infestation by Ascaris lumbricoides or Clonorchis sinensis. Any obstruction to the flow of bile can give rise to stasis with the formation of stones within the duct. The consequences of duct stones are either obstruction to bile flow or infection. Stones in the bile ducts are more often associated with infected bile (80 per cent) than are stones in the gall bladder.

Symptoms
The patient may be asymptomatic but usually has bouts of pain, jaundice and fever. The patient is often ill and feels unwell. The term ‘cholangitis’ is given to the triad of pain, jaundice and fevers sometimes known as ‘Charcot’s triad’.

Signs
Tenderness may be elicited in the epigastrium and the right hypochondrium. In the jaundiced patient, it is useful to remember Courvoisier’s law – ‘in obstruction of the common bile duct due to a stone, distension of the gall bladder seldom occurs; the organ usually is already shrivelled’. In obstruction from other causes, distension is common by comparison. However, if there is no disease in the gall bladder and the obstruction is due to a cancer of the ampulla, pancreas or bile duct, then the gall bladder may well be distended.

Management
It is essential to determine whether the jaundice is due to liver disease, disease within the duct, such as sclerosing cholangitis, or obstruction. Ultrasound scanning, liver function tests, liver biopsy if the ducts are not dilated, and MRI or ERCP will identify the nature of the obstruction.

Jean-Martin Charcot, 1825–1893, physician, neurologist and professor of anatomical pathology, La Salpêtrière, Paris, France. His name is associated with a host of medical eponyms.
The patient may be ill. Pus may be present within the biliary tree and liver abscesses may be developing. Full supportive measures are required with rehydration, attention to clotting, exclusion of diabetes and starting the appropriate broad-spectrum antibiotics. As soon as resuscitation has taken place, relief of the obstruction is essential. Endoscopic papillotomy is the preferred first technique with a sphincterotomy, removal of the stones using a Dormia basket or the placement of a stent if stone removal is not possible (Figure 67.32 and 67.33). If this technique fails, percutaneous transhepatic cholangiography can be performed to provide drainage and subsequent percutaneous cholecodochoscopy. Surgery, in the form of choledochotomy, is now rarely used for this situation as most patients can be managed by minimally invasive techniques (Figure 67.34).

**Choledochotomy**

When faced with a sick patient whose investigations show that the cause of the cholangitis is stones in the common bile duct and minimally invasive techniques for stone extraction are not available, the surgeon has no alternative but to undertake a laparotomy. The aim of this surgery is to drain the common bile duct and remove the stones through a longitudinal incision in the duct. When the duct is clear of stones, a T-tube is inserted and the duct closed around it; the long limb is brought out on the right side and the bile allowed to drain externally. When the bile has become clear and the patient recovered, a cholangiogram is performed by the radiologist. If residual stones are found, the tube is left in place for 6 weeks so that the track is ‘mature’. The radiologist can then use the track for percutaneous removal of the stones (Figure 67.34). Once the radiologist has removed the tube, the track will close and the patient make a rapid recovery.

**Stricture of the bile duct**

The causes of benign biliary stricture are given in Summary box 67.5. Bile duct strictures may be investigated radiologically (Summary box 67.6).

---

**Summary box 67.5**

**Causes of benign biliary stricture**

- Congenital
  - Biliary atresia
- Bile duct injury at surgery
- Cholecystectomy
- Choledochotomy
- Gastrectomy
- Hepatic resection
- Transplantation
- Inflammatory
  - Stones
  - Cholangitis
  - Parasitic
  - Pancreatitis
  - Sclerosing cholangitis
- Radiotherapy
- Trauma
- Idiopathic

---

**Summary box 67.6**

**Radiological investigation of biliary strictures**

- Ultrasonography
- Cholangiography via T-tube, if present
- ERCP
- MRCP
- Percutaneous transhepatic cholangiography (Figure 67.18)
- CT scan

---

**PRIMARY SCLEROSING CHOLANGITIS**

Primary sclerosing cholangitis is an idiopathic fibrosing inflammatory condition of the biliary tree which affects both
Parasitic infestation of the biliary tract

Intrahepatic and extrahepatic ducts. It is of unknown origin, but the association of hypergammaglobulinaemia and elevated markers such as smooth muscle antibodies and antinuclear factor suggest an immunological basis. The majority of patients are between 30 and 60 years. There appears to be a male predominance and a strong association with inflammatory bowel disease especially ulcerative colitis.

Common symptoms include right upper quadrant discomfort, jaundice, pruritus, fever, fatigue and weight loss. Investigation reveals a cholestatic pattern to the liver function tests with elevation of the serum alkaline phosphatase and gamma glutamyl transferase and smaller rises in the aminotransferases. Bilirubin values can be variable and may fluctuate. Imaging studies such as MRCP or ERCP may demonstrate stricturing and beading of the bile ducts (Figure 67.35). A liver biopsy is helpful in confirming the diagnosis and may help guide therapy by excluding cirrhosis. The important differential diagnoses are secondary sclerosing cholangitis and cholangiocarcinoma. The latter condition may be very difficult to diagnose and a high index of suspicion is required especially in the setting of an unexplained deterioration.

Medical management with antibiotics, vitamin K, cholestyramine, steroids and immunosuppressant drugs, such as azathioprine, is generally unsuccessful. Endoscopic stenting of dominant strictures and, in selected patients with predominantly extrahepatic disease, operative resection may be worthwhile. For patients with cirrhosis, liver transplantation is the best option. Five-year survival following transplantation in high-volume centres is in excess of 80 per cent.

PARASITIC INFESTATION OF THE BILIARY TRACT

Biliary ascariasis

The round worm, Ascaris lumbricoides, commonly infests the intestine of inhabitants of Asia, Africa and Central America. It may enter the biliary tree through the ampulla of Vater and cause biliary pain. Complications include strictures, supplicative cholangitis, liver abscesses and empyema of the gall bladder. In the uncomplicated case, antispasmodics can be given to relax the sphincter of Oddi and the worm will return to the small intestine to be dealt with by antihelminthic drugs. Operation may be necessary to remove the worm or deal with complications. Worms can be extracted via the ampulla of Vater by ERCP.

Clonorchiasis ( Asiatic cholangiohepatitis)

The disease is endemic in the Far East. The fluke, up to 25 mm long and 5 mm wide, inhabits the bile ducts, including the intrahepatic ducts. Fibrous thickening of the duct walls occur. Many cases are asymptomatic. Complications include biliary

Figure 67.33 (a) Endoscopic sphincterotomy; (b) extraction of a stone from the bile duct through the ampulla.

Figure 67.34 Extraction of a stone from the common bile duct by the Burhenne technique. (a) A T-tube in situ with a stone in the duct. (b) A steerable catheter has been manipulated into the duct and a basket placed around the stone. (c) The stone being extracted from the bile duct along the T-tube track.
pain, stones, cholangitis, cirrhosis and bile duct carcinoma. Cholecystectomy and T-tube drainage and, in some cases, cholecdochojejunostomy are required. Because a process of recurrent stone formation is set up, a choledochojejunostomy with a Roux loop fixed to the adjacent abdominal wall is performed in some centres to allow easy subsequent access to the duct system.

**Hydatid disease**

A large hydatid cyst may obstruct the hepatic ducts. Sometimes, a cyst will rupture into the biliary tree and its contents cause obstructive jaundice or cholangitis, requiring appropriate surgery (see Chapters 6 and 65).

**TUMOURS OF THE BILE DUCT**

**Benign tumours of the bile duct**

These are uncommon and need to be distinguished from other benign conditions. They may be an incidental finding on imaging. For symptomatic patients, the duration of symptoms may vary from a few days to months and their clinical presentation may in fact mimic the more common conditions, such as cholecystitis, choledocholithiasis, cholangiocarcinoma or pancreatic cancer.

Benign neoplasms causing biliary obstruction may be classified as follows:

- papilloma and adenoma
- multiple biliary papillomatosis
- granular cell myoblastoma
- neural tumours
- leiomyoma
- endocrine tumours.

**Papilloma and adenoma**

The most common benign neoplasms arise from the glandular epithelium lining the bile ducts. They can occur throughout the biliary system, but are more frequent in the peripancreatic area. Lesions in this area may protrude through the ampulla of Vater and be visible at endoscopy. Jaundice is the most common symptom occurring in greater than 90 per cent of cases. Coexisting gallstones are uncommon.

Treatment depends on the age, general status of the patient and site of the disease, but in general should consist of total resection of the lesion. In some cases, a wide local resection can be performed.

**Papillomatosis**

This rare condition is characterised by the presence of multiple mucus-secreting tumours of the biliary epithelium. Patients present with obstructive jaundice which may be intermittent often complicated by cholangitis. These tumours have a malignant potential and should be resected. This may involve liver resection if the disease is confined to a hepatic lobe. If both lobes are affected, then liver transplantation may be required.

Granular cell myoblastoma, neural tumours, leiomyomata and endocrine tumours are extremely uncommon. In general, if biliary obstruction occurs it should be relieved by either biliary resection, bypass or endoscopic stenting.

**Malignant tumours of the biliary tract**

Malignant tumours of the gall bladder and extrahepatic biliary tree are uncommon. Gall bladder cancer is the predominant type accounting for 60–70 per cent of cases with the remainder distributed between the intra- and extrahepatic biliary tree (Summary box 67.7).

**Summary box 67.7**

**Bile duct cancer (cholangiocarcinoma)**

- Rare, but incidence increasing
- Most patients present with abnormal liver function tests or frank jaundice
- Diagnosis by ultrasound, MDR-CT or MRCP scanning
- Majority of patients receive palliative care only
- Complete surgical excision possible in less than 10 per cent
- Prognosis poor – 90 per cent dead in one year from liver failure or biliary sepsis
- Adjuvant chemoradiation therapy has limited role

Unfortunately, due to advanced stage at presentation, surgical resection, which offers the best survival, is only possible in a minority of patients. Thus for most patients treatment is generally palliative in nature and survival limited.

**Incidence**

Cholangiocarcinoma is a rare malignancy accounting for 1–2 per cent of new cancers in a western practice. The overall annual incidence is 1–1.5 per 100 000 with two-thirds of patients being older than 65 years. It appears to be more common in males with a male:female ratio of approximately 1.5:1.

Anatomically, tumours involving the biliary confluence (hilar cholangiocarcinoma or Klatskin tumours) account for 60 per cent of cases with the remainder in the distal bile duct (20–30 per cent) or intrahepatic (10–20 per cent).

**Risk factors**

A minority of patients presenting with cholangiocarcinoma are noted to have a known risk factor (Summary box 67.8). The major risk factor in western practice is primary sclerosing
tive jaundice (elevated bilirubin, alkaline phosphatase and γ-glutamyltransferase). The tumour marker CA 19-9 may also be elevated. Imaging studies, such as ultrasound, multidetector row computed tomography (MDR-CT) and MRI/MRCP, are essential for diagnosis and staging. These studies allow the level of biliary obstruction to be defined and determine the loco-regional extent of disease and the presence of metastases (Figure 67.36).

Direct cholangiography using ERCP or PTC are also used following non-invasive studies. Both can define the level of obstruction and allow access to the biliary system for biopsy and placement of endobiliary stents for biliary drainage. The choice between either modality depends on local availability and the anatomical site of the tumour with PTC preferred for more proximal lesions and ERCP favoured for distal tumours. Cytology can be obtained from either procedure, but it is often non-diagnostic.

Recent work has suggested that combined positron emission tomography (PET) and MDR-CT scanning may be useful in staging cholangiocarcinoma, but further work is required to determine the true value of this modality.

**Treatment**

A multidisciplinary approach is required in all cases. The choice of treatment depends on the site of the disease and its extent. Unfortunately, the majority of patients present with advanced disease. However, 10–15 per cent are suitable for surgical resection which offers the only hope for long-term survival. The aim of surgical resection is to achieve a complete resection with negative pathological margins and safely restore biliary-enteric continuity. Depending on the site of disease, resections may involve excision of a lobe of the liver and reconstruction of the biliary tree. With the improved techniques associated with hepatic resection, the perioperative mortality rate is now less than 5 per cent. Distal common duct tumours may require a pancreatectoduodenectomy (Whipple procedure).

Liver transplantation has been suggested by some authors for selected patients who have locally unresectable disease

---

**Summary box 67.8**

**Risk factors for cholangiocarcinoma**

- Chronic inflammatory conditions
  - Primary sclerosing cholangitis
  - Oriental cholangiohepatitis
  - Hepatitis C infection
- Parasitic infections
  - *Opisthorchis viverrini*
  - *Clonorchis sinensis*
- Congenital
  - Choledochal cysts
  - Caroli’s disease
- Chemical agents
  - Thorium dioxide (Thorotrast®)
  - Vinyl chloride
  - Dioxin
  - Asbestos
- Postsurgical
  - Biliary-enteric anastomosis

Congenital cystic disease (Carolii’s disease, choledochal cysts), hepatolithiasis, oriental cholangiohepatitis, hepatitis C viral infection and infestation with liver flukes have also been associated with an increased risk of cholangiocarcinoma. Liver fluke infestations are particularly important in South-East Asia. *Opisthorchis viverrini* and *Clonorchis sinensis* infestation is important in Thailand, Laos and western Malaysia. While the pathophysiology is unclear, it is hypothesised that these parasites cause chronic inflammation which leads to DNA changes and mutations through production of carcinogens and free radicals, which stimulate cellular proliferation in the intrahepatic bile ducts and ultimately can lead to invasive cancer.

Other risk factors suggested include chemical carcinogens, such as thorium dioxide, vinyl chloride, dioxin and asbestos.

**Clinical features**

Early symptoms of cholangiocarcinoma are often non-specific with abdominal pain, early satiety, anorexia and weight loss commonly seen. Symptoms associated with biliary obstruction (puritus and jaundice) may be present in a minority of patients. In these patients, examination often demonstrates clinical signs of jaundice, cachexia is often noticeable and a palpable gall bladder is present if the obstruction is in the distal common bile duct (Courvoisier’s sign).

**Investigations**

Biochemical investigations will confirm the presence of obstructive jaundice (elevated bilirubin, alkaline phosphatase and 

---

**Figure 67.36** A computed tomography scan demonstrating a hilar cholangiocarcinoma (arrowed).
without evidence of distant metastases. Transplantation is often combined with neoadjuvant chemoradiation therapy. While emerging data are encouraging, this aggressive approach remains unproven and is reserved for selected patients in specialised centres.

Following resection, the median survival is approximately 18 months, with 20 per cent of patients surviving five years post-resection. Survival appears better for distal tumours compared to those involving the upper third of the biliary tree. Adjuvant chemotherapy or radiotherapy has a limited role to play and has not been demonstrated to add survival benefit following surgical resection. However, patients at high risk for recurrence (positive surgical margins or node positive) may benefit from adjuvant therapy and should be referred for a medical or radiation oncology opinion.

The majority of patients who present with unresectable disease are candidates for palliative therapy. The aim is to maintain or improve quality of life by relieving symptoms and preventing cholestatic liver failure. Biliary obstruction can be relieved by either endoscopic (ERCP) or percutaneous (PTC) methods. Surgical bypass rarely has a role apart from patients who present with a distal bile duct lesion and are found to have unresectable disease at operation.

Carcinoma of the gall bladder

Incidence

This is a rare disease, but extremely variable by geographical region and racial–ethnic groups. The highest incidence is among Chileans, American Indians and residents in parts of northern India, where it accounts for as much as 9 per cent of all biliary tract disease. Women appear to have a higher incidence across all geographic areas. In western practice, gall bladder cancer accounts for less than 1 per cent of new cancer diagnoses. The disease usually presents in the seventh or eighth decade. The aetiology is unclear, but there appears to be an association with pre-existing gallstone disease suggesting that chronic inflammation may play a role in a manner similar to tumours of the common bile duct. Calcification of the gall bladder wall, presumably due to chronic inflammation (porcelain gall bladder), is also associated with an increased risk of cancer (Figure 67.5). Chronic infection may also promote development of gall bladder cancer and the risk in typhoid carriers is significantly increased over the general population.

Gall bladder polyps may be found in approximately 5 per cent of patients who undergo ultrasonography (Figure 67.37). The majority are either adenomyomatosis or cholesterol polyps and have no malignant potential. True adenomatous polyps do occur and have malignant potential (Summary box 67.9).

Summary box 67.9

Gall bladder cancer

- Very rare
- Similar presentation to benign biliary disease, i.e. gallstones
- Diagnosis by ultrasound, CT scan, MRI/MRCP
- Most patients present with advanced disease
- Surgical resection in less than 10 per cent – remainder receive palliative treatment
- Prognosis is poor – median survival approximately six months

Pathology

The majority (90 per cent) of cases are adenocarcinoma. Squamous carcinomas also occur and are believed to arise from areas of mucosal squamous metaplasia.

At operation, localised carcinomas are difficult to differentiate from chronic cholecystitis; the most commonly presenting tumour is nodular and infiltrative, with thickening of the gall bladder wall, often extending to the whole gall bladder. The tumour spreads by direct extension into the liver, seeding of the peritoneal cavity and involvement of the perihilar lymphatics and neural plexuses. At the time of presentation, the majority of tumours are advanced (Figure 67.38).

Clinical features

Patients may be asymptomatic at the time of diagnosis. Symptoms, if present, are usually indistinguishable from those of benign gall bladder disease, such as biliary colic or cholecystitis, particularly in older patients. Jaundice and anorexia are late features. A palpable mass is a late sign.
Investigation

Laboratory findings are generally non-specific, but may be consistent with biliary obstruction. Non-specific findings, such as anaemia, leukocytosis, mild elevation in transaminases and increased inflammatory markers, such as ESR or C-reactive protein, may be present. Serum CA19-9 is elevated in approximately 80 per cent of patients.

The preoperative diagnosis is often made on ultrasonography, and confirmed by a MDR-CT scan or MRI/MRCP. Preoperative staging should be aimed at determining the local extent of diseases and excluding the presence of distant metastases (Summary box 67.10). A percutaneous biopsy under radiological guidance is often done to obtain tissue for pathological examination. In selected cases, a laparoscopic examination is useful in staging the disease. Laparoscopy can detect peritoneal or liver metastases which would preclude further surgical resection (Figure 67.38).

Summary box 67.10

Aim of staging gall bladder cancer

- Assessment of local disease
- Detection of metastatic disease
  - Liver
  - Peritoneal
  - Lymphatic
  - Extra-abdominal disease

Treatment and prognosis

The majority of patients have advanced disease at presentation, and are not candidates for surgical therapy. Surgery is indicated in only very selected cases.

Cholecystectomy should be performed for all gall bladder polyps greater than 1 cm. Polyps less than 1 cm can be followed with serial ultrasonography to detect any change in size or character as the incidence of malignancy in polyps less than 1 cm is extremely low.

Radical en-bloc resections which may include segmental or extended hepatectomy, bile duct resection and regional lymphadenectomy should be considered in selected patients. The aim is to remove the tumour entirely and achieve negative histopathological margins.

Patients can have the disease diagnosed following histopathological examination of the gall bladder removed for presumed benign disease. In these cases, the need for further surgery is determined by the stage of disease. For early stage disease confined to the mucosa or muscle of the gall bladder, no further treatment is indicated. However, for transmural disease, a radical en-bloc resection of the gall bladder fossa and surrounding liver along with the regional lymph nodes should be performed. If the initial procedure was performed laparoscopically, the surgeon should examine the laparoscopic port sites. Routine resection of port sites is no longer recommended. However, it is recognised that the finding of disease at the port sites is a sign of generalised peritoneal disease and portends a very poor prognosis.

For the majority of patients, a non-operative approach to palliation is best. Obstructive jaundice can be relieved by endoscopic and/or percutaneous methods. The value of adjuvant therapy is unproven.

Gall bladder cancer for most patients is a lethal disease with a grim prognosis. The median survival is less than six months and a five-year survival figure of 5 per cent reported.

FURTHER READING

The name ‘pancreas’ is derived from the Greek ‘pan’ (all) and ‘kreas’ (flesh). For a long time, its glandular function was not understood, and it was thought to act as a cushion for the stomach. The pancreas is situated in the retroperitoneum. It is divided into a head, which occupies 30 per cent of the gland by mass, and a body and tail, which together constitute 70 per cent. The head lies within the curve of the duodenum, overlying the body of the second lumbar vertebra and the vena cava. The aorta and the superior mesenteric vessels lie behind the neck of the gland. Coming off the side of the pancreatic head and passing to the left and behind the superior mesenteric vein is the uncinate process of the pancreas. Behind the neck of the pancreas, near its upper border, the superior mesenteric vein joins the splenic vein to form the portal vein (Figures 68.1 and 68.2). The tip of the pancreatic tail extends up to the splenic hilum.

The pancreas weighs approximately 80 g. Of this, 80–90 per cent is composed of exocrine acinar tissue, which is organised into lobules. The main pancreatic duct branches into interlobular and intralobular ducts, ductules and, finally, acini. The main duct is lined by columnar epithelium, which becomes cuboidal in the ductules. Acinar cells are clumped around a central lumen, which communicates with the duct system. Clusters of endocrine cells, known as islets of Langerhans, are distributed throughout the pancreas. Islets consist of different cell types: 75 per cent are B cells (producing insulin); 20 per cent are A cells (producing glucagon); and the remainder are D cells (producing somatostatin) and a small number of pancreatic polypeptide cells. Within an islet, the B cells form an inner core surrounded by the other cells. Capillaries draining the islet cells drain into the portal vein, forming a pancreatic portal system.

There are nine key processes that occur during pancreatic embryogenesis (Table 68.1). Malrotation of the ventral bud in the fifth week results in an annular pancreas, while the mode of ductule fusion in the seventh week produces the various possible ductular patterns. Between the 12th and 40th weeks of fetal life, the pancreas differentiates into exocrine and endocrine glands.

Paul Langerhans, 1847–1888, Professor of Pathological Anatomy, Freiberg, Germany, described the islets in 1869, in his doctoral thesis. He later contracted tuberculosis, resigned and moved to warmer climes in Madeira, where he also studied marine worms.

Johann Georg Wirsung, 1589–1643, Professor of Anatomy, Padua, Italy, described the pancreatic duct in 1642, when dissecting the cadaver of a man hanged for murder. He died a year later from an assassin’s bullet, on his doorstep.
elements. The primitive ducts and their ductules are responsible for the lobular arrangement of the pancreas. Congenital anomalies of the pancreas are varied and arise during the early phase of development (Summary box 68.1). The anatomy of the pancreatic duct is variable as a result of the primordial bud development. The dorsal duct is expressed in a variable manner in the adult, as outlined in Figure 68.3. Approximately 10 per cent of patients will have a significant flow from the main duct through the accessory papilla. The anatomy of the main duodenal papilla, also known as the ampulla of Vater, is also variable (Figure 68.4). The outlet of each duct is protected by a complex sphincter mechanism (sphincter of Oddi) (Figure 68.5).

Gallstone pancreatitis is more likely with (a) and (b).
INVESTIGATIONS

Estimation of pancreatic enzymes in body fluids

When the pancreas is damaged, enzymes such as amylase, lipase, trypsin, elastase and chymotrypsin are released into the serum. Measurement of serum amylase is the most widely used test of pancreatic damage (serum lipase is more sensitive and specific, but is not widely available). The serum amylase rises within a few hours of pancreatic damage and declines over the next 4–8 days. A markedly elevated serum level is highly suspicious but not diagnostic of acute pancreatitis (Summary box 68.2). Urinary amylase and amylase–creatinine clearance ratios add little to diagnostic accuracy. If confirmation of the diagnosis is required, computed tomography (CT) of the pancreas is of greater value (Table 68.2).

Pancreatic function tests

Pancreatic exocrine function can be assessed by directly measuring pancreatic secretion in response to a standardised stimulus. The stimulus to secretion can be physiological, e.g. ingestion of a test meal, as in the Lundh test, or pharmacological, e.g. intravenous injection of a hormone, such as secretin or CCK. Duodenal intubation has to be performed with a triple-lumen tube so that the gastric and duodenal juices can be aspirated, and a non-absorbable marker, such as polyethylene glycol, is administered orally and degraded in the gut by a pancreatic enzyme, and the breakdown product (PABA) is absorbed by the intestine and excreted in the urine; its urinary level is measured. The Pancreolauryl test works on a similar principle. These tests are cheap and easy to perform, but are non-specific, especially following gastrectomy and in conditions that may alter gastrointestinal transit and intestinal absorptive capacity. Measurement of the enzyme elastase in stool is simple, specific and now used widely. A low level of faecal elastase indicates exocrine insufficiency.

Imaging investigations

Ultrasonography

Ultrasonography is the initial investigation of choice in patients with jaundice to determine whether or not the bile duct is dilated, the coexistence of gallstones or gross disease within...
the liver, such as metastases. It may also define the presence or absence of a mass in the pancreas (Figure 68.6). However, obesity and overlying bowel gas often make interpretation of the pancreas itself unsatisfactory.

**Computed tomography**
Most significant pathologies within the pancreas can be diagnosed on high-quality CT scans, with three-dimensional reconstruction if necessary. A specific pancreatic protocol should be followed. An initial unenhanced CT scan is essential to determine the presence of calcification within the pancreas and gall bladder (Figure 68.7). Then, following rapid injection of intravenous contrast, scanning is performed in the arterial and venous phases. The stomach and duodenum should be outlined with water and distended to define the duodenal loop. Pancreatic carcinomas of 1–2 cm in size can usually be demonstrated whether in the head, body or tail of the pancreas (Figure 68.8). Endocrine tumours are also well imaged on CT (Figure 68.9). In patients with pancreatitis, necrotic areas within the gland can be identified by the absence of contrast enhancement on CT. Inflammatory collections and pseudocysts can be seen (Figure 68.10). CT-guided drainage is helpful in the treatment of pancreatic collections, cysts and pseudocysts, and facilitates percutaneous fine-needle or Trucut biopsy.

**Magnetic resonance imaging**
With magnetic resonance imaging (MRI), the pancreas can be clearly identified, and the anatomy of the bile duct and the pancreatic duct, together with fluid collections, can be defined. Magnetic resonance cholangiography and pancreatography (MRCP) may well replace diagnostic endoscopic retrograde cholangiography and pancreatography (ERCP) as it is non-invasive and less expensive (Figure 68.11). Using the technique in conjunction with intravenous injection of secretin, emptying of the pancreatic duct can be demonstrated to show the absence or presence of obstruction.

**Endoscopic retrograde cholangiopancreatography**
ERCP is performed using a side-viewing fibreoptic duodenoscope. The ampulla of Vater is intubated, and contrast is

---

**Abraham Vater**, 1684–1751, Professor of Anatomy and Botany, and later of Pathology and Therapeutics, Wittenberg, Germany. Apart from the ampulla, he also described what later came to be known as Pacinian corpuscles in the skin.
injected into the biliary and pancreatic ducts to display the anatomy radiologically (Figure 68.12). In pancreatic carcinoma, the main pancreatic duct may be narrowed or completely obstructed at the site of the tumour (Figure 68.13), or the distal bile duct may be narrowed. Concurrent narrowing of both ducts results in the so-called double duct sign (Figure 68.14). Changes seen in chronic pancreatitis include the presence of pancreatic duct strictures, dilatation of the main pancreatic duct with stones, abnormalities of pancreatic duct side branches, communication of the pancreatic duct with cysts, and bile duct strictures (Figures 68.15, 68.16 and 68.17). A plain radiograph before contrast studies is essential to delineate calcification (Figure 68.18). In addition to imaging, bile or pancreatic fluid and brushings from duct strictures can yield cells that confirm the suspected diagnosis of carcinoma (Figure 68.19). Brush cytology taken from malignant strictures at the time of ERCP yields a positive diagnosis in 40–50 per cent of patients. ERCP also allows the placement of biliary and pancreatic stents.

**Endoscopic ultrasound**

Endoscopic ultrasound (EUS) is performed using a special endoscope that has a high-frequency ultrasonic transducer at its tip. When the endoscope is in the lumen of the stomach or duodenum, the pancreas and its surrounding vasculature and ducts can be imaged. EUS is particularly useful for identifying lesions within the pancreas, assessing the relationship of lesions to major blood vessels, and guiding biopsies.

**Figure 68.9** Computed tomography scan showing a hypervascular insulinoma adjacent to the splenic vein. Local excision of the tumour resulted in normoglycaemia.

**Figure 68.10** Computed tomography scan of a large pseudocyst in relation to the body and tail of the pancreas.

**Figure 68.11** Magnetic resonance cholangiopancreatography in a patient with obstructive jaundice. A dilated common bile duct was seen on ultrasound, but no pancreatic mass lesion was visible on computed tomography. The bile duct and the main pancreatic duct are seen very well, with a stone visible in the lower part of the bile duct and another in the neck of the gall bladder.

**Figure 68.12** (a) Endoscopic retrograde cholangiopancreatography: normal pancreatic duct with filling of the duct of Santorini from the duct of Wirsung. (b) Diagrammatic outline of (a).
lymph nodes can be assessed (Figure 68.20). This is particularly useful in identifying small tumours that may not show up well on CT or MRI, and in demonstrating the relationship of a pancreatic tumour to major vessels nearby. EUS can clarify the relationship of a neuroendocrine tumour to the main pancreatic duct (important if enucleation is being considered). It helps to distinguish cystic tumours from pseudocysts. Transduodenal or transgastric fine needle aspiration (FNA) or Trucut biopsy performed under EUS guidance avoids spillage of tumour cells into the peritoneal cavity.

CONGENITAL ABNORMALITIES

Cystic fibrosis

This is inherited as an autosomal recessive condition. It occurs most frequently among Caucasians, in whom it is the most common inherited disorder (incidence of 1:2500 live births in the UK). Cystic fibrosis (CF) develops when there is a mutation in the CFTR (cystic fibrosis transmembrane conductance regulator) gene on chromosome 7. This gene creates a cell membrane protein that helps to control the movement of chloride across the cell membrane.

CF is a multisystem disorder of exocrine glands that affects the lungs, intestines, pancreas and liver, and is characterised by
The mother may notice that the child is salty when kissed. Most of the organ damage is due to blockage of narrow passages by thickened secretions. Chronic pulmonary disease arises from plugging of bronchi and bronchioles. CF is the most common cause of chronic lung disease among children in developed countries. Cor pulmonale may develop later. At birth, the meconium may set in a sticky mass and produce intestinal obstruction (meconium ileus) (see Chapter 8). Secretions precipitate in the lumen of the pancreatic duct causing blockage, which results in duct ectasia and fatty replacement of exocrine acinar tissue. Pancreatic exocrine insufficiency leads to fat malabsorption. Steatorrhea is usually present from birth, resulting in stools that are bulky, oily and offensive. The islets...
of Langerhans usually appear normal, but diabetes mellitus can occur in older patients. The liver may become cirrhotic as a result of bile duct plugging, and signs of portal hypertension may appear. Infertility is common, due to the absence of the vas deferens in men and thick cervical mucus in women.

Outside the newborn period, the earliest clinical signs of CF are poor growth, poor appetite, rancid greasy stools, abdominal distension, chronic respiratory disease and finger clubbing. The appearance of secondary sexual characteristics may be delayed. The diagnosis can be made by genetic testing (which may be part of prenatal or newborn screening) and by the sweat test. Levels of sodium and chloride ions in the sweat above 90 mmol/L confirm the diagnosis.

Treatment is aimed at control of the secondary consequences of the disease. Pulmonary function is preserved with aggressive physiotherapy and antibiotics. Malabsorption is treated by administration of oral pancreatic enzyme preparations. The diet should be low in fat but contain added salt to replace the high losses in the sweat. With early diagnosis and optimal treatment, patients in the western world can now expect to survive to their mid-thirties. Those with end-stage lung disease may be considered for lung transplantation. Heterozygous carriers of the various gene mutations are asymptomatic, but can be identified by DNA analysis. There is a suggestion that such patients may develop pancreatitis later in life.

**Pancreas divisum**

Pancreas divisum occurs when the embryological ventral and dorsal parts of the pancreas fail to fuse (Figure 68.3). The dorsal pancreatic duct becomes the main pancreatic duct and drains most of the pancreas through the minor or accessory papilla. The incidence of pancreas divisum ranges from 5 per cent in an autopsy series to 10 per cent in some ERCP and MRCP series. Pancreas divisum found incidentally in an asymptomatic person does not warrant any intervention. However, the incidence of pancreas divisum ranges from 25 to 50 per cent in patients with recurrent acute pancreatitis, chronic pancreatitis and pancreatic pain. The minor papilla is substantially smaller than the major papilla (and many of these patients probably have papillary stenosis). A large volume of secretions flowing through a narrow papilla probably leads to incomplete drainage, which may then cause obstructive pain or pancreatitis. Certainly in patients with idiopathic recurrent pancreatitis, pancreas divisum should be excluded. The diagnosis can be arrived at by MRCP, EUS or ERCP, augmented by injection of secretin if necessary. There may be changes indicative of obstruction or chronic inflammation in the dorsal duct system. Endoscopic sphincterotomy and stenting of the minor papilla may relieve the symptoms. Surgical intervention can take the form of sphincteroplasty, pancreaticojejunostomy or even resection of the pancreatic head.

**Annular pancreas**

This is the result of a failure of complete rotation of the ventral pancreatic bud during development, so that a ring of pancreatic tissue surrounds the second or third part of the duodenum. It is most often seen in association with congenital duodenal stenosis or atresia and is therefore more prevalent in children with Down’s syndrome. Duodenal obstruction typically causes vomiting in the neonate (see Chapter 8). The usual treatment is bypass (duodenoduodenostomy). The disease may occur in later life as one of the causes of pancreatitis, in which case resection of the head of the pancreas is preferable to lesser procedures.

**Ectopic pancreas**

Islands of ectopic pancreatic tissue can be found in the submucosa in parts of the stomach, duodenum or small intestine (including Meckel’s diverticulum), the gall bladder, adjoining the pancreas, in the hilum of the spleen and within the liver. Ectopic pancreas may also be found in the wall of an alimentary tract duplication cyst (see Chapter 8).

**Congenital cystic disease of the pancreas**

This sometimes accompanies congenital disease of the kidneys and liver, and occurs as part of the von Hippel–Lindau syndrome.

**INJURIES TO THE PANCREAS**

**External injury**

**Presentation and management**

The pancreas, thanks to its somewhat protected location in the retroperitoneum, is not frequently damaged in blunt abdominal trauma. If there is damage to the pancreas, it is often concomitant with injuries to other viscera, especially the liver, the spleen and the duodenum. Occasionally, a forceful blow to the epigastrium may crush the body of the pancreas against the vertebral column. Penetrating trauma to the upper abdomen or the back carries a higher chance of pancreatic injury. Pancreatic injuries may range from a contusion or laceration of the parenchyma without duct disruption to major parenchymal destruction with duct disruption (sometimes complete transection) and, rarely, massive destruction of the pancreatic head. The most important factor that determines treatment is whether the pancreatic duct has been disrupted.

Blunt pancreatic trauma usually presents with epigastric pain, which may be minor at first, with the progressive development of more severe pain due to the sequelae of leakage of pancreatic fluid into the surrounding tissues. The clinical presentation can be quite deceptive; careful serial assessments and a high index of suspicion are required. A rise in serum amylase occurs in most cases. A CT scan of the pancreas will delineate the damage that has occurred to the pancreas (Figure 68.21). If there is doubt about duct disruption, an urgent ERCP should be sought. MRCP may also provide the answer, but the images can be difficult to interpret. Support with intravenous fluids and a nil by mouth regimen should be instituted while these investigations are performed. There is no need to rush to a laparotomy if the patient is haemodynamically stable, without peritonitis. It is preferable to manage conservatively at first, investigate and, once the extent of the damage has been ascertained, undertake appropriate action. Operation is indicated if there is disruption of the main pancreatic duct; in almost all other cases, the patient will recover with conservative management. In penetrating injuries, especially if other organs are injured and the patient’s condition...
A distal pancreatectomy was performed.

is unstable, there is a greater need to perform an urgent surgical exploration.

Assessment of pancreatic damage and duct disruption at the time of surgery can be difficult, because the bruising associated with the retroperitoneal damage prevents clear visualisation of the pancreas. A patient and thorough examination of the gland should be carried out. Haemostasis and closed drainage is adequate for minor parenchymal injuries. If the gland is transected in the body or tail, a distal pancreatectomy should be performed, with or without splenectomy. However, if the plane of transection is flat and clean, it may be possible to anastomose the stump of the distal pancreas to a Roux loop of jejunum as an end-to-side pancreatojejunostomy. If damage is purely confined to the head of the pancreas, haemostasis and external drainage is normally effective. In the emergency setting, in an unstable patient with concomitant injuries, a surgeon unaccustomed to pancreatic surgery should refrain from trying to ascertain whether the duct in the pancreatic head is intact or embarking on a major resection. However, if there is severe injury to the pancreatic head and duodenum, then a pancreato-duodenectomy may be necessary (Summary box 68.3).

**Summary box 68.3**

**External injury to the pancreas**

- Other organs are likely to be injured
- It is important to ascertain whether the pancreatic duct has been disrupted
- CT and ERCP are the most useful tests
- Surgery is indicated if the main pancreatic duct is disrupted

**Prognosis**

The most common cause of death in the immediate period is bleeding, usually from associated injuries. Once the acute phase has passed, the mortality and morbidity related to the pancreatic injury itself are treatable, with a complete return to normal activity the usual outcome.

Persistent drain output occurs in up to a third of patients (see below under Pancreatic fistula). Sometimes, in the aftermath of trauma that has been treated conservatively, duct stricture develops, leading to recurrent episodes of pancreatitis. The appropriate treatment in such cases is resection of the tail of the pancreas distal to the site of duct disruption.

Also, a pancreatic pseudocyst may develop. If the main duct is intact, the cyst can be aspirated percutaneously in the first instance; it may not be necessary to undertake a cystgastrostomy. If the cyst develops in the presence of complete disruption of the pancreas, there is no alternative but to undertake a cystgastrostomy or even a distal resection or, occasionally, a pancreato-jejunostomy with a Roux-en-Y loop. In a patient who presents with a peripancreatic cyst and a history of previous blunt abdominal trauma, do not assume that it is a post-traumatic pseudocyst. The possibility of a cystic neoplasm should be considered and excluded.

**Iatrogenic injury**

This can occur in several ways:

- Injury to the tail of the pancreas during splenectomy, resulting in a pancreatic fistula.
- Injury to the accessory pancreatic duct (Santorini), which is the main duct in 7 per cent of patients, during Billroth II gastrectomy. A pancreatogram performed by cannulating the duct at the time of discovery of such an injury will demonstrate whether it is safe to ligate and divide the duct. If no alternative drainage duct can be demonstrated, then the duct should be reanastomosed to the duodenum.
- Enucleation of islet cell tumours of the pancreas can result in fistulae.
- Duodenal or ampullary bleeding following sphincterotomy. This injury may require duodenotomy to control the bleeding.

**Pancreatic fistula**

Pancreatic fistula usually follows operative trauma to the gland or occurs as a complication of acute or chronic pancreatitis. It is important to define the site of the fistula and the epithelial structure with which it communicates (e.g. externally to skin or internally to bowel). If there is uncertainty about whether the fluid issuing from a drain site or a wound is pancreatic, measurement of the amylase content will be diagnostic.

Management includes correction of metabolic and electrolyte disturbances and adequate drainage of the fistula into a stoma bag with protection of the skin. Investigation of the cause of the fistula is required as the underlying cause must be treated before the fistula will close. Frequently, the cause is related to obstruction within the pancreatic duct, which can be overcome by the insertion of a stent or catheter endoscopically into the pancreatic duct. While waiting for closure of the fistula, the patient should be given parenteral or nasojejunal nutritional support (as opposed to nasogastric or oral feeding; the rationale is that parenteral or nasojejunal feeding reduces the volume of pancreatic secretion). The use of octreotide will also suppress pancreatic secretion (Summary box 68.4) (see also Chapter 20).

---

**Giovanni Domenico Santorini** 1681–1737, Professor of Anatomy and Medicine, Venice, Italy. His drawings of the accessory pancreatic duct were published after his death.

**Christian Albert Theodor Billroth** 1829–1894, Professor of Surgery, Vienna, Austria. A hugely influential surgical teacher and an early proponent of surgical audit, Billroth performed the first oesophagectomy, first laryngectomy and first successful gastrectomy. He was also a talented musician and a friend of the composer Brahms.
Acute pancreatitis

Incidence

Acute pancreatitis accounts for 3 per cent of all cases of abdominal pain among patients admitted to hospital in the UK. The hospital admission rate for acute pancreatitis is 9.8 per year per 100,000 population in the UK, although worldwide, the annual incidence may range from 5 to 50 per 100,000. The disease may occur at any age, with a peak in young men and older women.

Aetiology

The two major causes of acute pancreatitis are biliary calculi, which occur in 50–70 per cent of patients, and alcohol abuse, which accounts for 25 per cent of cases. Gallstone pancreatitis is thought to be triggered by the passage of gallstones down the common bile duct. If the biliary and pancreatic ducts join to share a common channel before ending at the ampulla, then obstruction of this passage may lead to reflux of bile or activated pancreatic enzymes into the pancreatic duct. Patients who have small gallstones and a wide cystic duct may be at a higher risk of passing stones. The proposed mechanisms for alcoholic pancreatitis include the effects of diet, malnutrition, direct toxicity of alcohol, concomitant tobacco smoking, hypersecretion, duct obstruction or reflux, and hyperlipidaemia. The remaining cases may be due to rare causes or be idiopathic (Summary box 68.5).

Among patients who undergo ERCP, 1–3 per cent develop pancreatitis, probably as a consequence of duct disruption and enzyme extravasation. Patients with sphincter of Oddi dysfunction or a history of recurrent pancreatitis, and those who undergo sphincterotomy or balloon dilatation of the sphincter, carry a higher risk of developing post-ERCP pancreatitis. Patients who have undergone upper abdominal or cardiothoracic surgery may develop acute pancreatitis in the postoperative phase, as may those who have suffered blunt abdominal trauma.

Hereditary pancreatitis is a rare familial condition associated with mutations of the cationic trypsinogen gene. Patients have a tendency to suffer acute pancreatitis while in their teens, progress to chronic pancreatitis in the next two decades and
have a high risk (possibly up to 40 per cent) of developing pancreatic cancer by the age of 70 years.

Occasionally, tumours at the ampulla of Vater may cause acute pancreatitis. It is important to check the serum calcium level, a fasting lipid profile, autoimmunity markers, and viral titres in patients with so-called idiopathic acute pancreatitis. It is equally important to take a detailed drug history and remember the association of corticosteroids, azathioprine, asparaginase, and valproic acid with acute pancreatitis. A careful search for the aetiology must be made in all cases, and no more than 20 per cent of cases should fall into the idiopathic category (Summary box 68.6).

**Summary box 68.6**

**Aetiology of acute pancreatitis**
- It is essential to establish the aetiology
- Investigate thoroughly before labelling it as ‘idiopathic’
- After the acute episode resolves, remember further management of the underlying aetiology
- If the aetiology is gallstones, cholecystectomy is desirable during the same admission

**Clinical presentation**

Pain is the cardinal symptom. It characteristically develops quickly, reaching maximum intensity within minutes rather than hours and persists for hours or even days. The pain is frequently severe, constant, and refractory to the usual doses of analgesics. Pain is usually experienced first in the epigastrium but may be localised to either upper quadrant or felt diffusely throughout the abdomen. There is radiation to the back in about 50 per cent of patients, and some patients may gain relief by sitting or leaning forwards. The suddenness of onset may simulate a perforated peptic ulcer, while biliary colic or acute cholecystitis can be mimicked if the pain is maximal in the right upper quadrant. Radiation to the chest can simulate myocardial infarction, pneumonia, or pleuritic pain. In fact, acute pancreatitis can mimic most causes of the acute abdomen and should seldom be discounted in differential diagnosis.

Nausea, repeated vomiting, and retching are usually marked accompaniments. The retching may persist despite the stomach being kept empty by nasogastric aspiration. Hiccoughs can be troublesome and may be due to gastric distension or irritation of the diaphragm.

On examination, the appearance may be that of a patient who is well or, at the other extreme, one who is gravely ill with profound shock, toxicity, and confusion. Tachypnoea is common, tachycardia is usual, and hypotension may be present. The body temperature is often normal or even subnormal, but frequently rises as inflammation develops. Mild ileus can be caused by biliary obstruction in gallstone pancreatitis, and an acute swinging pyrexia suggests cholangitis. Bleeding into the fascial planes can produce bluish discoloration of the flanks (Grey Turner’s sign) or umbilicus (Cullen’s sign). Neither sign is pathognomonic of acute pancreatitis; Cullen’s sign was first described in association with rupture of an ectopic pregnancy. Subcutaneous fat necrosis may produce small, red, tender nodules on the skin of the legs.

Abdominal examination may reveal distension due to ileus or, more rarely, ascites with shifting dullness. A mass can develop in the epigastrium due to inflammation. There is usually muscle guarding in the upper abdomen, although marked rigidity is unusual. A pleural effusion is present in 10–20 per cent of patients. Pulmonary oedema and pneumonitis are also described and may give rise to the differential diagnosis of pneumonia or myocardial infarction. The patient may be confused and exhibit the signs of metabolic derangement together with hypoxaemia.

**Investigations**

Typically, the diagnosis is made on the basis of the clinical presentation and an elevated serum amylase level. A serum amylase level three to four times above normal is indicative of the disease. A normal serum amylase level does not exclude acute pancreatitis, particularly if the patient has presented a few days later. If the serum lipase level can be checked, it provides a slightly more sensitive and specific test than amylase. If there is doubt, and other causes of acute abdomen have to be excluded, contrast-enhanced CT is probably the best single imaging investigation (see below under Imaging) (Summary box 68.7).

**Summary box 68.7**

**Investigations in acute pancreatitis should be aimed at answering three questions:**
- Is a diagnosis of acute pancreatitis correct?
- How severe is the attack?
- What is the aetiology?

**Assessment of severity**

On account of the difference in outcome between patients with mild and severe disease, it is important to define that group of patients who will develop severe pancreatitis. Various scoring systems have been introduced, such as the Ranson and Glasgow scoring systems (Table 68.3). The APACHE II scoring system, used in intensive care units, can also be applied. A severe attack may be heralded by an initial clinical impression of a very ill patient and an APACHE II score above 8. At 48 hours after the onset of symptoms, a Glasgow score of 3 or more, a C-reactive protein level greater than 150 mg/L and a worsening clinical state with sepsis or persisting organ failure indicate a severe attack. Severity stratification should be performed in all patients within 48 hours of diagnosis. Patients with a body mass index over 30 are at higher risk of developing complications.

**Imaging**

Plain erect chest and abdominal radiographs are not diagnostic of acute pancreatitis, but are useful in the differential diagnosis. Non-specific findings in pancreatitis include a generalised or local ileus (sentinel loop), a colon cut-off sign and a renal halo.
Pancreatitis

1129

sign. Occasionally, calcified gallstones or pancreatic calcification may be seen. A chest radiograph may show a pleural effusion and, in severe cases, a diffuse alveolar interstitial shadowing may suggest acute respiratory distress syndrome.

Ultrasound does not establish a diagnosis of acute pancreatitis. The swollen pancreas may be seen, but ultrasonography should be performed within 24 hours in all patients to detect gallstones as a potential cause, rule out acute cholecystitis as a differential diagnosis and determine whether the common bile duct is dilated.

CT is not necessary for all patients, particularly those deemed to have a mild attack on prognostic criteria. However, a contrast-enhanced CT is indicated in the following situations:

- if there is diagnostic uncertainty;
- in patients with severe acute pancreatitis, to distinguish interstitial from necrotising pancreatitis (Figure 68.22). In the first 72 hours, CT may underestimate the extent of necrosis. The severity of pancreatitis detected on CT may be staged according to the Balthazar criteria;
- in patients with organ failure, signs of sepsis or progressive clinical deterioration;
- when a localised complication is suspected, such as fluid collection, pseudocyst or a pseudoaneurysm.

Cross-sectional MRI can yield similar information to that obtained by CT. EUS and MRCP can help in detecting stones in the common bile duct and directly assessing the pancreatic parenchyma, but are not widely available. ERCP allows the identification and removal of stones in the common bile duct in gallstone pancreatitis. In patients with severe acute gallstone pancreatitis and signs of ongoing biliary obstruction and cholangitis, an urgent ERCP should be sought (see below under Management).

The presentation is so variable that sometimes even an experienced clinician can be mistaken. While this is not desirable, occasionally the diagnosis is only made at laparotomy. The appearances at laparotomy are characteristic (Figure 68.23).

**Management**

If after initial assessment a patient is considered to have a mild attack of pancreatitis, a conservative approach is indicated with intravenous fluid administration and frequent, but non-invasive, observation. A brief period of fasting may be sensible in a

[Figure 68.22](#) Contrast-enhanced computed tomography scan showing acute necrotising pancreatitis. Note the area of reduced enhancement in the pancreas (marked X), the peripancreatic oedema and stranding of the fatty tissues (courtesy of Dr Niall Power).
The pancreas, but are widespread in the greater omentum and the mesentery. At necropsy, they can sometimes be demonstrated beneath the pleura and pericardium, and even in the sub synovial fat of the knee joint. Fat necroses consist of small islands of saponification caused by the liberation of lipase, which splits into glycerol and fatty acids. Free fatty acids combine with calcium to form soaps (fatty necrosis) (courtesy of Dr GD Adhia, Mumbai, India).

There is some evidence to support the use of prophylactic antibiotics in patients with severe acute pancreatitis, but there is no consensus. The rationale is to prevent local and other septic complications. The regimens used include intravenous cefuroxime, or imipenem, or ciprofloxacin plus metronidazole. The duration of antibiotic prophylaxis should not exceed 14 days. Additional antibiotic use should be guided by microbiological cultures.

If gallstones are the cause of an attack of predicted or proven severe pancreatitis, or if the patient has jaundice, cholangitis or a dilated common bile duct, urgent ERCP should be carried out within 72 hours of the onset of symptoms. There is evidence that sphincterotomy and clearance of the bile duct can reduce the incidence of infective complications in these patients. In patients with cholangitis, sphincterotomy should be carried out or a biliary stent placed to drain the duct. ERCP is an invasive procedure and carries a small risk of worsening the pancreatitis.

**Systemic complications**

Pancreatitis may involve all organ systems (Table 68.5) and place demands on the surgeon beyond his or her skills. Patients with systemic complications should be managed by a multidisciplinary team that includes intensive care specialists. When there is organ failure, appropriate supportive therapies may include inotropic support for haemodynamic instability, haemofiltration in the event of renal failure, ventilatory support for respiratory failure and correction of coagulopathies (including DIC). There is no role for surgery during the initial period of resuscitation and stabilisation; surgical intervention is contemplated only in the patient who deteriorates as a result of local complications following successful stabilisation.

**Local complications and their management**

Once the acute phase has been survived, usually by the end of...
to begin with, but can become subsequently infected, probably due to translocation of gut bacteria. Infected necrosis is associated with a mortality rate of up to 50 per cent. Sterile necrotic material should not be drained or interfered with. However, if the patient shows signs of sepsis, then one should determine whether the necrotic pancreas or the peripancreatic fluid is infected (Figure 68.24). A CT scan should be performed and a needle passed into the area under CT guidance, choosing a path that does not traverse hollow viscera. This may be done under ultrasonographic guidance as well. If the aspirate is purulent, percutaneous drainage of the infected fluid should be carried out. The tube drain inserted should have the widest bore possible. The aspirate should be sent for microbiological assessment, and appropriate antibiotic therapy should be commenced as per the sensitivity report. The fluid can be quite viscous with particulate matter, and the drain may need regular flushing with full aseptic precautions. Often, repeated imaging and repeated insertion of drains is necessary.

If the sepsis worsens despite this, then a pancreatic necrosectomy should be considered. This is a challenging operation that carries a high morbidity and mortality, and is best carried out in a specialist unit. The overwhelming majority of patients with peripancreatic sepsis can be successfully treated by conservative means, and necrosectomy should be necessary in a very small proportion of patients. The surgical approach may be through a mid-line laparotomy, especially if the area involved is around the head of the gland. The duodenocolic and gastrocolic ligaments should be divided and the lesser sac opened. Thorough debridement of the dead tissue around the pancreas should be carried out. If the body and tail of the gland are primarily involved (Figure 68.25), a retroperitoneal approach though a left flank incision may be more appropriate. The tissues are inevitably friable, and one should be careful not to precipitate excessive bleeding or inadvertently breach the bowel wall. Blunt dissection is preferable to sharp dissection. A feeding jejunostomy is a useful adjunct to the procedure. If gallstones are the precipitating factor of the pancreatitis, a cholecystectomy should be included. Some prefer a minimally invasive approach to a formal laparotomy. A rigid laparoscope is inserted into the peripancreatic area through a retroperitoneal approach, and vigorous

ARDS, acute respiratory distress syndrome; DIC, disseminated intravascular coagulation.

Acute fluid collection
This occurs early in the course of acute pancreatitis and is located in or near the pancreas. The wall encompassing the collection is ill defined. The fluid is sterile and most such collections resolve. No intervention is necessary unless a large collection causes symptoms or pressure effects, in which case it can be percutaneously aspirated under ultrasound or CT guidance. Transgastric drainage under EUS guidance is another option. An acute fluid collection that does not resolve can evolve into a pseudocyst or an abscess if it becomes infected.

Sterile and infected pancreatic necrosis
The term ‘pancreatic necrosis’ refers to a diffuse or focal area of non-viable parenchyma that is typically associated with peripancreatic fat necrosis. Necrotic areas can be identified by an absence of contrast enhancement on CT. These are sterile to begin with, but can become subsequently infected, probably due to translocation of gut bacteria. Infected necrosis is
irrigation and suction is combined with a gradual nibbling away of the necrotic debris.

Once a necrosectomy has been completed, further necrotic tissue may form. There are several possible ways of dealing with this (listed below), none of which has been proved to be more effective than the others. The last two approaches make greater logistic demands as one is committed to a re-exploration every 48–72 hours.

- **Closed continuous lavage.** Tube drains are left in and the raw area flushed (Beger) (Figure 68.26).
- **Closed drainage.** The incision is closed, but the cavity is packed with gauze-filled Penrose drains and closed suction drains. The Penrose drains are brought out through the flank and slowly pulled out and removed after 7 days.
- **Open packing.** The incision is left open and the cavity is packed with the intention of returning to the operating theatre at regular intervals and repacking until there is a clean granulating cavity.

- **Closure and relaparotomy.** The incision is closed with drains with the intention of performing a series of planned relaparotomies every 48–72 hours until the raw area granulates (Bradley).

There is a subgroup of patients who respond initially to percutaneous treatment but then develop recurrent sepsis that requires repeated insertion of drains, and fail to thrive. Necrosectomy should be considered in these patients, but it can be a difficult judgement call.

Patients with peripancreatic sepsis are ill for long periods of time, and may require management in an intensive care unit. Nutritional support is essential. The parenteral and nasojejunal approaches are more popular (on the assumption that they rest the pancreas), although there is little evidence to show that nasogastric feeding, if tolerated, is harmful in any way.

### Pancreatic abscess

This is a circumscribed intra-abdominal collection of pus, usually in proximity to the pancreas. It may be an acute fluid collection or a pseudocyst that has become infected. The principles of diagnosis and management are as outlined above for infected pancreatic necrosis. Percutaneous drainage with the widest possible drains placed under imaging guidance is the treatment, along with appropriate antibiotics and supportive care. Repeated scans may be required depending on the progress of the patient, and drains may need to be flushed, repositioned or reinserted. Very occasionally, open drainage of the abscess may be necessary.

### Pancreatic ascites

This is a chronic, generalised, peritoneal, enzyme-rich effusion usually associated with pancreatic duct disruption. Pancreatic ascites will reveal turbid fluid with a high amylase level. Adequate drainage with wide-bore drains placed under imaging guidance is essential. Measures that can be taken to suppress pancreatic secretion include parenteral or nasojejunal feeding and administration of octreotide. An ERCP may allow demonstration of the duct disruption and placement of a pancreatic stent.

### Pancreatic effusion

This is an encapsulated collection of fluid in the pleural cavity, arising as a consequence of acute pancreatitis. Concomitant pancreatic ascites may be present, or there may be a communication with an intra-abdominal collection. Percutaneous drainage under imaging guidance is necessary.

### Haemorrhage

Bleeding may occur into the gut, into the retroperitoneum or into the peritoneal cavity. Possible causes include bleeding into a pseudocyst cavity, diffuse bleeding from a large raw surface, or a pseudoaneurysm. The last is a false aneurysm of a major peri-pancreatic vessel confined as a clot by the surrounding tissues and often associated with infection. Recurrent bleeding is common, often culminating in fatal haemorrhage. CT, angiography or magnetic resonance angiography (MRA) helps to make the diagnosis. Treatment involves embolisation or surgery.

### Portal or splenic vein thrombosis

This may often develop silently and is identified on a CT scan. A marked rise in the platelet count should raise suspicions. In
demonstrate communication of the cyst with the pancreatic duct system, demonstrate ductal anomalies or diagnose chronic pancreatitis and thus help in planning treatment.

Pseudocysts will resolve spontaneously in most instances, but complications can develop (Table 68.6). Pseudocysts that are thick-walled or large (over 6 cm in diameter), have lasted for a long time (over 12 weeks) or have arisen in the context of chronic pancreatitis are less likely to resolve spontaneously, but these factors are not specific indications for intervention. Therapeutic interventions are advised only if the pseudocyst causes symptoms, if complications develop or a distinction has to be made between a pseudocyst and a tumour.

There are three possible approaches to draining a pseudocyst: percutaneous, endoscopic and surgical. Percutaneous drainage to the exterior under radiological guidance should be avoided. It carries a very high likelihood of recurrence. Moreover, it is not advisable unless one is absolutely certain that the cyst is not neoplastic and that it has no communication with the pancreatic duct (or else a pancreaticocutaneous fistula will develop). A percutaneous transgastric cystgastrostomy can be done under imaging guidance, and a double-pigtail drain placed with one end in the cyst cavity and the other end in the gastric lumen. This requires specialist expertise but, in experienced hands, the recurrence rates are no more than 15 per cent. Endoscopic drainage usually involves puncture of the cyst through the stomach or duodenal wall under EUS guidance, and placement of a tube drain with one end in the cyst cavity and the other end in the gastric lumen. The success rates depend on operator expertise. Occasionally, ERCP and placement of a pancreatic stent across the ampulla may help to drain a pseudocyst that is in communication with the duct. Surgical drainage involves internally draining the cyst into the gastric or jejunal lumen (Figure 68.28). Recurrence rates should be no more than 5 per cent, and this still remains the standard against which the evolving radiological and endoscopic approaches are measured. The approach is conventionally through an open incision, but laparoscopic cystgastrostomy is also feasible. Pseudocysts that have developed complications are best managed surgically (Summary box 68.8).

Figure 68.27 Barium meal. Pseudocyst displacing the stomach (courtesy of Professor VK Kapoor, Lucknow, India).
PART 11  |  ABDOMINAL  THE PANCREAS

Figure 68.28 Cystgastrostomy for the pancreatic pseudocyst shown in Figure 68.10. The anterior wall of the stomach has been opened and the edges drawn back, held by Babcock’s forceps. An opening has been made through the posterior wall of the stomach into the pseudocyst, and the tips of the dissecting forceps are in the cavity of the pseudocyst, which is lined by slough and granulation tissue. The tip of a nasogastric tube is visible. A running stitch will next be placed along the edges of this opening, suturing the full thickness of the posterior gastric wall to the capsule of the pseudocyst.

Outcomes and follow up of acute pancreatitis

The overall mortality from acute pancreatitis has remained at 10–15 per cent over the past 20 years. There is a clear responsibility before the patient is discharged to determine the aetiology of the attack of pancreatitis, and the causes listed in Summary box 68.5 must be looked for and excluded. Failure to remove a predisposing factor could lead to a second attack of pancreatitis, which could be fatal. A proportion of patients in the idiopathic group who suffer repeated attacks may prove to have biliary microlithiasis, which can be identified only by bile sampling at ERCP or by endoscopic ultrasound. In a patient who has gallstone pancreatitis, the gallbladder and gallstones should be removed as soon as the patient is fit to undergo surgery and, preferably, before discharge from hospital.

Chronic pancreatitis

Chronic pancreatitis is a progressive inflammatory disease in which there is irreversible destruction of pancreatic tissue. Its clinical course is characterised by severe pain and, in the later stages, exocrine and endocrine pancreatic insufficiency. In the early stages of its evolution, it is frequently complicated by attacks of acute pancreatitis, which are responsible for the recurrent pain that may be the only clinical symptom. The incidence of chronic pancreatitis in several European, North American and Japanese studies ranges from two to ten new cases per 100,000 population per year, with a prevalence of around 13 cases per 100,000, although there are suspicions that the prevalence is actually higher. In certain parts of the world, such as southern India, the prevalence is much higher (100–200 per 100,000). The disease occurs more frequently in men (male to female ratio of 4:1), and the mean age of onset is about 40 years.

Aetiology and pathology

High alcohol consumption is the most frequent cause of chronic pancreatitis, accounting for 60–70 per cent of cases, but only 5–10 per cent of people with alcoholism develop chronic pancreatitis. The exact mechanism of how alcohol causes chronic inflammation in these patients is unclear; genetic and metabolic factors may be at play.

Other causes include pancreatic duct obstruction resulting from stricture formation after trauma, after acute pancreatitis or even occlusion of the duct by pancreatic cancer. Congenital abnormalities, such as pancreas divisum and annular pancreas, if associated with papillary stenosis, are rare causes of chronic pancreatitis.

Hereditary pancreatitis, CF, infantile malnutrition and a large unexplained idiopathic group make up the remainder. Normally, if trypsinogen does become prematurely activated within the pancreas, it is inhibited by SPINK1 and then gets destroyed. Hereditary pancreatitis is an autosomal dominant disorder with an 80 per cent penetrance, associated with a gain-of-function mutation in the cationic trypsinogen gene (PRSS1) on chromosome 7, which leads to production of a degradation-resistant form of trypsin. A loss-of-function mutation in SPINK1 also predisposes to idiopathic pancreatitis. Some patients with idiopathic chronic pancreatitis have mutations in the CFTR gene. Idiopathic chronic pancreatitis accounts for approximately 30 per cent of cases and has been subdivided into early-onset and late-onset forms.

Tropical pancreatitis is a form of idiopathic pancreatitis that begins at a young age and is associated with a high incidence of diabetes mellitus and stone formation. This has been described in Kerala, in southern India, as well as in other developing countries in Asia, Africa and central America. Malnutrition, ingestion of cyanogenic glycosides in cassava, and exposure to hydrocarbons released by kerosene or paraffin lamps have been proposed as possible mechanisms for tropical pancreatitis. The importance of hereditary pancreatitis and pancreatitis occurring at a young age is that there is a markedly increased risk of developing pancreatic cancer, particularly if the patient smokes tobacco. Hyperlipidaemia and hypercalcaemia can lead to chronic pancreatitis.

Autoimmune pancreatitis has been described relatively recently. Features include diffuse enlargement of the pancreas, diffuse and irregular narrowing of the main pancreatic duct. It may occur in association with other autoimmune diseases, as a multi-system disorder, or may affect the pancreas alone. The changes may be confused with neoplasia. Autoantibodies may be present and levels of the immunoglobulin subtype IgG4 are elevated.

At the onset of the disease when symptoms have developed, the pancreas may appear normal. Later, the pancreas enlarges and becomes hard as a result of fibrosis. The ducts become distorted and dilated with areas of both stricture formation and ectasia. Calcified stones weighing from a few milligrams to 200 mg may form within the ducts. The ducts may become occluded with a gelatinous proteinaceous fluid and debris, and inflammatory cysts may form. Histologically, the lesions affect the lobules, producing ductular metaplasia and atrophy of acini, hyperplasia of duct epithelium and interlobular fibrosis.

**Clinical features**

Pain is the outstanding symptom in the majority of patients. The site of pain depends to some extent on the main focus of the disease. If the disease is mainly in the head of the pancreas, then epigastric and right subcostal pain is common, whereas if it is limited to the left side of the pancreas, left subcostal and back pain are the presenting symptoms. In some patients, the pain is more diffuse. Radiation to the shoulder, usually the left shoulder, occurs. Nausea is common during attacks and vomiting may occur. The pain is often dull and gnawing. Severe flare up of pain may occur superimposed on background discomfort. All the complications of acute pancreatitis can occur with chronic pancreatitis. Weight loss is common, because the patient does not feel like eating. The pain prevents sleep and time off work is frequent. The number of hospital admissions for acute exacerbations is a pointer towards the severity of the disease. Analgesic use and abuse is frequent. This, too, gives an indication of the severity of the disability. The patient’s lifestyle is gradually destroyed by pain, analgesic dependence, weight loss and inability to work. Loss of exocrine function leads to steatorrhoea and becomes hard as a result of fibrosis. The ducts become distorted and dilated with areas of both stricture formation and ectasia. Calcified stones weighing from a few milligrams to 200 mg may form within the ducts. The ducts may become occluded with a gelatinous proteinaceous fluid and debris, and inflammatory cysts may form. Histologically, the lesions affect the lobules, producing ductular metaplasia and atrophy of acini, hyperplasia of duct epithelium and interlobular fibrosis.

**Investigations**

Only in the early stages of the disease will there be a rise in serum amylase. Tests of pancreatic function merely confirm the presence of pancreatic insufficiency or that more than 70 per cent of the gland has been destroyed.

Pancreatic calcifications may be seen on abdominal x-ray (see Figure 68.18). CT or MRI scan will show the outline of the gland, the main area of damage and the possibilities for surgical correction (Figure 68.29; see also Figure 68.7). Calcification is seen very well on CT, but not on MRI. An MRCP will identify the presence of biliary obstruction and the state of the pancreatic duct (Figure 68.30). The use of intravenous secretin during the study may demonstrate a pancreatic duct stricture that is not apparent on a standard MRCP, but a normal-looking pancreas on CT or MRI does not rule out chronic pancreatitis. ERCP is the most accurate way of elucidating the anatomy of the duct and, in conjunction with the whole organ morphology, can help to determine the type of operation required, if operative intervention is indicated (Figures 68.15 and 68.17). Histologically proven chronic pancreatitis can, however, occur in the setting of normal findings on pancreatography. EUS can also be very useful. Sonographic findings characteristic of chronic pancreatitis include the presence of stones, visible side branches, cysts, lobularity, an irregular main pancreatic duct, hyperechoic foci and strands, dilation of the main pancreatic duct and hyperechoic margins of the main pancreatic duct. The presence of four or more of these features is highly suggestive of chronic pancreatitis.

**Treatment**

Most patients can be managed with medical measures. There is no single therapeutic agent that has been shown to relieve symptoms (Summary box 68.9).

Endoscopic, radiological or surgical interventions are indicated mainly to relieve obstruction of the pancreatic duct, bile duct or the duodenum, or in dealing with complications (e.g. pseudocyst, abscess, fistula, ascites or variceal haemorrhage). Decompressing an obstructed pancreatic duct can provide pain relief in some patients (the assumption is that ductal hypertension causes the pain).

Endoscopic pancreatic sphincterotomy might be beneficial in patients with papillary stenosis and a high sphincter pressure and pancreatic ductal pressure. Patients with a dominant pancreatic duct stricture and upstream dilatation may benefit by placement of a stent across the stricture. The stent should be left in for no more than 4–6 weeks as it will block. The complication rate is high, and less than two-thirds of patients experience pain relief,
but those who do get relief may benefit from a surgical bypass. Pancreatic duct stones may be extracted at ERCP, and this may sometimes be combined with extracorporeal shock wave lithotripsy. Pseudocysts may be drained internally under EUS guidance. Percutaneous or transgastric drainage of pseudocysts under ultrasound or CT guidance may be performed.

The role of surgery is to overcome obstruction and remove mass lesions. Some patients have a mass in the head of the pancreas, for which either a pancreaticoduodenectomy or a Beger procedure (duodenum-preserving resection of the pancreatic head) is appropriate. If the duct is markedly dilated, then a longitudinal pancreaticojejunostomy or Frey procedure can be of value (Figure 68.31). The natural evolution of the disease may not be altered significantly, but around half the patients get long-term pain relief. The rare patient with disease limited to the tail will be cured by a distal pancreatectomy. Patients with intractable pain and diffuse disease may plead for a total pancreatectomy in the expectation that removing the offending organ will relieve their pain. However, one should keep in mind that pancreatic function and quality of life are significantly impaired after this procedure, and the operative mortality rate is not trivial. Moreover, there is no guarantee of pain relief (approximately a third of patients get resolution, a third show some benefit, and a third see no benefit at all). Total pancreatectomy and islet autotransplantation has been reported in selected patients, but it is difficult to demonstrate any overall benefit.

**Prognosis**

Chronic pancreatitis is a difficult condition to manage. Patients often suffer a gradual decline in their professional, social and personal lives. The pain may abate after a surgical or percutaneous intervention, but tends to return over a period of time. In a proportion of patients, the inflammation may gradually burn out over a period of years, with disappearance of the pain, leaving only the exocrine and endocrine insufficiencies. Development of pancreatic cancer is a risk in those who have had the disease for more than 20 years. New symptoms or a change in the pattern of symptoms should be investigated and malignancy excluded.

**Sphincter of Oddi dysfunction**

Separate mention is warranted of this condition, which should be considered in the differential diagnosis of chronic biliary or pancreatic pain. The sphincter of Oddi is 6–10 mm long and lies within the duodenal wall. A part of it encircles the common channel, and then there are separate biliary and pancreatic components (see Figure 68.5). Scarring or stenosis of the sphincter can result from passage of stones, pancreatitis or prior endoscopic sphincterotomies. Sphincter of Oddi dyskinesia or dysfunction (SOD) is a clinical syndrome in which pain, biochemical abnormalities and dilatation of the bile duct and/or pancreatic duct are attributed to abnormal function of the sphincter of Oddi. The true incidence of SOD is unknown. Females are more commonly affected than males.

There are two types of SOD. Biliary-type SOD is characterised by biliary pain, which may be accompanied by abnormally raised liver enzymes and/or dilation of the bile duct and/or evidence of delayed emptying on biliary scintigraphy. It may be a cause of persistent post-cholecystectomy symptoms. A predominance of pancreatic problems, especially recurrent episodes

---

**Summary box 68.9**

**Medical treatment of chronic pancreatitis**

- Treat the addiction
  - Help the patient to stop alcohol consumption and tobacco smoking
  - Involve a dependency counsellor or a psychologist
- Alleviate abdominal pain
- Eliminate obstructive factors (duodenum, bile duct, pancreatic duct)
- Escalate analgesia in a stepwise fashion
- Refer to a pain management specialist
- For intractable pain, consider CT/EUS-guided coeliac axis block
- Nutritional and pharmacological measures
  - Diet: low in fat and high in protein and carbohydrates
  - Pancreatic enzyme supplementation with meals
  - Correct malabsorption of the fat-soluble vitamins and vitamin B12
  - Micronutrient therapy with methionine, vitamins C and E, selenium (may reduce pain and slow disease progression)
  - Steroids (only in autoimmune pancreatitis, for relief of symptoms)
  - Medium-chain triglycerides in patients with severe fat malabsorption (they are directly absorbed by the small intestine without the need for digestion)
  - Reducing gastric secretions may help
- Treat diabetes mellitus
of acute pancreatitis, is known as pancreatic-type SOD. The biliary and pancreatic sphincters can be evaluated at the time of ERCP with manometry, and high sphincter pressures may be demonstrated. Sphincterotomy and/or stenting of the involved duct system may be performed if deemed appropriate. SOD is, however, associated with a particularly high risk of post-ERCP pancreatitis, and such treatments are best carried out in tertiary units by expert gastroenterologists.

In a small subgroup of patients who have experienced significant but short-lived relief with sphincterotomy or stenting, surgical transduodenal sphincteroplasty may be considered. Although SOD can cause severe symptoms (and the patient may therefore be keen to have something done), it is not fatal. However, post-ERCP pancreatitis and surgery both carry a small but definite risk of mortality.

### CARCINOMA OF THE PANCREAS

Pancreatic cancer is the sixth leading cause of cancer death in the UK, and the incidence is ten cases per 100,000 population per year. Worldwide, it constitutes 2–3 per cent of all cancers and, in the United States, is the fourth highest cause of cancer death. The incidence has declined slightly over the last 25 years. There is no simple screening test; however, patients with an increased inherited risk of pancreatic cancer (Table 68.7) should be referred to specialist units for screening and counselling.

#### Pathology

More than 85 per cent of pancreatic cancers are ductal adenocarcinomas. The remaining tumours constitute a variety of pathologies with individual characteristics. Endocrine tumours of the pancreas are rare. They are covered in Chapter 52.

Ductal adenocarcinomas arise most commonly in the head of the gland. They are solid, scirrhous tumours, characterised by neoplastic tubular glands within a markedly desmoplastic fibrous stroma. Fibrosis is also a characteristic of chronic pancreatitis, and histological differentiation between tumour and pancreatitis can cause diagnostic difficulties. Ductal adenocarcinomas infiltrate locally, typically along nerve sheaths, along lymphatics and into blood vessels. Liver and peritoneal metastases are common. Proliferative lesions in the pancreatic ducts can precede invasive ductal adenocarcinoma. These are termed ‘pancreatic intrapapillary mucinous neoplasia’ or PanIN, and can demonstrate a range of structural complexity and cellular atypia.

Cystic tumours of the pancreas may be serous or mucinous. Serous cystadenomas are typically found in older women, and are large aggregations of multiple small cysts, almost like bubble-wrap. They are benign. Mucinous tumours, on the other hand, have the potential for malignant transformation. They include mucinous cystic neoplasms (MCNs) and intraductal papillary mucinous neoplasms (IPMNs). MCNs are seen in perimenopausal women, show up as multilocular thick-walled cysts in the pancreatic body or tail and, histologically, contain an ovarian-type stroma. IPMNs are more common in the pancreatic head and in older men, but an IPMN arising from a branch duct can be difficult to distinguish from an MCN. IPMNs arising within the main duct are often multifocal and have a greater tendency to prove malignant. Thick mucus seen extruding from the ampulla at ERCP is diagnostic of a main duct IPMN. Mucinous tumours can be confused with pseudocysts (see Summary box 68.8). Occasionally, lymphoepithelial cysts, lymphangiomata, dermoid cysts and intestinal duplication cysts can show up in the pancreas. Solid pseudopapillary tumour is a rare, slowly progressive but malignant tumour, seen in women of childbearing age, and manifests as a large, part-solid, part-cystic tumour.

Tumours arising from the ampulla or from the distal common bile duct can present as a mass in the head of the pancreas, and constitute around a third of all tumours in that area. Adenomas of the ampulla of Vater are diagnosed at endoscopy as polypoid submucosal masses covered by a smooth epithelium. They can harbour foci of invasive carcinoma; the larger the adenoma, the greater the risk. Biopsies taken at endoscopy may not always include the malignant focus. Endoscopic surveillance, endoscopic resection or even surgical transduodenal ampullary excision should be considered (Figure 68.32). Patients with familial adenomatous polyposis (FAP) can present with multiple duodenal polyps. Malignant transformation in a duodenal polyp is a significant cause of mortality in these patients, mandating endoscopic follow up and pancreatoduodenectomy in selected patients with high-grade dysplasia within the polyph.

Ampullary adenocarcinomas often present early with biliary obstruction. Their natural history is distinctly more favourable compared with pancreatic ductal adenocarcinoma. Ampullary carcinomas are relatively small when diagnosed, which may account for their better prognosis. Occasionally, other malignant neoplasms can arise at the ampulla, such as carcinoid tumours and high-grade neuroendocrine carcinomas.

#### Clinical features

Jaundice secondary to obstruction of the distal bile duct is the most common symptom that draws attention to ampullary and pancreatic head tumours. It is characteristically painless jaundice but may be associated with nausea and epigastric
discomfort. Pruritus, dark urine and pale stools with steatorrhoea are common accompaniments of jaundice. In the absence of jaundice, symptoms are often non-specific, namely vague discomfort, anorexia and weight loss, and are frequently dismissed by both patient and doctor. Upper abdominal symptoms in a recently diagnosed diabetic, especially in one above 50 years of age, with no family history or obesity, should raise suspicion. Occasionally, a patient will present with an unexplained attack of pancreatitis; all such patients should have follow-up imaging of the pancreas. Tumours of the body and tail of the gland often grow silently, and present at an advanced unresectable stage. Back pain is a worrying symptom, raising the possibility of retroperitoneal infiltration.

On examination, there may be evidence of jaundice, weight loss, a palpable liver and a palpable gall bladder. Courvoisier first drew attention to the association of an enlarged gall bladder and a pancreatic tumour in 1890, when he noted that, when the common duct is obstructed by a stone, distension of the gall bladder (which is likely to be chronically inflamed) is rare; when the duct is obstructed in some other way, such as a neoplasia, distension of the normal gall bladder is common. Other signs of intra-abdominal malignancy should be looked for with care, such as a palpable mass, ascites, supraclavicular nodes and tumour deposits in the pelvis; when present, they indicate a grim prognosis.

Investigation

In a jaundiced patient, the usual blood tests and ultrasound scan should be performed. Ultrasound will determine whether or not the bile duct is dilated. If it is, and there is a genuine suspicion of a tumour in the head of the pancreas, the preferred test is a contrast-enhanced CT scan (see Figure 68.8). In the majority of instances, this should establish if there is a tumour in the pancreas and if it is resectable. The presence of hepatic or peritoneal metastases, lymph node metastases distant from the pancreatic head, encasement of the superior mesenteric, hepatic or coeliac artery by tumour are clear contraindications to surgical resection. Tumour size, continuous invasion of the duodenum, stomach or colon, and lymph node metastases within the operative field are not contraindications. If the tumour abuts or minimally invades the portal or superior mesenteric vein, this is not a contraindication to surgery (as part of the vein can be resected if necessary), but complete encasement and occlusion of the vein is. MRI and MRA can provide information comparable to CT.

ERCP and biliary stenting should be carried out if there is any suggestion of cholangitis, if there is diagnostic doubt (small ampullary lesions may not be seen on CT, and ERCP is the best way to identify them), if the patient is deeply jaundiced (serum bilirubin >250 μmol/L), or there are distressing symptoms (e.g. pruritus) and there is likely to be a delay between diagnosis and surgery. It relieves the jaundice and can also provide a brush cytology or biopsy specimen to confirm the diagnosis (see Figures 68.13, 68.14 and 68.19). Otherwise, however, preoperative ERCP and biliary stenting is not mandatory in patients with resectable disease; there is evidence to suggest that it is associated with a slightly higher incidence of infective complications after surgery. The prothrombin time should be checked, and clotting abnormalities should be corrected with vitamin K or fresh-frozen plasma prior to ERCP. If a stent is placed in a patient who may undergo resection, it should be a plastic stent or a covered metal stent that can be easily removed. EUS is useful if CT fails to demonstrate a tumour, if tissue diagnosis is required prior to surgery (e.g. a mass has developed on a background of chronic pancreatitis and a distinction needs to be made between inflammation and neoplasia), if vascular invasion needs to be confirmed and in separating cystic tumours from pseudocysts (Figure 68.33; see also Figure 68.20). Transduodenal or transgastric FNA or Trucut biopsy performed under EUS guidance avoids spillage of tumour cells into the peritoneal cavity. Percutaneous transperitoneal biopsy of potentially resectable pancreatic tumours should be avoided as far as possible. Histological confirmation of malignancy is desirable but not essential, particularly if the imaging clearly demonstrates a resectable tumour. The lack of a tissue diagnosis should not delay appropriate surgical therapy. In patients judged to have unresectable disease, tissue diagnosis should be obtained prior to starting palliative therapy.

Diagnostic laparoscopy prior to an attempt at resection can spare a proportion of patients an unnecessary laparotomy by identifying small peritoneal and liver metastases. It can be combined with laparoscopic ultrasonography. The tumour marker CA19-9 is not highly specific or sensitive, but a baseline level should be established; if it is initially raised, it can be useful later in identifying recurrence.

Management

At the time of presentation, more than 85 per cent of patients with ductal adenocarcinoma are unsuitable for resection because the disease is too advanced. If imaging shows that the tumour is potentially resectable, the patient should be considered for surgical resection, as that offers the only (albeit small) chance of a cure. Comorbidities should be carefully taken into account. Biological rather than chronological age should be the consideration. If a cystic tumour is encountered, no matter how large, surgical resection should be considered, as it carries a reasonable chance of cure. Tumours of the ampulla have a good prognosis and should, if at all possible, be resected. Some of the rare
tumours and the neuroendocrine lesions should also be resected if at all possible. For those patients who have inoperable disease, palliative treatment should be offered.

**Surgical resection**

The standard resection for a tumour of the pancreatic head or the ampulla is a pylorus-preserving pancreatoduodenectomy (PPPD). This involves removal of the duodenum and the pancreatic head, including the distal part of the bile duct. The original pancreatoduodenectomy as proposed by Whipple included resection of the gastric antrum. Preserving the antrum and the pylorus is thought to result in a more physiological outcome with no difference in survival or recurrence rates. The Whipple procedure is now reserved for situations in which the entire duodenum has to be removed (e.g. in FAP) or where the tumour encroaches on the first part of the duodenum or the distal stomach and a PPPD would not achieve a clear resection margin. Total pancreatectomy is warranted only in situations where one is dealing with a multifocal tumour (e.g. a main duct IPMN), or the body and tail of the gland are too inflamed or too friable to achieve a safe anastomosis with the bowel. The PPPD procedure includes a local lymphadenectomy. Extended lymphadenectomy has not been shown to be beneficial in improving survival and is associated with increased morbidity. If the tumour is adherent to the portal or superior mesenteric vein, but can still be removed by including a patch or a short segment of vein in the resection, with an appropriate reconstruction of the vessel, then that should be done. This is not associated with an increase in the morbidity or mortality of the procedure, and the outcomes are similar.

For tumours of the body and tail, distal pancreatectomy with splenectomy is the standard. Infiltration of the splenic artery or vein by the tumour is not a contraindication to resection. When resecting the pancreatic tail for a benign lesion, one may attempt to preserve the spleen if possible. When removing the spleen, prior vaccinations against pneumococci, meningococci and *Haemophilus influenzae* B should be administered, and subsequent antibiotic prophylaxis given (see Chapter 66).

Attempts to downstage unresectable disease with chemotherapy or chemoradiation and render it resectable are rarely successful. Neoadjuvant chemotherapy or chemoradiation for resectable disease should only be considered within a clinical trial; it carries the risk that the disease may progress despite the neoadjuvant therapy and become unresectable.

**Pancreatoduodenectomy**

The patient’s coagulation screen should be checked preoperatively and adequate hydration ensured. The patient should be aware of the diagnosis, the gravity of the operation and the risks involved. The operation has three distinct phases:

- exploration and assessment;
- resection;
- reconstruction.

A cholecystectomy is performed. The bile duct and hepatic artery are exposed, removing the lymphatic tissue in this area. Exposure of the hepatic artery enables division of the gastroduodenal artery and visualisation of the portal vein. The distal part of the gastric antrum is mobilised. The duodenum and right colon are mobilised from the retroperitoneal tissues. The superior mesenteric vein is exposed inferior to the pancreatic neck. Careful dissection into the plane between the vein and the pancreatic substance (see Figure 68.2) will reveal whether the tumour is adherent to the vein. At this juncture, a decision has to be made whether to proceed to the next phase of resection or not. If resection is to be performed, the fourth part of the duodenum is dissected and freed from the ligament of Treitz so that the tumour is adherent to the portal or superior mesenteric vein, but can still be removed by including a patch or a short segment of vein in the resection, with an appropriate reconstruction of the vessel, then that should be done. This is not associated with an increase in the morbidity or mortality of the procedure, and the outcomes are similar.

**Wenzel Treitz** (1819–1872), Professor of Anatomy and Pathology, at Krakow, Poland, and later at Prague, Czech Republic. He was involved in the struggle for Czech nationalism.

**Allen Oldfather Whipple** (1881–1963), Director of Surgical Services, The Presbyterian Hospital, and Professor of Surgery, Columbia University, New York, NY, USA, began to perform two-stage pancreatoduodenectomies in 1934 and shortened the procedure into a one-stage process in 1940.

**Alessandro Codivilla** (1861–1912) and **Walter Kausch** (1867–1928) had performed the operation before him, but Whipple was the surgeon who established pancreatoduodenectomy as an operation.
the operative field are completely removed with the specimen. Reconstruction is carried out as in Figure 68.35. The pancreatic stump, the divided bile duct and the duodenal stump are anastomosed on to jejunum, in that order. Some surgeons prefer to anastomose the pancreas to the posterior wall of the stomach instead; others prefer to create a separate Roux loop of the jejunum and anastomose the pancreas to that. The operation should take between 3 and 6 hours. Blood loss should be low, and transfusion is often not necessary. The patients are usually nursed in a high dependency area for the first 24–48 hours after surgery. Prolonged nasogastric drainage is unnecessary, and early feeding can be commenced.

Resection for pancreatic cancer should be carried out in specialist units. There is a clear correlation between higher caseload volume and lower hospital mortality and morbidity. PPPD should carry a mortality of no more than 3–5 per cent. The morbidity remains high, with some 30–40 per cent of patients developing a complication in the postoperative period. These complications are usually infective, but a leak from the anastomosis between the pancreas and the bowel is known to occur in at least 10 per cent of patients, and this may give rise to major complications. Octreotide may be administered in the perioperative period to suppress secretion and reduce the likelihood of a leak, but the evidence for its efficacy is still debatable. Following surgical resection, the pathological tumour–node–metastasis (TNM) stage should be documented.

Adjuvant therapy

The reported five-year survival following resection of a pancreatic adenocarcinoma ranges from 7 to 25 per cent. The median survival is 11–20 months. Considering that, at best, 15 per cent of patients have resectable disease to begin with, this means only two or three of 100 patients with this disease can expect to survive for five years. Moreover, recurrences can and do show up even beyond the five-year cut off. It should be emphasised, however, that these depressing statistics apply to ductal adenocarcinomas. Patients with resected ampullary tumours have a five-year survival of 40 per cent, and cystic tumours and neuroendocrine tumours can often be cured by surgical resection.

The high recurrence rate following resection has inevitably led to the consideration of adjuvant treatments to improve outcome. In a large multicentre European study (ESPAC-1), adjuvant radiotherapy or chemoradiotherapy was shown to confer no advantage, but chemotherapy with 5-fluorouracil (5-FU) provided an overall benefit; median survival with chemotherapy was 20 months compared with 16 months without. Another trial (ESPAC-3) showed that gemcitabine works equally well. Most patients with resected ductal adenocarcinoma are now offered adjuvant chemotherapy, using gemcitabine or 5-FU. A further trial is in progress of gemcitabine alone versus gemcitabine with capcitabine (a fluorouracil that can be taken orally). Some centres continue to offer chemoradiotherapy, particularly in patients with involved (R1) resection margins, and further trials of adjuvant chemoradiation are also in progress.

Palliation

The median survival of patients with unresectable, locally advanced, non-metastatic pancreatic cancer is between six and ten months and, in patients with metastatic disease, it is two to six months.

If unresectable disease is found in the course of a laparotomy that was commenced with the intent to resect, a choledochoenterostomy and a gastroenterostomy should be carried out to relieve (or pre-empt) jaundice and duodenal obstruction. The bile duct may be anastomosed to the duodenum, or to a loop of jejunum. It is preferable to use the bile duct rather than the gall bladder. Cholecystojejunostomy is easier to perform, but the bile must then drain through the cystic duct, which is narrow and, if the cystic duct is inserted low into the bile duct, it is vulnerable to occlusion by tumour growth. A coeliac plexus block can also be administered. A transduodenal Trucut biopsy of the tumour should be obtained.

In patients found to have unresectable disease on imaging, jaundice is relieved by stenting at ERCP (Figure 68.36b). Stents may be made of plastic or self-expanding metal mesh. Plastic stents are cheaper but tend to occlude faster and, if the patient is likely to have a longer life expectancy, a metal stent can be used. If the patient is not a suitable candidate for endoscopic biliary stenting, a percutaneous transhepatic stent can be placed (Figure 68.36a). Obstruction of the duodenum occurs in approximately 15 per cent of cases. If this occurs early in the course of the disease, surgical bypass by gastrojejunostomy is appropriate but, if it is late in the course of the disease, then the use of expanding
metal stents inserted endoscopically is preferable, as many of these patients have prolonged delayed gastric emptying following surgery (Figure 68.36c). If both biliary and duodenal metal stents are to be placed endoscopically, the biliary one should be placed first.

If no operative procedure is undertaken, an EUS-guided or percutaneous biopsy of the tumour should be performed before consideration of chemotherapy or chemoradiation. The role of chemotherapy in the management of pancreatic cancer remains ill defined. If the tumour is a lymphoma, then benefit is without doubt. Lymphomas of the pancreas are rare and constitute less than 3 per cent of all pancreatic cancers. For patients with ductal adenocarcinoma, 5-FU or gemcitabine will produce a remission in 15–25 per cent, while the remainder will receive no benefit from the therapy. No long-term cures have been described with chemotherapy or radiotherapy.

Steatorrhoea is treated with enzyme supplementation. Diabetes mellitus, if it develops, is treated with oral hypoglycaemics or insulin as appropriate, and pain with either analgesics or an appropriate nerve block (Summary box 68.10).
Summary box 68.10

Palliation of pancreatic cancer

- Relieve jaundice and treat biliary sepsis
  - Surgical biliary bypass
    - Stent placed at ERCP or percutaneous transhepatic cholangiography
- Improve gastric emptying
  - Surgical gastroenterostomy
  - Duodenal stent
- Pain relief
  - Stepwise escalation of analgesia
  - Coeliac plexus block
  - Transdiaphragmatic splanchnicectomy
- Symptom relief and quality of life
  - Encourage normal activities
  - Enzyme replacement for steatorrhoea
  - Treat diabetes
- Consider chemotherapy

FURTHER READING

The small intestine

Although the duodenum is anatomically indistinguishable from the small intestine, it is subject to some specific pathologies and surgical therapies, so, in purely surgical terms may be regarded as a distinct entity, covered in Chapter 63. The length of the small bowel may vary from 300 to 850 cm between the duodeno-jejunal (DJ) flexure to the ileocaecal valve. It is notoriously difficult to establish the length of the small intestine, and estimates gathered at surgery, post-mortem and during radiological investigations vary widely, even in the same individual. In addition, there may be considerable interindividual variability and the small intestine is believed to be longer in men.

The proximal 40 per cent of the small intestine is referred to as the jejunum; the remainder is the ileum. There is no clear demarcation between jejunum and ileum, but the small bowel does change gradually in character from proximal to distal. The jejunum tends to have a wider diameter and a thicker wall, with more prominent mucosal folds (valvulae conniventes), while the ileum has a thicker, more fatty mesentery with more complex arterial arcades. The ileum also contains larger aggregates of lymph nodes (Peyer's patches), which can occasionally become lead points in intussusception in childhood.

The small intestine has a very rich blood supply, from the superior mesenteric artery, while venous drainage is via the portal venous system, into which the portal vein drains in turn. The lymphatic drainage of the small intestine follows the arterial supply. The small intestine has a rich autonomic innervation arising from the splanchnic nerves, which contribute a dense network of sympathetic fibres around the superior mesenteric artery and its branches. Referred pain from the small intestine is usually felt in the periumbilical region (T10). The blood and nerve supply to the small intestine all runs in the attached mesentery which originates on the posterior abdominal wall and runs obliquely downwards to the right between the DJ flexure to the left of the second lumbar vertebra and the right sacroiliac joint. Surgical resection of the small bowel requires careful division not only of the arteries and veins, but also the mesentery (see Summary box 69.1).

Summary box 69.1

Anatomy of the small and large intestine

- Small intestine
  - Comprises jejunum and ileum
  - Has valvulae conniventes
  - Blood supply from superior mesenteric artery

- Large intestine
  - Comprises caecum, ascending, transverse, descending and sigmoid colon
  - Has appendices epiploicae and taenia coli
  - Blood supply from branches of superior and inferior mesenteric arteries
  - Marginal artery runs round the length of the colon

To appreciate:
- The basic anatomy and physiology of the small and large intestines
- The range of conditions that may affect the intestines

To understand:
- The aetiology and pathology of common intestinal conditions
- The principles of investigation of intestinal symptoms

- The importance of non-surgical management of intestinal problems
- The principles of intestinal surgery
- That complex intestinal problems are best managed by a multidisciplinary team
- The management of acute surgical problems of the intestines
Large intestine

The large intestine begins at the ileocaecal valve and extends to the anus. It is divided into the caecum, with its attached vermiform appendix (discussed in Chapter 71), the ascending colon, which runs up to the hepatic flexure, the transverse colon with attached greater omentum, running up to the splenic flexure, the descending colon, sigmoid and rectum (discussed separately in Chapter 72). The large intestine is approximately 1.5 m long, although at colonoscopy the bowel can be straightened so the caecum can be reached with as little as 70 cm of colonoscope.

The large intestine is less mobile than the small bowel as the ascending and descending colon are fixed to the retroperitoneum following embryological rotation. The colon is also distinguished by having fat-filled peritoneal tags known as appendices epiploicae and the presence of taeniae. The taenia coli are three flat bands of longitudinal muscle that run the length of the large intestine from the appendix base to the rectosigmoid junction and they act to pull the colon into its typical sacculated state, producing a series of frustrations. Distended small and large intestine can be distinguished on an abdominal radiograph as the small bowel has complete transverse markings caused by the valvulae conniventes, while the colon has incomplete lines from the sacculation caused by the taeniae. The important posterior relations of the caecum and ascending colon are the right ureter, right gonadal vessels and duodenum, and these must be carefully protected at surgery. Similarly, the left ureter, left gonadal vessels and tail of the pancreas must be protected when operating on the left colon.

The blood supply of the large intestine is derived from branches of the superior mesenteric artery proximally as far as the distal transverse colon (which is derived embryologically from the primitive midgut) and the inferior mesenteric artery and its branches more distally (derived from the primitive hindgut). Adjacent branches of the superior and inferior mesenteric arteries anastomose so there is usually a complete vascular supply along the colon named the 'marginal artery of Drummond'. This vessel is often the key blood supply to the vascular arcades ensuring adequate perfusion of a colonic anastomosis, but blood flow in the 'watershed' area of the splenic flexure representing the junction between the superior and inferior mesenteric supply may be quite tenuous. The consequences of this might be, for example, that sudden occlusion of the inferior mesenteric artery may leave the area of the splenic flexure (at the most distal point of supply from the superior mesenteric artery) poorly perfused, leading to an ischaemic colitis. Venous and lymphatic drainage of the colon follows the arterial supply and as for the small intestine system, venous drainage is into the portal system. High ligation of the artery supplying a segment of colon will therefore remove the lymph nodes draining the area, a key technical point in cancer surgery. The nerve supply to the large intestine is derived from the splanchic nerves, via a dense sympathetic plexus surrounding the superior and inferior mesenteric arteries. Visceral pain from the part of the colon supplied by the superior mesenteric artery is thus felt, like that of the small intestine, in the periumbilical region, while pain from the colon distal to that point is felt suprapubically (T12–L1).

Physiology of the small and large intestines

Small intestine

The main function of the small intestine is the digestion of food and the absorption of nutrients and fluid. Carbohydrates and proteins are broken down by pancreatic enzymes, but the final hydrolysis takes place at the brush border of the jejunum after which they are absorbed. The products of fat digestion, fatty acids and monoglycerides separate from bile salts in the jejunum and are absorbed for further processing. The jejunum is the principal site for digestion and absorption of fluid, electrolytes, iron, folate, fat, protein and carbohydrate, but the absorption of bile salts and vitamin B12 occurs in the terminal ileum where there are specific transporters. If the jejunum is resected, the ileum can assume all the required absorptive functions, but resection of the terminal ileum will result in a diminished bile salt pool, B12 deficiency and may lead to deficiency of the fat-soluble vitamins A, D and K.

The small intestine plays an important role in the metabolism of plasma lipoproteins, as it is the main site of synthesis of high-density, low-density and very low-density lipoproteins (HDL, LDL, VLDL). The small bowel also synthesises intestinal hormones, which interact with the enteric nervous system to modulate intestinal function, growth and differentiation.

Large intestine

The principal function of the colon is absorption of water; 1000 mL of ileal contents enter the caecum every 24 hours of which only about 150–250 mL is excreted as faeces. Sodium absorption is efficiently accomplished by an active transport system, while chloride and water are absorbed passively following gradients established by the sodium pump. Fermentation of dietary fibre in the colon by the normal colonic microflora (principally anaerobic bacteria, such as bacteroides and bifidobacteria) leads to the generation of short chain fatty acids (SCFAs) such as butyrate, which is an important metabolic fuel for the colonic mucosa and may also contribute to normal daily energy requirements. Thus, diversion of the faecal stream (for example by a temporary ‘loop’ ileostomy) may lead to inflammatory changes in the colon downstream, a condition referred to as ‘diversion colitis’. Some absorption of nutrients including glucose, fatty acids, amino acids and vitamins can also take place in the colon, although under normal circumstances only a tiny amount of this occurs.

Colonic motility is variable. In general, faecal residue reaches the caecum 4 hours after a meal and the rectum after 24 hours. Passage of stool is not orderly, however, because of mixing within the colon. It is thus common for residue from a single meal to still be passed 4 days later.

Inflammatory bowel disease

By definition, the term ‘inflammatory bowel disease’ is reserved for conditions characterised by the presence of idiopathic intesti-
tinal inflammation, i.e. ulcerative colitis (UC) and Crohn’s disease (CD). Conditions such as infective or ischaemic colitis or enteritis are thus excluded. Although the availability of population genetics and molecular biology has contributed to our understanding of the pathogenesis of inflammatory bowel disease, the cause of these conditions remains unknown.

ULCERATIVE COLITIS

Ulcerative colitis is a disease of the rectum and colon with extraintestinal manifestations. The incidence is 10 per 100,000 in the UK with a prevalence of 160 per 100,000. The prevalence of UC is stable (unlike Crohn’s disease, which is increasing). UC is said to be more common in the Ashkenazi Jewish population and affects men and women equally in early life, although it is said to be more common in males in later life. It is most commonly diagnosed between the ages of 20 and 40. There is a marked geographical distribution of the disease which is far more common in the United States and Western Europe, but relatively rare in the Far East and the Tropics. The incidence in the Asian population of the UK seems to be determined by where childhood was spent. Asians who spent their childhood before the age of 14 in Asia have a much lower incidence of UC than Asians born and raised in the UK, suggesting an important effect of environmental exposure in childhood.

Aetiology

The cause of UC is unknown. There is clearly a genetic contribution as 10–20 per cent of patients with UC have a first-degree relative with inflammatory bowel disease. UC is more common in Caucasians than in the Afro-Caribbean or Asian population. No causative link with any specific organism has been identified, although studies of patients with severe colitis have suggested a reduction in the number of anaerobic bacteria and a reduction in the variability of bacterial strains in the colon. Whether this is a primary feature of the disease or a secondary consequence of mucosal inflammation is unclear. Animal studies, using models of colitis, have suggested that the presence of a bacterial flora is important in the development of colitis, even if no specific organism is involved. For example, mice with a genetic deficiency predisposing them to colitis (e.g. strains with the genes for IL-10 or PGP knocked out) appear to be protected if reared in a germ-free environment. Although it has been suggested that the mechanism of UC may relate to a primary abnormality of mucosal permeability, resulting in bacterial antigens being able to cross the colonic mucosal barrier and thus triggering an inflammatory response, the data to support this hypothesis are unclear and more recent studies in animal models have shown that genes involved in mucosal inflammation and bacterial recognition are already activated long before evidence of abnormal permeability or overt inflammation appear. This suggests that the demonstration of increased colonic mucosal permeability in colitis may be a consequence, rather than a cause of the disease. Unlike Crohn’s disease, smoking seems to have a protective effect in UC and has even been the basis of therapeutic trials of nicotine therapy. Patients often comment that relapses are associated with periods of stress, but personality and psychiatric profiles in patients with UC are the same as those of the normal population.

Pathology

In virtually all cases, the disease starts in the rectum and extends proximally in continuity. The rectum is involved in all circumstances except in those using topical rectal preparations (rectal sparing). Failure of colonic inflammation to adhere to this pattern should lead to strong suspicion that the diagnosis is not one of UC. Colonic inflammation in UC is diffuse, confluent and superficial, primarily affecting the mucosa and superficial submucosa. In very severe cases, the inflammation may extend full thickness through the wall of the colon, making interpretation difficult. Chronic mucosal ulceration is associated with formation of granulation tissue and regeneration, leading to a polyp-like appearance, ‘pseudopolyposis’, which occurs in almost one-quarter of cases. Stricture in UC is very unusual and should prompt urgent assessment because of the possibility of coexisting carcinoma. A small proportion of patients with colonic dysplasia may develop irregular mucosal swellings (dysplasia-associated lesions or mass, DALMs), which are highly predictive of the likelihood of coexisting carcinoma.

Histological examination reveals an increase in inflammatory cells in the lamina propria, the walls of the crypts of Lieberkuhn are infiltrated by inflammatory cells and there are crypt abscesses. There is depletion of goblet cell mucin. With time, precancerous changes can develop (dysplasia). The precise incidence of dysplasia in UC is unclear. It seems to increase with time and may range from 2 per cent, up to 18 per cent at 30 years. Dysplasia is classified into low- or high-grade dysplasia. In general, high-grade dysplasia is regarded as an absolute indication for colectomy, as 40 per cent of colectomy specimens in which high-grade dysplasia was detected will have evidence of a colorectal cancer. In contrast, optimum management of low-grade dysplasia is currently controversial. Although the decision to proceed to colectomy must be individualized, 10–30 per cent of patients with low-grade dysplasia will have a cancer at colectomy. The progression rate of low-grade dysplasia to invasive cancer is unclear, and it is likely that many cancers in patients with low-grade dysplasia develop without an intervening period of high-grade dysplasia.

Symptoms

Clinical presentation depends in large part on the extent of disease and the presence or otherwise of complications (see Summary box 69.2). If confined to the rectum (proctitis), there is usually no systemic upset and extra-alimentary manifestations are rare. The main symptoms will be rectal bleeding, tenesmus and mucous discharge. The disease remains confined to the rectum in 90 per cent of cases but proctitis may spread proximally over time. Colitis is almost always associated with bloody diarrhoea and urgency that can be incapacitating. Pain is unusual. Children with poorly controlled colitis may have impaired growth. The more extensive the disease, the more likely extraintestinal manifestations are to occur. Extensive colitis is also associated with systemic illness, characterised by malaise, loss of appetite and fever. Diarrhoea may be profuse and bloody, resulting in anaemia, hypoproteinaemia and electrolyte disturbance. Approximately 30 per cent of patients have inflammation extending to the sigmoid colon and spread proximal to the splenic flexure occurs in 20 per cent.
Complications of ulcerative colitis

- Acute
  - Toxic dilatation
  - Perforation
  - Haemorrhage
- Chronic
  - Cancer
  - Extra-alimentary manifestations: skin lesions, eye problems and liver disease

Classification of colitis severity

The assessment of severity of UC is determined by frequency of bowel action and the presence of systemic signs of illness:

- **Mild disease** is characterised by fewer than four stools daily, with or without bleeding. There are no systemic signs of toxicity, and a normal erythrocyte sedimentation rate (ESR).
- **Moderate disease** corresponds to more than four stools daily, but with few signs of systemic illness. There may be anaemia (but not sufficient to require transfusions). Abdominal pain may occur. Inflammatory markers, including ESR and C-reactive protein (CRP) are often raised.
- **Severe disease** corresponds to more than six bloody stools a day, and evidence of systemic illness with fever, tachycardia, anaemia and raised inflammatory markers. Hypoalbuminaemia is common and an ominous finding.
- **Fulminant disease** is associated with more than ten bowel movements daily, fever, tachycardia, continuous bleeding, anaemia, hypoalbuminaemia, abdominal tenderness and distension, blood transfusion requirement and in the most severe cases, progressive colonic dilation (‘toxic megacolon’). This is a very significant finding, suggestive of disintegrative colitis and an indication for immediate surgery if colonic perforation is to be avoided.

Extraintestinal manifestations

Arthritis occurs in around 15 per cent of patients and is of the large joint polyarthritis type, affecting knees, ankles, elbows and wrists. Sacroiliitis and ankylosing spondylitis are 20 times more common in patients with UC than the general population and are associated with HLA-B27. Sclerosing cholangitis is associated with UC and can progress to cirrhosis and hepatocellular failure. Patients with UC and sclerosing cholangitis are also at a greater risk of development of large bowel cancer. Cholangiocarcinoma is an extremely rare association and its frequency is not influenced by colectomy. The skin lesions erythema nodosum and pyoderma gangrenosum are associated with UC and both normally get better with good colitis control. The eyes can also be affected with uveitis and episcleritis.

Acute colitis

Around 5 per cent of patients present with severe acute (fulminant) colitis characterised by frequent bloody diarrhoea, weight loss and dehydration. Intensive medical treatment and fluid resuscitation leads to remission in 70 per cent, but the rest will require urgent surgery. Toxic dilatation should be suspected in patients with active colitis who develop severe abdominal pain and confirmed by the presence on a plain abdominal radiograph of colon with a diameter of more than 6 cm (megacolon, Figure 69.1). A reduction in stool frequency is not always a sign of improvement in patients with severe UC, and the presence of a falling stool frequency, abdominal distension and abdominal pain (resulting from progression of the inflammatory process through the colonic wall) are strongly suggestive of the development of disintegrative colitis and impending perforation. Severe UC must be differentiated from dysentery, typhoid and amoebic colitis (which can also lead to colonic perforation). Plain abdominal radiographs should be obtained daily in patients with severe colitis, and a progressive increase in diameter in spite of medical therapy is an indication for surgery. Colonic perforation in UC is a grave complication with a mortality rate of 40 per cent. Steroids may mask the physical signs. Severe haemorrhage is uncommon (1–2 per cent), but may occasionally require urgent surgical intervention.

Cancer risk in colitis

The risk of cancer in ulcerative colitis increases with duration of disease. At ten years from diagnosis, it is around 1 per cent. This increases to 10–15 per cent at 20 years and may be as high as 20 per cent at 30 years. There is some evidence to suggest that these figures may be an overestimate of cancer risk and that good control of colonic inflammation may significantly reduce risk. Nevertheless, most patients with pancolitis of more than ten years’ duration should be entered into screening programmes in order to detect clinically silent dysplasia, which is predictive of increased cancer risk. The value of screening programmes remains somewhat controversial, however, with most UC patients who develop cancer (approximately 3.5 per cent) presenting with their tumours in between attendances for screening colonoscopy. Carcinoma is more likely to occur if the whole colon is involved (Figure 69.2) or if the disease started early in life. Carcinomatous change, often atypical and high grade, may occur at many sites at once. Colonoscopic

![Figure 69.1 Fulminating ulcerative colitis with toxic dilatation of the transverse colon (courtesy of Dr Ian Talbot, St Mark’s Hospital, London).](image-url)
surveillance with multiple biopsies is advised to detect dysplasia, which can occur in a flat mucosa, or a DALM. If on biopsy, there is epithelial dysplasia, surgery should be considered, as cancers may be found in 40 per cent of colectomy specimens for colitis-associated dysplasia.

**Investigations**

**Endoscopy and biopsy**

Rigid/flexible sigmoidoscopy can detect proctitis in the clinic: the mucosa is hyperaemic and bleeds on touch, and there may be a purulent exudate. Where there has been remission and relapse, there may be the presence of regenerative mucosal nodules or pseudopolyps. Later, tiny ulcers may be seen that appear to coalesce. This is quite different from the picture of amoebic dysentery, in which there are large, deep ulcers with intervening normal mucosa. Colonoscopy and biopsy has a key role in diagnosis and management:

- to establish the extent of inflammation;
- to distinguish between UC and Crohn’s colitis (although this can be exceptionally difficult, Table 69.1);
- to monitor the response to treatment;
- to assess long-standing cases for malignant change.

In the last case, detailed colonoscopic assessment using dye-spray to look for subtle mucosal abnormalities and taking multiple random biopsies every 10 cm is required.

**Radiology**

A plain abdominal film may indicate the severity of disease in the acute setting and is particularly valuable in demonstrating the development of toxic megacolon (Figure 69.3). Faeces are present only in parts of the colon that are normal or only mildly inflamed. Mucosal islands can sometimes be seen. Small bowel loops in the right lower quadrant may be a sign of severe disease.

Figure 69.2 Resection specimen from a patient with long-standing ulcerative colitis showing a narrow tubular colon with areas of cancerous change in the rectum and sigmoid (courtesy of Dr B Warren, John Radcliffe Hospital, Oxford, UK).

Figure 69.3 Supine abdominal radiograph in toxic megacolon. The transverse colon is dilated (7 cm), there is no formed residue in the colon, and large mucosal islands are present in the ascending colon and hepatic flexure. No haustration is present in the transverse colon, which distinguishes this from ileus of obstruction. Mucosal islands are due to oedematous remnants or mucosa where there has been extensive ulceration (courtesy of Dr C Bartram, St Mark’s Hospital, London, UK).
Barium enema has been replaced by computed tomography (CT) in the majority of centres, although a contrast study will give an excellent view of loss of haustra, especially in the distal colon, pseudopolyps and in chronic cases a narrow, featureless, shortened ‘hosepipe’ colon (Figure 69.4). CT findings in pancolitis may show significant thickening of the colonic wall, as well as inflammatory stranding in the colonic mesentery (Figure 69.5).

**Bacteriology**

A stool specimen should be sent for microbiology analysis when UC is suspected, in order to exclude infective colitides, notably *Campylobacter*, which may be very difficult to distinguish from acute severe UC. Other infective causes include *Shigella* and *amoebiasis*. Pseudomembranous colitis occurs in hospital patients on antibiotic treatment and, occasionally, those on non-steroidal anti-inflammatory drugs (NSAIDs). The causative organism is *Clostridium difficile*. Immunocompromised patients are at risk of infective proctocolitis from cytomegalovirus and *cryptosporidia*.

**Treatment**

Effective treatment of UC requires a multidisciplinary approach to management. This involves the gastroenterologist, nurses, nutritionist, enterostomal therapists and occasionally clinical psychologists and social workers, as well as the surgeon (see Summary box 69.3).

**Summary box 69.3**

**Principles of management of ulcerative colitis**

- Many patients can be adequately maintained for years on medical therapy
- Toxic dilatation must be suspected in any colitic patient who develops severe abdominal pain; missed colonic perforation is associated with a high mortality
- Colitic patients are at increased risk of developing cancer; those with pancolitis of long duration are at most risk

**Medical treatment**

Medical therapy is based on anti-inflammatory agents. The 5-aminosalicylic acid (5-ASA) derivatives can be given topically (per rectum) or systemically. They act as inhibitors of the cyclo-oxygenase (COX) enzyme system and are formulated to protect the aspirin-related drug from degradation before reaching the colon. They can be used long term as maintenance therapy. Corticosteroids are the mainstay of treatment for any ‘flare up’, either topically or systemically and have a widespread anti-inflammatory action. The immunosuppressive drugs azathioprine and cyclosporin can be used to maintain remission and as ‘steroid-sparing’ agents. More recently, monoclonal antibodies have entered clinical practice; infliximab and adalimumab both act against tumour necrosis factor alpha, which has a central role in inflammatory cascades.

**Proctitis**

The majority of patients can be managed with rectal steroids for an acute attack and oral 5-ASA compounds to maintain remission. Occasionally, a reducing course of oral steroids is required. It is very unusual for patients with purely rectal disease to require surgery.
Acute colitis

Patients with a mild attack (up to four motions a day) usually respond to a course of oral prednisolone given over a 3- to 4-week period. One of the 5-ASA compounds can be given concurrently. A moderate attack often responds to oral prednisolone, twice-daily steroid enemas and 5-ASA. Failure to achieve remission as an outpatient is an indication for admission. Severe attacks of UC occur in up to 10 per cent of patients and are emergencies requiring hospital admission. Regular assessment of vital signs, weight and the abdomen is required. A stool chart should be kept and a plain abdominal radiograph is taken daily and inspected for dilatation of the transverse colon. The presence of mucosal islands or intramural gas on plain radiographs (see Figure 69.6), increasing colonic diameter or a sudden increase in pulse and temperature may indicate a colonic perforation. Fluid and electrolyte balance is maintained, anaemia corrected and adequate nutrition is provided, sometimes intravenously in severe cases. If the patient is not having immediate surgery, then oral nutrition is important. It is important to ensure that calorie and nitrogen requirements are met by dietary supplementation or intravenous feeding. The patient is treated with intravenous hydrocortisone four times daily, as well as rectal steroids. There is no evidence that antibiotics modify the course of a severe attack. If there is failure to gain an improvement within 48 hours of commencing high-dose intravenous steroids, then surgery should be seriously considered and it is certainly advisable if there has been no improvement within 3–5 days. Regular and joint review by gastroenterologist and surgeon is essential to identify patients who are failing to make anticipated progress and to ensure that surgery is neither inappropriately delayed nor undertaken. Some gastroenterologists will use azathioprine, cyclosporin A or infliximab in severe attacks to try and induce remission.

Indications for surgery

The greatest likelihood of a patient with UC requiring surgery is during the first year after diagnosis. The overall risk of colectomy is 20 per cent. Indications for surgery in UC are:

- severe or fulminating disease failing to respond to medical therapy;
- chronic disease with anaemia, frequent stools, urgency and tenesmus;
- steroid-dependent disease (here, the disease is not severe, but remission cannot be maintained without substantial doses of steroids);
- inability of the patient to tolerate medical therapy required to control the disease (steroid psychosis or other side effects, azathioprine-induced pancreatitis), such that remission cannot be maintained;
- neoplastic change: patients who have severe dysplasia or carcinoma on review colonoscopy;
- extraintestinal manifestations;
- rarely, severe haemorrhage or stenosis causing obstruction.

Operative treatment for UC

Emergency

In the emergency situation (or for a patient who is malnourished or on steroids), the ‘first aid procedure’ is a subtotal colectomy and end ileostomy. The rectal stump (really rectosigmoid) is left long and can either be brought out as a mucous fistula or closed just beneath the skin. Ideally, the rectal stump is exteriorised as a mucous fistula in the left iliac fossa, and not through the lower end of the wound, which creates significant problems for stoma management. This operation has the advantages that the patient avoids a pelvic operation while unstable, that colonic histology can be assessed and restorative surgery can be contemplated at a later date when the patient is no longer on steroids and has fully recovered from systemic illness and is optimally nourished. The operation is performed in a similar manner to an extended right hemicolecctiony – the omentum should be preserved if possible and the dissection of the left colon is continued to divide the sigmoid at a level which will comfortably reach the skin as a mucous fistula. In colitis, it is not necessary to take the mesenteric vessels at their origin. Unless the rectosigmoid is itself disintegrating, the temptation to close the rectal stump and leave it stapled off in the pelvis should be avoided if at all possible. The diseased rectum may disintegrate, causing a pelvic abscess and severe sepsis, with potentially fatal consequences. Allowing the rectal remnant to discharge through the mucus fistula not only minimises the risk of this serious complication, but may also allow the delivery of high-dose topical steroid or 5-ASA compound, via the mucous fistula, into the isolated rectum.

Elective surgery

The indications for elective surgery include:

- failure of medical therapy/steroid dependence;
- growth retardation in the young;
- extraintestinal disease (polychondritis and pyoderma gangrenosum respond to colectomy);
- malignant change.

In the elective setting, four operations are available:

1. Subtotal colectomy and ileostomy (as in an emergency)
2. Proctocolectomy and permanent end ileostomy
3. Restorative proctocolectomy with ileoanal pouch
4. Subtotal colectomy and ileorectal anastomosis.

Figure 69.6 Abdominal radiograph demonstrating gas in the wall of the caecum (courtesy of Dr D Kasir, Hope Hospital, Salford, UK).
Segmental resections are not recommended as even when the right side is not obviously involved, there is a high recurrence rate in the remaining colon. Subtotal colectomy with ileostomy is performed electively for a frail patient, a patient who cannot be weaned from steroids and when there is doubt as to whether the colitis may represent Crohn’s disease. A pouch, a completion proctectomy and even an ileorectal anastomosis can all then be considered at a future date. All of these procedures including formation of a pouch, can be performed laparoscopically in experienced hands.

**Proctocoecotomy and ileostomy**

This operation removes all the colon and rectum, removing any risk of colorectal neoplasia or colitic symptoms, but it leaves a permanent stoma. It has a lower complication rate compared with a pouch procedure, although the perineal wound can be problematic (10 per cent fail to heal) and stoma problems are common. It is indicated for patients who are not candidates for restorative surgery due to sphincter problems or patient preference. The colectomy is performed as above. Provided there is no concern around rectal cancer a close rectal dissection may be performed to minimise damage to the pelvic nerves, avoiding erectile and bladder dysfunction. An intersphincteric excision of the anus is undertaken, which results in a smaller perineal wound and fewer healing problems. A permanent end ileostomy is formed, as described later, with scrupulous attention to detail to ensure a good functional and cosmetic result. It is particularly important to ensure that an adequate spout is created and the stoma is sited adequately to ensure that it is appropriate for the patient’s build. The position of the ileostomy should be carefully chosen by the patient with the help of a stoma care nurse specialist. There is an argument for making the trephine incision before entering the abdomen to prevent any problems of distortion of the abdominal wall after opening. If performed laparoscopically, the specimen is removed through the perineal wound and so there is no requirement for any abdominal incision other than the port sites.

**Restorative proctocolectomy with an ileoanal pouch (Parks)**

In this operation, a pouch is made out of ileum (Figure 69.7) as a substitute for the rectum and sewn or stapled to the anal canal. This avoids a permanent stoma. It is reserved for patients with adequate anal sphincters and should be avoided when Crohn’s disease is a possibility. Various pouch designs have been described, but the ‘J’ is the most popular and the most easily made using staplers (Figure 69.8). The ‘S’ (three loop) has been associated with evacuation difficulties due to the short efferent spout. The ‘W’ (four loop) pouch has a larger reservoir, which results in less bowel frequency. There is some controversy over the correct technique for ileoanal anastomosis. In the earliest operations, the mucosa from the dentate line up to midrectum was stripped off the underlying muscle, but it is now known that a long muscle cuff is not needed. Although mucosectomy of the upper anal canal with an anastomosis at the dentate line is claimed to remove all of the at-risk mucosa and any problem of subsequent cancer, it may also increase the risk of incontinence with nocturnal seepage. The alternative is an anastomosis double-stapled to the top of the anal canal, preserving the upper anal canal mucosa. Continence appears to be better, but there is a theoretical risk of leaving inflamed mucosa behind. The procedure can be carried out in stages. In most cases, a covering loop ileostomy is used as described later.

Complications include pelvic sepsis (usually resulting from a leak at the ileoanal anastomosis or, in a J pouch, from the top of the ‘J’), postoperative small bowel obstruction (which may occur in as many as 10–15 per cent of patients) and perineal fistula. Frequency of evacuation is determined by pouch volume, completeness of emptying, reservoir inflammation and intrinsic small bowel motility, but is typically between three and eight evacuations in each 24-hour period. Increased frequency, urgency and faecal incontinence can be seen (20, 5 and 5 per cent, respectively), but these reduce with time. Approximately 50 per cent of patients with ileoanal pouches have a very good quality of life, whereas 35 per cent of patients are less satisfied but choose to retain their pouches. Pouch function is so poor in 15 per cent that the pouch is removed. The main reasons for failure are pelvic sepsis (50 per cent), poor function (30 per cent)
Crohn’s disease (regional enteritis)

and pouchitis or inflammation of the pouch (10 per cent). It is also important for women of reproductive age to be advised that they may suffer from reduced fertility, as well as vaginal dryness, due to denervation of the secretory glands of the vaginal mucosa. Women who have not completed their families may elect for a colectomy with ileostomy and a pouch later. If it turns out that the patient actually has Crohn’s disease, there is a high rate of pouch failure and the operation is not usually recommended in this disease.

In expert hands, a restorative proctocolectomy can be performed safely laparoscopically. This has a longer operative time but is likely to result in shorter lengths of stay. In young patients, the better cosmetic result with preservation of body image is a consideration. Striking images of well patients with tiny laparoscopic scars and no stoma can act as an advert for the laparoscopic approach. There is also the as yet unproven possibility that laparoscopic pouch surgery will result in a reduction in incisional hernias and small bowel obstruction and less effect on female fertility than open surgery. The key factors still to be determined for the laparoscopic approach are functional outcomes as there is a significant technical challenge to cross-stapling at the pelvic floor and there is the potential to leave a longer rectal cuff, than via an open approach, although this might be circumvented by a new perineal approach dubbed the APPEAR technique.

Pouchitis describes an inflammatory condition, which may affect 30 per cent of patients with an ileal pouch. It is characterised not only by the presence of inflammation in the pouch (which is common and frequently asymptomatic), but also by symptoms of pouch dysfunction (increased frequency, tenesmus, bleeding, purulent discharge) and systemic illness (malaise, fever, raised inflammatory markers). The cause of pouchitis is unknown, but it appears to relate to inflammatory bowel disease (pouchitis does not seem to occur in pouches created for patients for other indications). Alterations in bacteria flora in the pouch may be relevant as pouchitis usually responds to a short course of antibiotic therapy, notably with metronidazole or ciprofloxacin.

Colectomy and ileorectal anastomosis

This procedure is occasionally performed in UC if there is minimal rectal inflammation after total colectomy. It is rarely appropriate as a very considerable percentage (at least 50 per cent) of patients with a quiescent rectum after total colectomy will develop significant mucosal inflammation in the rectum, once the faecal stream has been re-established. Although rectal inflammation can be controlled with medical treatment, functional results may be disappointing. If the rectum is preserved, then annual rectal inspection is advocated. Although this procedure has the advantage of avoiding a stoma and the risk to sexual function associated with rectal dissection, it has fallen out of favour due to the ongoing risk of persisting inflammation and malignancy in the retained rectum.

Indeterminate colitis

Ten per cent of patients with colitis present with histological features that make their disease difficult to characterise. They may, for example, have a patchy colitis, with evidence of fissuring and/or transmural ulceration, or cobblestoning of the colonic mucosa, raising the possibility of Crohn’s disease, but without clear pathognomonic features of Crohn’s disease, such as epithelioid granulomata (see below); such patients may be said to have an ‘indeterminate colitis’. Indeterminate colitis is not, therefore, a specific disease entity so much as an indication by a pathologist that the underlying pattern of colitis (and therefore the course of the illness) is unclear. While the clinical history may suggest the diagnosis in some cases (for example, a history of recurrent perianal sepsis and fistulation would make a diagnosis of Crohn’s disease more likely), in others, it may remain, despite colectomy, unclear whether a patient has UC or Crohn’s disease. In such cases, it may still be appropriate to offer a pouch, but the risks of pouch failure appear to be significantly higher (up to 25–30 per cent) and patients should be advised accordingly.

Crohn’s disease (regional enteritis)

The label ‘Crohn’s disease’ became attached to a chronic inflammatory disease of the ileum following a key publication by Burrill Crohn and colleagues in 1932. CD is characterised by a chronic full thickness inflammatory process that can affect any part of the gastrointestinal tract from the lips to the anal margin. It is most common in North America and Northern Europe with an incidence of 5 per 100 000. Prevalence rates of around 50 per 100 000 have been reported in the UK. Over the last four decades, there seems to have been a rise in the incidence, which

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, along with Leon Ginzburg and Gordon Oppenheimer described regional ileitis in 1932.
cannot be accounted for by increased diagnosis. It is slightly more common in women than in men, and is most commonly diagnosed in young patients between the ages of 25 and 40 years. There does, however, seem to be a second peak of incidence around the age of 70 years. In those countries with high prevalence of CD, the groups with the highest prevalence seem to be Caucasian, notably American Whites and Northern Europeans, whereas it is less common, even in high prevalence countries, in those originating from Central Europe and less prevalent still in those originating from South America, Asia and Africa. CD seems to be especially prevalent (three- to five-fold higher) in the Ashkenazi Jewish population, although interestingly, the prevalence of CD in the Jewish population in Israel is lower than that in Europe or the United States, suggesting the importance of environmental factors.

Aetiology
The aetiology of Crohn’s disease is incompletely understood but is thought to involve a complex interplay of genetic and environmental factors. Although CD shares some features with chronic infection, no causative organism has ever been demonstrated. An intriguing similarity to Johne’s disease of cattle, a chronic inflammatory enteropathy resulting from infection with Mycobacterium paratuberculosis, suggests that CD in man may share a common aetiology. Some studies in which molecular biological analyses of tissue affected by CD have identified mycobacterial DNA more frequently in patients with CD than in controls, but others have been less conclusive and, in particular, randomised controlled trials have failed to show a significant therapeutic benefit of treating CD with antituberculous drugs. A wide variety of foods have been implicated, and in particular, a diet high in refined foodstuffs, but none conclusively. An association with high levels of sanitation in childhood has been suggested. Smoking increases the relative risk of CD threefold and is certainly an exacerbating factor after diagnosis, contrary to the protective effect seen in UC. Genetic factors are clearly important. Approximately 10 per cent of patients have a first-degree relative with the disease, and concordance has been shown to approach 50 per cent in monozygotic twins. Inheritance is thought to involve multiple genes with low penetrance. The NOD2/CARD15 gene has excited particular interest as variants of this gene have been shown to have strong associations with CD. Genetic manipulation of these genes in mice seems to induce the development of a disease resembling CD and abnormalities of these genes have been shown to be present in some members of families with a particularly high incidence of CD. It should be noted, however, that abnormalities of these genes have not been found in the vast majority of individuals with CD. Since these genes are involved in intracellular recognition of bacteria, their discovery provides potentially valuable insight into the pathogenesis of CD, as a disease in which the relationship between the gut mucosa and the normal gut bacteria becomes deranged, resulting in uncontrolled intestinal inflammation.

Pathology
The terminal ileum is most commonly involved (60 per cent), either in isolation or in combination with colonic disease. Colitis alone occurs in up to a third of cases and the remainder are patients with more proximal small bowel involvement. The stomach and duodenum are affected in around 5 per cent, but perianal lesions are common, affecting up to 50–75 per cent of patients. Perianal disease occurs in 25 per cent of patients with small bowel disease, but in 75 per cent of patients with Crohn’s colitis.

Macroposcopically, resection specimens show a fibrotic thickening of the intestinal wall with a narrow lumen and fat wrapping (encroachment of mesenteric fat around the bowel, Figure 69.9). There is usually dilated bowel just proximal to the stricture and deep mucosal ulcerations with linear or snake-like patterns in the strictured area itself. Oedema in the mucosa between the ulcers gives rise to a cobblestone appearance. The transmural inflammation (which is a key feature of CD) may lead to segments of bowel becoming adherent to each other and to surrounding structures, inflammatory masses with mesenteric abscesses and fistulae into adjacent organs. The serosa is usually oapque, with thickening of the mesentry and enlarged lymph nodes. Perianal disease occurs in 25 per cent of patients, most commonly in women, and is not related to the extent of bowel involvement. It is often chronic and extensive, affecting the anus and perianal skin. Fistulae, abscesses and sinus tracts may be present, particularly in longstanding disease.

Pathogenesis
As in UC, there is thought to be an increased permeability of the mucus membrane. This may lead to increased passage of luminal antigens, which then induce a cell-mediated inflammatory response. This results in the release of proinflammatory cytokines, such as interleukin-2 and tumour necrosis factor, which coordinate local and systemic inflammatory responses. It has been suggested that CD is associated with a defect in suppressor T cells, which usually act to prevent escalation of the inflammatory process. As in UC, however, it remains unclear whether the proposed increase in intestinal permeability is a cause or consequence of the disease process. Studies of intestinal permeability in healthy and apparently unaffected first degree relatives of patients with CD have also, however, suggested that gut permeability is increased, suggesting that a global, and potentially genetically determined increase in gut permeability, combined perhaps with an abnormal immune-mediated response to colonisation of the gut with subspecies of the normal enteric microflora, may initiate the disease.

Figure 69.9 Crohn’s disease of the ileocaecal region showing typical thickening of the wall of the terminal ileum with narrowing of the lumen (courtesy of Dr B Warren, John Radcliffe Hospital, Oxford, UK).

Eugen Joanda Alexander Polyja, 1876–1944, surgeon, St Stephen’s Hospital, Budapest, Hungary.
mesenteric lymph nodes. CD is characteristically discontinuous, with inflamed areas separated from normal intestine, so-called ‘skip’ lesions.

Microscopically, there are focal areas of chronic inflammation involving all layers of the intestinal wall with lymphoid aggregates. Non-caseating giant cell granulomas are found in 60 per cent of patients and clearly define Crohn’s disease. They are most common in anorectal disease. Multifocal arterial occlusions are found in the muscularis propria, which is thickened. There is deep, fissuring ulceration within affected areas. Characteristically, and unlike in UC, there may be completely normal areas immediately next to areas of severe inflammation.

Clinical features

Presentation depends upon the pattern of disease. Very infrequently, CD presents acutely with acute ileal inflammation and symptoms and signs resembling those of acute appendicitis, or even free perforation of the small intestine, resulting in a local peritonitis. CD may present with fulminant colitis but this is considerably less common than in UC (see Summary box 69.4).

Summary box 69.4

Differences between ulcerative colitis and Crohn’s disease

- Ulcerative colitis affects the colon; Crohn’s disease can affect any part of the gastrointestinal tract, but particularly the small and large bowel
- UC is a mucosal disease, whereas CD affects the full thickness of the bowel wall
- UC produces confluent disease in the colon and rectum, whereas CD is characterised by skip lesions
- CD more commonly causes strictureing and fistulation
- Granulomas may be found on histology in CD, but not in UC
- CD is often associated with perianal disease, whereas this is unusual in UC
- CD affecting the terminal ileum may produce symptoms mimicking appendicitis, but this does not occur in UC
- Resection of the colon and rectum cures the patient with UC, whereas recurrence is common after resection in CD

Crohn’s disease more commonly presents with features of chronicity. Chronic small bowel CD often manifests as mild diarrhoea extending over many months, occurring in bouts accompanied by intestinal colic. Patients may complain of pain, particularly in the right iliac fossa, and a tender mass may be palpable. Intermittent fevers, secondary anaemia and weight loss are common. After months of repeated attacks with acute inflammation, the affected area of intestine begins to narrow with fibrosis, causing obstructive symptoms. Children developing the illness before puberty may have retarded growth and sexual development. With progression of the disease, adhesions and transmural fissuring, intra-abdominal abscesses and fistulae may develop.

Fistulation may occur into adjacent loops of bowel (enteroenteric fistulae), and, most notably the (healthy) sigmoid loop may become adherent to the affected terminal ileum, resulting in ileosigmoid fistulation and profuse diarrhoea. Fistulation may also occur into the bladder (ileovesical) or the female genital tract and, less commonly, the duodenum. Fistulation into the abdominal wall (enterocutaneous fistulation) may also develop spontaneously, but more commonly occurs as a complication of abdominal surgery.

Colon CD presents with symptoms of colitis and proctitis as described for UC, although toxic megacolon is much less common (Figure 69.10). Many patients with CD present with perianal problems. In the presence of active disease, the perianal skin appears bluish. Superficial ulcers with undermined edges are relatively painless and can heal with bridging of epithelium. Deep cavitating ulcers are usually found in the upper anal canal; they can be painful and cause perianal abscesses and fistulae, discharging around the anus and sometimes forwards into the genitalia. Fistulation through the posterior wall of the vagina may lead to rectovaginal fistula and continuous leakage of gas and/or faeces per vagina.

The rectal mucosa is often spared and may feel normal on rectal examination. If it is involved however, it will feel thickened, nodular and irregular. Perianal disease is frequently associated with dense, fibrous strictureing at the anorectal junction. Incontinence may develop as a result of destruction of the anal sphincter musculature because of inflammation, abscess formation, fibrotic change and repeated episodes of surgical drainage. In severe cases, the perineum may become densely fibrotic, rigid and covered with multiple discharging openings (watering-can perineum).

Extraintestinal manifestations

The extraintestinal manifestations of Crohn’s disease are similar to those that occur in UC and are outlined in Summary box 69.5. Gallstones are common due to an inflamed or excised terminal ileum leading to reduced absorption of bile salts. Amyloidosis is common at post-mortem, but is rarely symptomatic. ‘Metastatic’ CD can occur in the vagina or skin with nodular ulcers, which demonstrate non-caseating granulomas when biopsied. The appearances can be indistinguishable macroscopically from hidradenitis suppurativa.
PART 11 | ABDOMINAL

1154 THE SMALL AND LARGE INTESTINES

Summary box 69.5

**Extraintestinal manifestations of Crohn’s disease**
- Related to disease activity
  - Erythema nodosum
  - Pyoderma gangrenosum
  - Arthropathy
  - Eye complications (iritis/uveitis)
  - Aphthous ulceration
  - Amyloidosis
- Unrelated to disease activity
  - Gallstones
  - Renal calculi
  - Primary sclerosing cholangitis
  - Chronic active hepatitis
  - Sacroiliitis

Investigations

**Laboratory**
A full blood count should be performed, as anaemia is common and usually multifactorial, it may result from the anaemia of chronic disease, or from iron deficiency as a result of blood loss or malabsorption. Vitamin B12 deficiency may occur as a consequence of terminal ileal disease or resection. Active inflammatory disease is usually associated with a fall in serum albumin, magnesium, zinc and selenium. Acute phase protein measurements (C-reactive protein and orosomucoid) may correlate with disease activity.

**Endoscopy**
Colonoscopic examination may be normal or show patchy inflammation. There will be areas of normal colon or rectum in between areas of inflamed mucosa that are irregular and ulcerated, with a mucopurulent exudate. The earliest appearances are aphthous ulcers surrounded by a rim of erythematous mucosa. These become larger and deeper with increasing severity of disease. There may be stricturing, and it is important to exclude malignancy in these sites. An irregular Crohn’s stricture with polypoid mucosa may be almost indistinguishable from malignancy. The terminal ileum may be ulcerated and strictured. In patients who have had previous ileocaecal resection, recurrent disease usually presents first with aphthous ulceration proximal to the anastomosis.

Upper gastrointestinal symptoms may require upper gastrointestinal endoscopy, which may reveal deep longitudinal ulcers and cobblestone mucosa in the duodenum, stomach or, rarely, in the oesophagus. Enteroscopy may reveal jejunal ulceration and stricturing. Capsule endoscopy should not be undertaken where there is a risk of stricture, because of the possibility of the capsule becoming stuck in the narrow segment. It may, however, have a useful role in those patients with evidence of chronic gastrointestinal blood loss where no evidence of ulceration can be found with more conventional endoscopic assessment.

**Imaging**
High-resolution ultrasound in expert hands can demonstrate inflamed and thickened bowel loops, as well as fluid collections and abscesses. The small intestine is traditionally imaged by a small bowel enema (Figure 69.11). This will show up areas of stricturing and prestenotic dilatation. The involved areas tend to be narrowed, irregular and, sometimes, when a length of terminal ileum is involved, there may be the string sign of Kantor. CT scans with luminal contrast are widely used in the investigation of abdominal symptoms and can demonstrate fistulae, intra-abdominal abscesses and bowel thickening or dilatation (Figure 69.12). Magnetic resonance imaging (MRI) is useful in assessing complex perianal disease, but more recently has been shown to be an excellent method for investigating the small bowel. MR enteroclysis is particularly effective at demonstrating small bowel stricturing (Figure 69.13) and avoids the need for repeated exposure to large doses of ionising radiation in young patients. In patients with enterocutaneous fistulae, fistulography will be required to demonstrate the anatomy and complexity of fistulae and allow adequate planning for future surgery.

TREATMENT

**Medical treatment**

**Steroids**
Steroids are the mainstay of treatment for CD. They induce remission in 70–80 per cent of cases with moderate to severe disease. They should be used in short courses and tapered after response has been achieved. They reduce inflammation and will not therefore be effective against fibrostenotic disease, where the symptoms relate mainly to obstruction. Steroids can also be used as topical agents in the rectum with reduced sys.

---

John Leonard Kantor, 1890–1947, gastroenterologist, the Presbyterian Hospital, New York, NY, USA, described his ‘string sign’ in 1934.
temic bioavailability, but long-term use can still cause adrenal suppression. More recent oral steroid formulations have been devised to ensure that the steroid moiety is removed from the portal circulation, reducing systemic side effects. Steroids should not be used for maintenance therapy for CD and are usually replaced with immunomodulatory agents (see below under Immunomodulatory agents) in order to minimise the risk of side effects associated with long-term steroid use.

Aminosalicylates

Colonic symptoms can be treated by 5-ASA agents in a similar manner to that in UC. These agents have been traditionally believed to help with management of small bowel CD, but this has recently been questioned. Some studies of patients who have undergone previous resection have suggested that 5-ASA drugs may reduce the incidence of recrudescent disease.

Antibiotics

Metronidazole and ciprofloxacin may be used, particularly for periods of a few weeks at a time, especially in perianal disease. Long-term use of metronidazole is to be especially avoided, as there is a risk of peripheral neuropathy. Antibiotics may also be used when there is evidence of a mass or an abscess. In general, however, a confirmed abscess should be treated by drainage plus or minus resection as antibiotics alone will not treat a Crohn’s mass effectively.

Immunomodulatory agents

Azathioprine is used for its additive and steroid-sparing effect and is now standard maintenance therapy. It is a purine analogue, which is metabolised to 6-mercaptopurine (6-MP) and works by inhibiting cell-mediated immune responses. 6-Mercaptopurine may be given directly for the same reasons. Cyclosporin also acts by inhibiting cell-mediated immunity. Short-course intravenous cyclosporin treatment is associated with 80 per cent remission; however, there is relapse after completion of treatment.

Monoclonal antibody

Several commercially available agents have been developed based upon monoclonal antibodies targeting tumour necrosis factor alpha. Infliximab, the murine chimaeric monoclonal antibody and Adalimumab (human monoclonal) are used for patients with severe, active disease who are refractory to other forms of treatment and who would otherwise be at high risk of requiring surgical intervention. There is some evidence to suggest that early and aggressive use of these agents in patients with evidence of early recrudescent disease after surgery (for example, by colonoscopy showing aphthous ulceration at the anastomosis at one year) may reduce the need for subsequent surgery. These agents also appear to be effective treatments for fistulae, particularly in perianal disease. Recent studies have suggested, however, that they reduce the inflammation associated with the process of fistulation and that the fistula tracks may remain unhealed, even if the skin defects close. Cessation of therapy is associated with a high risk of reactivation of the fistulae. These are very expensive forms of treatment and active infection, tuberculosis and a past history of malignancy are contraindications.

Nutritional support

It is essential that nutritional status is evaluated in all patients with CD. Nutritional support is frequently required. Patients with moderate nutritional impairment will require nutritional supplementation and severely malnourished patients may require nasoenteric or even intravenous feeding. Anaemia, hypoproteinaemia and electrolyte, vitamin and metabolic bone problems must all be addressed. Elemental diet or parenteral nutrition can induce remission in up to 80 per cent of patients, an effect comparable to steroids. Almost all patients relapse rapidly after cessation of therapy (Summary box 69.6).

Non-operative management of Crohn’s disease

Although perforating and fistulating disease will require surgical treatment (see below under Surgery), stricturing may be amenable to endoscopic treatment, provided the strictures can be reached with an endoscope and negotiated with a guide.
Summary box 69.6

Principles of management of Crohn’s disease
- Close liaison between physician and surgeon is crucial
- Medical therapy should always be considered as an alternative to surgery, although surgery should not be delayed when a clear indication for surgery exists
- Patients must be optimised as far as possible prior to surgery, and this may require preoperative total parenteral nutrition
- Crohn’s disease is a chronic relapsing disease with a high likelihood of reoperation; the surgeon must take every reasonable effort to preserve bowel length and sphincter function

Indications for surgery
Surgical resection will not cure CD. Surgery therefore focuses on the complications of the disease. As many of these indications for surgery may be relative, joint management by an aggressive physician and a conservative surgeon is thought to be ideal (see Figure 69.6). These complications include:
- recurrent intestinal obstruction
- bleeding
- perforation
- failure of medical therapy
- intestinal fistula
- fulminant colitis
- malignant change
- perianal disease.

Surgery
The main surgical principle is to preserve gut length and maintain adequate function. The whole of the gastrointestinal tract should be examined carefully at laparotomy/laparoscopy and intestinal resection kept to the minimum required to treat the local consequences of disease. If, on occasion, CD is diagnosed during the course of an operation for suspected appendicitis, it is reasonable to remove the appendix, although there may be concern about fistulation. If the ileum is thick, rigid and inflamed, an ileocaecal resection can be carried out immediately, although it is equally reasonable to try a period of medical therapy. A senior opinion is important to determine the optimum therapy, taking into account the patient’s history, fitness, comorbidity and operative findings.

The course of the disease after surgery is unpredictable, but recrudescence (a better term than ‘recurrence’ as surgery cannot cure) is common. Symptomatic recrudescence does not seem to be related to the presence of disease at the resection line. The cumulative probability of recrudescence requiring surgery for ileal disease is of the order of 20, 40, 60 and 80 per cent at 5, 10, 15 and 20 years, respectively, after previous resection.

Crohn’s surgery is technically demanding as mesenteries are thickened and oedematous, the bowel may be fragile and the patient may be malnourished, immunosuppressed or septic. A key decision has to be made after resection between anastomosis and defunctioning, as leaks and fistulation are a notorious problem. It has been established that anastomatic complications are more common with one or more of the following risk factors:
- steroids
- low albumin
- abscess
- fistula.

If more than two factors are present it is safer (and if all, imperative) to exteriorise the bowel and consider delayed anastomosis when the patient has fully recovered.

Laparoscopic surgery is possible for ileocaecal or colonic resections and has the potential advantage of smaller incisions and potentially shorter recovery time. Reoperative surgery is technically demanding but experienced laparoscopic surgeons have been able to carry out such procedures. A great range of operations is performed for Crohn’s disease depending on disease pattern – the most common are outlined below:
- Ileocaecal resection is the usual procedure for terminal ileal Crohn’s with a primary anastomosis between the ileum and the ascending or transverse colon, depending on the extent of the disease.
- Segmental resection of short segments of small or large bowel strictures can be performed.
- Colectomy and ileorectal anastomosis is commonly performed for colonic CD with rectal sparing and a normal anus.
- Subtotal colectomy and ileostomy for Crohn’s colitis accounts for 8 per cent of such procedures for acute colonic disease. The indications are similar to those for UC.
- Temporary loop ileostomy. This can be used either in patients with acute distal CD, allowing remission and later restoration of continuity, or in patients with severe perianal or rectal disease.
- Proctocolectomy. Patients with colonic and anal disease failing to respond to medical treatment will eventually require a permanent ileostomy.
- Strictureplasty. Multiple strictured areas of CD (Figure 69.14) can be treated by a local widening procedure, strictureplasty, to avoid small bowel resection (Figure 69.15).
INFECTIONS OF THE SMALL AND LARGE INTESTINE

Campylobacter
Infection with Campylobacter jejuni (a Gram-negative rod with a distinctive spiral shape) is the most common form of gastroenteritis in the UK, typically acquired from eating infected poultry. It causes diarrhoea and abdominal pain and may mimic an acute abdomen. Severe cases may resemble UC and cause diagnostic difficulty. The organism is very sensitive and may require several days to isolate on stool culture. Treatment is supportive as it usually resolves without antibiotics. It is a notifiable disease.

Yersinia
Yersinia enterocolitica is a Gram-negative rod, which can infect the terminal ileum, appendix, ascending colon and mesenteric lymph nodes, and can cause a granulomatous inflammatory process that mimics Crohn’s disease. Yersinia typically causes a fever and gastroenteritis, but may persist and cause a terminal ileitis, which, on occasion, may even perforate. The diagnosis may be made on stool culture, but is more often confirmed serologically. If discovered at laparotomy, the terminal ileum and mesenteric nodes will look thickened and inflamed and a lymph node biopsy can be taken. The disease is normally self-limiting, but also responds to treatment with co-trimoxazole or chloramphenicol.

Intestinal amoebiasis
Amoebiasis is an infestation with Entamoeba histolytica. This parasite has a worldwide distribution and is transmitted mainly in contaminated drinking water. It can cause colonic ulcers, which are described as ‘bottlenecked’ because they have considerably undermined edges. The ulcers typically also have a yellow necrotic floor, from which blood and pus exude. In the majority of cases, they are confined to the distal sigmoid colon and the rectum.

Clinically amoebiasis can mimic UC, most commonly causing bloody diarrhoea but more severe colonic complications can occur, including severe haemorrhage, stricture formation or perforation. A peritonitis is not uncommon and results in adhesions and may cause intestinal obstruction. Amoebiasis may cause liver abscesses or an amoebic mass (amoeboma) of the caecum or sigmoid which is difficult to distinguish from a carcinoma. Surgery is fraught with danger as the bowel is extremely friable.

Endoscopic biopsies or fresh hot stools are examined to look for the presence of amoebae (Figure 69.16). It is important to emphasise, however, that the presence of the parasite does not indicate that it is pathogenic. It is especially important to exclude amoebic infection in patients suspected of having UC.

Treatment is by metronidazole (Flagyl) in the acute setting, three times daily for 7–10 days. Difloxacin furoate is effective against chronic infections associated with the passage of cysts in stools.

Salmonellosis, typhoid and paratyphoid
Salmonella are a family of Gram-negative rods that can cause a range of enteric infections. Salmonella gastroenteritis is typically caused by S. enteritidis from poultry, and is most often a self-limiting illness comprising headache, fever and watery diarrhoea. When severe, antibiotics and indeed hospitalisation and intravenous fluids may be needed. The diagnosis is based on stool culture. Shigella and enteropathogenic strains of E. coli may cause similar diarrhoeal illnesses.

Typhoid fever is caused by S. typhi and presents with fever and abdominal pain after an incubation period of 10–20 days. Over the next week, the patient can develop distension, diarrhoea, splenomegaly and characteristic ‘rose spots’ on the abdomen caused by a vasculitis. A number of surgical complications can result:

- paralytic ileus
- intestinal haemorrhage
- perforation
- cholecystitis.

In addition, invasion of the systemic circulation, which is a characteristic feature of salmonellosis, may cause severe Gram-negative sepsis and septic shock may develop. Some patients develop metastatic sepsis, including septic arthritis and osteomyelitis, meningitis, encephalitis, disseminated intravascular coagulation and pancreatitis.
Perforation of a typhoid ulcer usually occurs during the third week and is sometimes the first sign of the disease. The ulcer is parallel to the long axis of the gut and is usually situated in the distal ileum. Diagnosis is confirmed by culture of blood or stool. Treatment is by antibiotics, usually chloramphenicol. Perforation requires surgery to wash out and close the perforated ulcer – resection is usually avoided. In unstable patients, notably with evidence of septic shock, the bowel should be exteriorised and the perforation closed after recovery. Paratyphoid infection (with *S. paratyphi*) resembles typhoid fever and is treated in a similar manner.

**Tuberculosis of the intestine**

Tuberculosis, like Crohn’s disease, can affect any part of the gastrointestinal tract from the mouth to the anus. The sites affected most often are the ileum, proximal colon and peritoneum. There are two principal presentations.

**Ulcerative tuberculosis**

Ulcerative tuberculosis is secondary to pulmonary tuberculosis and arises as a result of swallowing tubercle bacilli. Multiple ulcers, lying transversely, develop in the terminal ileum and the overlying serosa is thickened, reddened and covered in tubercles. Patients typically present with diarrhoea and weight loss, although subacute obstruction and even local perforation and fistula formation can occur. A barium follow-through or CT examination show absent filling of the lower ileum, caecum and the ascending colon as a result of narrowing of the ulcerated segment (Figure 69.17).

A course of chemotherapy (antituberculous antibiotics) usually leads to cure; provided the pulmonary tuberculosis is adequately treated. Surgery is usually undertaken only in the rare event of a perforation or complete intestinal obstruction.

**Hyperplastic tuberculosis**

This is caused by the ingestion of *Mycobacterium tuberculosis* by patients with a high resistance to the organism. The infection usually occurs in the ileocaecal region, although solitary and multiple lesions in the lower ileum are also sometimes seen. The infection establishes itself in lymphoid follicles, and the resulting chronic inflammation causes thickening of the intestinal wall and narrowing of the lumen. There is early involvement of the regional lymph nodes, which may caseate. Unlike in Crohn’s disease, abscess and fistula formation is rare.

Patients usually present with attacks of abdominal pain and intermittent diarrhoea. There is incomplete ileal obstruction, leading to stasis and bacterial overgrowth. This in turn causes steatorrhoea, anaemia and loss of weight. Patients may present with a mass in the right iliac fossa and vague ill health. The differential diagnosis is that of an appendix mass, lymphoma, carcinoma of the caecum, CD, tuberculosis or actinomycosis.

A barium follow-through or small bowel enema will show a long narrow filling defect in the terminal ileum. CT will also demonstrate the narrowed segment with proximal distension and can also demonstrate the lymphadenopathy. When the diagnosis is certain and the patient has not yet developed obstructive symptoms, treatment with chemotherapy is advised and may be curative. Where obstruction is present, surgery with ileocaecal resection is often required.

**Actinomycosis**

Abdominal actinomycosis is rare. It is caused by infection with *Actinomyces israelii* and infection usually develops several weeks after an apparently straightforward perforated appendicitis. A local abscess develops and spreads to the retroperitoneal tissues and the adjacent abdominal wall, becoming the seat of multiple indurated discharging sinuses. At first, the discharge from the sinuses is thin, watery and inoffensive, but it may later become thicker and malodorous. Secondary fistulation may occur and the tissues may become extensively indurated and woody. In contrast to tuberculosis, however, mesenteric lymph nodes are not involved and the lumen of the intestine is not narrowed. Haematogenous spread via the portal vein may lead to multiple liver abscesses.

**Human immunodeficiency virus**

Human immunodeficiency virus (HIV) infection is associated with a number of proctological problems as discussed in Chapter 73. Intestinal complications are common after the development of AIDS when opportunistic organisms can cause gastroenteritis (see Summary box 69.7). HIV1 may also cause a specific enter-

---

*Figure 69.17 Ileocaecal tuberculosis; absent ascending colon and caecum with dilatation of terminal ileum (courtesy of Dr VK Kapoor, Delhi, India).*

James Israel, 1848–1926, first found sulphur granules in pus from a discharging sinus in a man’s neck. Later, he became a famous Berlin urologist.
Opportunistic intestinal infections in patients with AIDS

- **Bacteria**
  - Salmonella
  - Shigella
  - Yersinia
  - Campylobacter
  - *Mycobacterium avium intracellulare* (MAI)
- **Viral**
  - Cytomegalovirus
- **Protozoa**
  - Cryptosporidium
  - Giardia
- **Fungal**
  - *Candida albicans*

**Clostridium difficile**

*Clostridium difficile* is a toxin producing Gram-positive bacillus that is an increasing worry in many hospitals. Although normally present in around 2 per cent of the population, it seems to proliferate after antibiotic treatment (especially cephalosporins) and can cause antibiotic-associated diarrhoea and pseudomembranous colitis.

Clinically, *C. difficile* infection presents with diarrhoea, abdominal pain and fever. It may progress to pseudomembranous colitis, so called because on visualisation of the bowel, plaques of inflammatory exudate between oedematous mucosa are seen.

Treatment is by metronidazole or vancomycin alongside supportive care. If the colitis does not settle, an emergency subtotal colectomy and ileostomy may be necessary.

**TUMOURS OF THE SMALL INTESTINE**

Small bowel tumours are rare and in total account for less than 10 per cent of gastrointestinal neoplasia.

**Benign**

The majority of small bowel neoplasms are benign, comprising adenomas, lipomas, haemangiomas and neurogenic tumours. They are frequently asymptomatic and identified incidentally, but can present with intussusception, small bowel obstruction and bleeding that may cause anaemia or may even be overt. Where these lesions do cause anaemia, the cause can be difficult to diagnose, as CT or small bowel contrast studies do not show them easily. Capsule endoscopy or small bowel endoscopy have been used successfully where the facilities exist. Symptomatic lesions can be treated by small bowel resection and anastomosis.

**Peutz–Jeghers syndrome**

This is an autosomal dominant disease characterised by melanosis of the mouth and lips and multiple hamartomatous (benign tumour-like malformation resulting from faulty development in an organ) polyps in the small bowel and colon (Figure 69.18). Melanin spots can also occur on the digits and perianal skin. The gene STK11 on chromosome 19 has been found in a proportion of patients with this condition. Long-term follow up of the original family described by Peutz has shown reduced survival, as a consequence of complications of bowel obstruction and the development of a wide range of cancers. It is logical to perform regular colonic surveillance and encourage female patients to attend breast and cervical screening.

Malignant change in the polyps rarely occurs and, in general the polyps can be left alone. Resection may be indicated for heavy and persistent or recurrent bleeding or intussusception. Polyps may be removed by enterotomy, or, at laparotomy, snared via a colonoscope introduced via an enterotomy. Heavily involved segments of small intestine may occasionally be resected.

**Malignant**

These are rare and classically present late, most often diagnosed after surgery for small bowel obstruction. Four types will be considered which account for over 99 per cent of small bowel malignancies: adenocarcinoma, carcinoid tumours, lymphomas and mesenchymal tumours (gastrointestinal stromal tumours (GIST)).

---

**Gregor Johann Mendel**, 1822–1884, an Austrian monk and naturalist who became Abbot of the Augustinian Monastery at Brunn, Czechoslovakia and discovered the laws of inheritance by studying the edible pea. In 1865, he described 'dominant' and 'recessive' traits in hybrids. His work passed unnoticed for 35 years.
Adenocarcinoma

Small bowel adenocarcinoma is more often found in the jejunum than the ileum and though the aetiology is unknown they are more common in patients with Crohn's disease, coeliac disease, familial adenomatous polyposis (FAP) and Peutz-Jeghers syndrome. They present with anaemia, overt gastrointestinal bleeding, intussusception or obstruction. Prognosis is poor, particularly in patients with Crohn's disease, in whom these tumours often present late because the symptoms may be mistaken for those of Crohn's disease and treated conservatively. When suspected, the advised surgical treatment is a resection of 5 cm of non-involved bowel either side of the lesion and the affected mesentery (Figure 69.19). A right hemicolectomy is likely to be required for tumours of the distal ileum.

Carcinoid tumour

These neuroendocrine tumours occur throughout the gastrointestinal tract, most commonly in the appendix, ileum and rectum in decreasing order of frequency. Appendiceal carcinoid tumours are most commonly noted as an incidental finding at appendicectomy. Carcinoid tumours arise from Kulchitsky cells at the base of intestinal crypts (of Lieberkühn). The primary is usually small, although significant lymph node metastases can occur. In up to one in three cases of small bowel carcinoids, the tumours may be multiple. They may produce dense fibrosis in the surrounding tissues, resulting in distortion and scarring of the bowel and associated mesentery.

The tumours can produce a number of vasoactive peptides, most commonly 5-hydroxytryptamine (serotonin), but also histamine, prostaglandins and kallikrein. When they metastasise to the liver, the carcinoid syndrome can become evident, because the vasoactive substances escape the filtering actions of the liver. The clinical syndrome itself consists of reddish-blue cyanosis, flushing attacks, diarrhoea, borborygmi, asthmatic attacks and, eventually, pulmonary and tricuspid stenosis (Summary box 69.8). Classically, the flushing attacks are induced by alcohol.

Surgical resection is usually sufficient for patients with primary disease, but the incidence of recurrence is significant. The extent of disease can be assessed preoperatively using octreotide scanning, which may detect otherwise clinically apparent primary and secondary tumours. Plasma markers of tumour bulk, such as chromogranin A concentrations, may be useful markers of disease recurrence, as well as of prognostic value.

In patients with metastatic disease, hepatic resection can be carried out. The treatment has been transformed by the use of octreotide (a somatostatin analogue), which reduces both flushing and diarrhoea, and octreotide cover is usually used in patients with a carcinoid syndrome who have surgery to prevent a carcinoid crisis. Carcinoid tumours generally grow more slowly than most metastatic malignancies; the patients may live with the syndrome of metastatic disease for many years. They are not usually sensitive to chemo- or radiotherapy.

Lymphoma

Small bowel lymphoma may be primary, or more commonly secondary to systemic lymphoma. Small bowel lymphoma is also more common in patients with Crohn's disease and immunodeficiency syndromes. The classification of lymphoma is beyond the scope of this chapter, however a number of points are notable for the surgeon. It is rare for Hodgkin's lymphoma to affect the small bowel and most western-type lymphomas are non-Hodgkin's B-cell lymphomas. They present with anaemia, bleeding, perforation, anorexia and weight loss.

T-cell lymphoma develops in patients with coeliac disease. Worsening of the patient's diarrhoea, with pyrexia of unknown origin together with local obstructive symptoms, are the usual features.

Mediterranean lymphoma is found mostly in North Africa and the Middle East and is often widespread at diagnosis. Burkitt's lymphoma can aggressively affect the ileocaecal region, particularly in children. The mainstay of treatment for these conditions is chemotherapy, however surgery may be required for obstruction, perforation or bleeding.

Gastrointestinal stromal tumours

These are mesenchymal tumours and the distinction between benign or malignant types is difficult even on histological examination. Increased size and high levels of c-kit (CD117) staining are associated with malignant potential. GIST tumours are found most commonly in the stomach, but can be found in other parts of the gut. They occur most commonly in the 50- to 70-year age group. Although the cause is unknown, patients with neurofibromatosis have an increased risk of developing these types of tumour.

Patients may be asymptomatic. Symptoms include lethargy, pain, nausea, haematemesis or melaena. Surgery is the most effective way of removing GISTs, as they are radioresistant. Glivec (imatinib) is a tyrosine kinase inhibitor that has been shown to be effective in advanced cases and may also have an adjuvant role.

Thomas Hodgkin, 1798–1866, Lecturer in Morbid Anatomy and Orator of the Museum, Guy's Hospital, London, described lymphadenoma in 1832.
TUMOURS OF THE LARGE INTESTINE

Benign
The term ‘polyp’ is a clinical description of any protrusion of the mucosa. It encompasses a variety of histologically different tumours shown in Table 69.2. Polyps can occur singly, synchronously in small numbers or as part of a polyposis syndrome. It is important to be sure of the histological diagnosis because colonic adenomas have significant malignant potential.

Adenomatous polyps
Adenomatous polyps vary from a tubular adenoma (Figure 69.20), rather like a berry on a stalk, to the villous adenoma, a flat spreading lesion. Solitary adenomas are usually found during the investigation of colonic symptoms and may be the cause of rectal bleeding. Villous tumours can cause diarrhoea, mucous discharge and, occasionally, hypokalaemia and hypoaalbuminaemia. The risk of malignancy developing in an adenoma increases with their size; there is a 10 per cent risk of cancer in a 1-cm diameter tubular adenoma, whereas with villous adenomas over 2 cm in diameter, there may be a 15 per cent chance of carcinoma. Almost one-third of large (>3 cm) colonic adenomas will have an area of invasive malignancy within them at the time of resection. Adenomas larger than 5 mm in diameter are usually excised because of their malignant potential. Colonoscopic snare polypectomy is usually possible for colonic polyps, but larger sessile polyps can require endoscopic mucosal resection (EMR) after saline infiltration. Larger rectal adenomas may require transanal resection or, where the adenoma is too high for safe conventional access, transanal endoscopic microsurgery (TEMS). Massive and extensive villous lesions of the rectum may require proctectomy when the patient is sufficiently fit, or argon beam ablation when the patient is frail but symptomatic.

Familial adenomatous polyposis
FAP is defined clinically by the presence of more than 100 colorectal adenomas, but also characterised by duodenal adenomas and multiple extraintestinal manifestations (Summary box 69.9). Over 80 per cent of cases come from patients with a positive family history. The remainder arise as a result of new mutations in the adenomatous polyposis coli (APC) gene. This has been identified on the short arm of chromosome 5. FAP is inherited as an autosomal dominant condition and is consequently equally likely in men and women. Although FAP is less common than hereditary non-polyposis colon cancer (HNPCC), and only accounts for 1 per cent or less of all colon cancer, the risk of colorectal cancer is 100 per cent in patients with FAP. FAP can also be associated with benign mesodermal tumours such as desmoid tumours and osteomas. Epidermoid cysts can also occur (Gardner’s syndrome); desmoid tumours in the abdomen spread locally to involve the intestinal mesentery and, although non-metastasising, they can become unresectable. Up to 50 per cent of patients with FAP have congenital hypertrophy of the retinal pigment epithelium (CHRPE), which can be used to screen affected families if genetic testing is unavailable.

Table 69.2 Classification of intestinal polyps.

| Classification | Inflammatory polyps (pseudopolyps in ulcerative colitis) |
|               | Metaplastic or hyperplastic polyps |
|               | Peutz–Jeghers polypl |
|               | Juvenile polypl |
| Neoplastic     | Adenoma |
|               | Tubular |
|               | Tubulovillous |

Summary box 69.9
Extracolonic manifestations of familial adenomatous polyposis
- Endodermal derivatives
  - Adenomas and carcinomas of the duodenum, stomach, small intestine, thyroid and biliary tree
  - Fundic gland polyps
  - Hepatoblastoma
- Ectodermal derivatives
  - Epidermoid cysts
  - Pilomatrixoma
  - Congenital hypertrophy of the retinal pigment epithelium (CHRPE)
  - Brain tumours
- Mesodermal derivatives
  - Desmoid tumours
  - Osteomas
  - Dental problems
Clinical features
Polyps are usually visible on sigmoidoscopy by the age of 15 years and will almost always be visible by the age of 30 years. Carcinoma of the large bowel occurs 10–20 years after the onset of the polyposis. One or more cancers will already be present in two-thirds of those patients presenting with symptoms at the time of diagnosis (see Summary box 69.10).

Symptomatic patients
These are either patients in whom a new mutation has occurred or those from an affected family who have not been screened. They may have loose stools, lower abdominal pain, weight loss, diarrhoea and the passage of blood and mucus. Colonoscopy is performed with biopsies to establish the number and histological type of polyps. If over 100 adenomas (Figure 69.21) are present, the diagnosis can be made confidently. If there are no adenomas by the age of 30 years, FAP is unlikely. If the diagnosis is made during adolescence, operation is usually deferred to the age of 17 or 18 years unless symptoms develop.

Screening policy
- At-risk family members are offered genetic testing in their early teens.
- At-risk members of the family should be examined at the age of 10–12 years, repeated every year.
- Most of those who are going to get polyps will have them at 20 years, and these require operation.
- If there are no polyps at 20 years, continue with five-yearly examination until age 50 years; if there are still no polyps, there is probably no inherited gene. Carcinomatous change may exceptionally occur before the age of 20 years. Examination of blood relatives, including cousins, nephews and nieces, is essential, and a family tree should be constructed and a register of affected families maintained. Referral to a medical geneticist is essential.

Treatment
The aim of surgery is to prevent the development of colorectal cancer. The surgical options are:
- colectomy with ileorectal anastomosis (IRA);
- restorative proctocolectomy (RPC) with an ileal pouch-anal anastomosis, the anastomosis may be defunctioned with a loop ileostomy;
- total proctectomy and end ileostomy (normally reserved for patients with a low rectal cancer).

The patient is almost always young and likely to prefer to avoid a permanent stoma and so the choice is normally between the first two options. The advantage of an IRA is that it avoids the temporary stoma frequently required for an RPC and avoids the potential compromise to sexual function that accompanies proctectomy. It also has a lower morbidity and mortality. However, the rectum is left and requires regular surveillance, as there is a risk of adenomas and carcinomas in the residual large bowel. Even with optimal surveillance of the rectal remnant, up to 10 per cent will develop invasive malignancy within a 30-year follow-up period. Restorative proctocolectomy has the advantage of removing the whole colon and rectum (although a small cuff of rectal mucosa may be left behind with a stapled anastomosis). However, there is a pouch failure rate of about 10 per cent. In addition, and particularly where a stapled anastomosis has been created, there remains a very small but definite incidence of cancer developing in the small strip of rectal mucosa between the pouch and the dentate line. This is why some colorectal surgeons advocate complete mucosectomy of the residual rectal cuff and a transanal pouch anal anastomosis, although it is acknowledged that this results in worse function.

Postoperative surveillance
Because of the risk of further tumour formation, follow up is important and takes the form of rectal/pouch surveillance, with biopsy of the pouch-anal anastomosis. Gastroscopies are also carried out to detect upper gastrointestinal tumours. Even with prevention of colorectal cancer, FAP patients have reduced life span due to the development of duodenal and ampullary cancers and the complications of desmoid tumours.

Hereditary non-polyposis colorectal cancer (Lynch syndrome)
This syndrome is characterised by increased risk of colorectal cancer and also cancers of the endometrium, ovary, stomach and small intestines. It is an autosomal dominant condition that is caused by a mutation in one of the DNA mismatch repair genes. The most commonly affected genes are MLH1 and MSH2. The lifetime risk of developing colorectal cancer in Lynch syndrome is 80 per cent, and the mean age of diagnosis is 45 years. Most cancers develop in the proximal colon. Females with HNPCC have a 30–50 per cent lifetime risk of developing endometrial cancer.

Summary box 69.10
Features of familial adenomatous polyposis
- Autosomal dominant inherited disease due to mutation of the APC gene
- More than 100 colonic adenomas are diagnostic
- Prophylactic surgery is indicated to prevent colorectal cancer
- Polyps and malignant tumours can develop in the duodenum and small bowel

Figure 69.21 Familial adenomatous polyposis.
Diagnosis
HNPCC can be diagnosed by genetic testing or the Amsterdam II criteria:
- three or more family members with an HNPCC-related cancer (colorectal, endometrial, small bowel, ureter, renal pelvis), one of whom is a first-degree relative of the other two;
- two successive affected generations;
- at least one colorectal cancer diagnosed before the age of 50 years;
- FAP excluded;
- tumours verified by pathological examination.
Patients with HNPCC are subjected to regular (every one to two years) colonoscopic surveillance.

Malignant

Epidemiology
In the UK, colorectal cancer is the second most common cause of cancer death accounting for 16000 deaths in 2004. About 35000 patients are diagnosed with colorectal cancer every year in the UK, of which around one-third are in the rectum and two-thirds in the colon. The burden of disease is similar in men and women. Colorectal cancer seems to occur less frequently in the developing world than in industrialised countries.

Aetiology
The accepted model of colorectal cancer development is that it arises from adenomatous polyps after a sequence of genetic mutations influenced by environmental factors. This adenoma–carcinoma sequence is based on strong observational evidence outlined in Summary box 69.11.

Summary box 69.11
Evidence for adenoma–carcinoma sequence
- The prevalence of adenomas and carcinomas is very similar – carcinoma patients are about five years older
- The distribution of adenomas in the colon is the same as that of cancers (70 per cent left sided)
- When small cancers are studied, they almost always have adjacent adenomatous tissue
- Adenomas are found in a third of specimens resected for colorectal cancer
- Sporadic adenomas are identical to the adenomas of familial adenomatous polyposis, which is associated with a 100 per cent chance of colorectal adenocarcinoma unless treated
- Larger adenomas are more likely to be dysplastic and to have higher grades of dysplasia than small adenomas
- Incidence of colorectal cancer falls within a screening programme that involves colonoscopy and polypectomy

The molecular genetics of sporadic colorectal cancer have been extensively studied. Mutations of the APC gene occur in two-thirds of colonic adenomas and carcinomas and are thought to develop early in the carcinogenesis pathway. K-ras mutations result in activation of cell signalling pathways and are more common in larger lesions. This suggests that they are later events in the mutagenesis pathway. The p53 gene is frequently mutated in carcinomas, but not in adenomas and is therefore thought to mark the development of invasion. The adenoma–carcinoma sequence is not, however, one of a simple stepwise progression of mutations, but a complicated array of multiple genetic alterations, ultimately resulting in an invasive tumour. While no single mutation is common to all cases of colorectal cancer, knowledge of certain mutations can be used to assess prognosis and, increasingly to direct adjuvant therapy. For example, the K-ras mutation is thought to be associated with an especially poor prognosis.

There has been much interest in the linkage between diet and colon cancer. Worldwide, the prevalence of colorectal cancer is closely associated with intake of red meat. There is ample evidence to suggest effects of red meat components (haem and N-nitroso compounds) on the DNA in the colorectal mucosa. The protective effect of dietary fibre is also suggested by epidemiological studies. The hypothesis is that increased roughage is associated with reduced transit times, and this in turn reduces the exposure of the mucosa to dietary carcinogens. Increased risk for colorectal cancer has also been associated with dietary animal fat, smoking and alcohol. Longstanding ulcerative colitis and Crohn’s colitis is associated with increased rates of colorectal cancer as discussed previously. It has been suggested that cholecystectomy may be associated with a slight increase in the risk of right-sided colon cancer, possibly as a consequence of increased bile acid exposure. There is also an increased risk of colorectal cancer after uretersigmoidostomy, although this procedure is now rarely performed.

Pathology
Macroscopically, the tumour may take one of four forms (Figure 69.22). The annular variety tends to give rise to obstructive symptoms, whereas the others will present more commonly with

Figure 69.22 The four common macroscopic varieties of carcinoma of the colon. (1) Annular; (2) tubular; (3) ulcer; (4) cauliflower.
bleeding. Microscopically, the neoplasm is an adenocarcinoma originating in the colonic epithelium.

**SPREAD OF CARCINOMA OF THE COLON**

**Direct spread**
Colonic cancer can spread locally or via the lymphatics, bloodstream or transectoelomically around the peritoneum. Direct spread can be longitudinal, transverse or radial. Radial spread to adjacent organs has the greatest impact on surgical resectability, as an adequate oncologic resection can still be achieved, despite longitudinal spread, by extension of proximal and distal margins. Radial spread may be retroperitoneal into the ureter, duodenum and posterior abdominal wall muscles, or intraperitoneal into the small intestine, stomach, pelvic organs or the anterior abdominal wall.

**Lymphatic spread**
In general, involvement of the lymph nodes by the tumour progresses in a gradual manner from those closest to the bowel along the course of the lymphatic vessels to those placed centrally. However, this orderly process does not always occur.

**Haematogenous spread**
The liver accounts for the majority of distant metastases presumably via the portal vein. Around a third of patients will have liver metastases at the time of diagnosis and 50 per cent will develop liver metastases at some point accounting for the majority of deaths. The lung is the next most common site: metastases to ovary, brain, kidney, brain and bone are less common. Occasionally, patients will present with metastatic disease in the lungs without evidence of liver metastases.

**Transcoelomic spread**
Colorectal cancer can spread by way of cells dislodging from the serosa of the bowel or via the subperitoneal lymphatics and settling on other structures within the peritoneal cavity, including peritoneum and omentum. Prognosis is typically grave in these circumstances although some units have reported encouraging results in selected patients treated with the combination of aggressive cytoreductive surgery and intraperitoneal chemotherapy.

**Staging colon cancer**
A variety of staging systems are described for colorectal cancer based on pathological reporting to predict prognosis and guide adjuvant treatment. Dukes' classification was originally described for rectal tumours (see Chapter 72), but has been adopted for histopathological reporting of colon cancer as well. It is simple and widely recognised (Summary box 69.12), but the more detailed TNM system is now regarded as the international standard (Summary box 69.13).

**Summary box 69.12**

**Dukes' staging for colorectal cancer**
- A, Invasion of but not breaching the muscularis propria
- B, Breaching the muscularis propria but not involving lymph nodes
- C, Lymph nodes involved

Dukes himself never described a stage D, but this is often used to describe metastatic disease

**Summary box 69.13**

**TNM classification for colorectal cancer**
- T, Tumour stage
  - T1, Into submucosa
  - T2, Into muscularis propria
  - T3, Into pericolic fat or sub-serosa but not breaching serosa
  - T4, Breaches serosa or directly involving another organ
- N, Nodal stage
  - N0, No nodes involved
  - N1, 1–3 nodes involved
  - N2, Four or more nodes involved
- M, Metastases
  - M0, No metastases
  - M1, Metastases

**Clinical features**
Carcinoma of the colon typically occurs in patients over 50 years of age and is most common in the eighth decade of life. Colorectal cancer is not rare in early adult life, however. Twenty per cent of cases present as an emergency with intestinal obstruction or peritonitis. An emergency presentation of colorectal cancer is, even when matched for disease stage, associated with a considerably worse prognosis. A careful family history should be taken. Those with first-degree relatives who have developed colorectal cancer at the age of 45 years or below are at higher risk and may be part of one of the colorectal cancer familial syndromes. Tumours of the left side of the colon which are far more common (Figure 69.23) usually present with a change in bowel habit or rectal bleeding, while more proximal lesions typically present later with iron deficiency anaemia or a mass. Patients may present for the first time with metastatic disease. Lesions of the flexures may present with vague upper abdominal symptoms for many months before other, more specific symptoms suggestive of colonic disease appear.
Investigation of colon cancer

Screening

Colon cancer is highly suited to screening as prognosis is better for early stage disease and polypectomy allows the prevention of cancer development. In the UK, a screening programme has been introduced based on faecal occult blood testing of people aged 60–69 years followed by colonoscopy in those who test positive. A guaiac-based test is used which detects the peroxidase-like activity of faecal haematin. Studies have suggested a 15–20 per cent reduction in colorectal cancer mortality in the screened population. Flexible sigmoidoscopy can also be used as the initial screening tool with a similar reduction in colorectal cancer mortality.

Endoscopy

The 60-cm, fibreoptic, flexible sigmoidoscope is increasingly being used in one-stop rectal bleeding clinics. The patient is prepared with an enema and sedation is not usually necessary. It is usually possible to assess the bowel up to the splenic flexure, which will detect up to 70 per cent of cancers and almost all that cause rectal bleeding. Colonoscopy is the investigation of choice if colorectal cancer is suspected, provided the patient is fit enough to undergo the required mechanical bowel preparation (Figure 69.24). It has the advantage of not only picking up a primary cancer, but also having the ability to detect synchronous polyps or even multiple carcinomas, which occur in 3–5 per cent of cases. Ideally, every case should be proven histologically by biopsy before surgery. Full mechanical bowel preparation is necessary, as well as intravenous sedation. There is a small risk of perforation (1:1000) and also even experienced endoscopists may fail to see the caecum in 10 per cent of cases.

Radiology

Double-contrast barium enema shows a cancer of the colon as a constant irregular filling defect often described as looking like an apple core (Figure 69.25). False positives occur in 1–2 per cent of cases and false negatives in 7–9 per cent of cases. CT is used as a diagnostic tool in patients with palpable abdominal masses. Use of spiral CT of the chest and abdomen is now standard to stage colonic cancer by assessing T stage and detecting metastases although chest x-ray and liver ultrasound are an alternative if CT is not readily available. The introduction of CT virtual colonoscopy, which is effective in picking up polyps down to 6 mm (Figure 69.26) provides another diagnostic modality and has largely replaced barium enema in many centres. It has the advantage of being less invasive than colonoscopy, but if a biopsy is required, an endoscopy will still be needed.

Surgical treatment

Preoperative preparation

There is good evidence that there is no benefit for mechanical bowel preparation in colonic cancer surgery and it may in fact be associated with an increased rate of wound infection. Rectal cancer seems to be different and recent trials suggest that mechanical bowel preparation is probably still appropriate. Thromboembolism is common in general surgical patients and the risk is increased by malignant disease, so antiembolic stockings should be fitted and the patient started on prophylactic low molecular weight heparin. If available, manual compression boots can be used perioperatively. Intravenous prophylactic antibiotics are given at the start of surgery, as there is good evidence that these reduce the risk of
would infection and sepsis. A single dose of antibiotics covering bowel organisms is as effective as multiple doses in preventing wound infection. In all cases where a stoma seems likely, careful preoperative counselling and marking of an appropriate site by an enterostomal therapist is essential.

**Operations**

The operations described are designed to remove the primary tumour and its draining locoregional lymph nodes. After spiral CT, it is unusual to find unsuspected metastases at laparotomy (or laparoscopy), but the presence of peritoneal metastases may predicate a palliative strategy with a segmental resection and less aggressive lymphadenectomy. The use of stapling and hand-suturing techniques for colonic anastomosis has been compared, and there is little difference in leak rate between the two. Recurrent disease does occur typically at the anastomosis and re-resection can be successful.

**Right hemicolecotomy**

Carcinoma of the caecum or ascending colon (Figure 69.27) is treated when resectable by right hemicolecotomy (Figure 69.28). At open surgery, the peritoneum lateral to the ascending colon is incised, and the incision is continued around the hepatic flexure. The right colon is elevated, with the leaf of peritoneum containing its vessels and lymph nodes, from the posterior abdominal wall, taking care not to injure the ureter, gonadal vessels or the duodenum. The ileocolic artery is ligated close to its origin off the superior mesenteric artery (‘high-tie’) and divided. Where the right colic artery has a separate origin from the superior mesenteric artery (around 10 per cent of patients), this is separately ligated. The leaf of raised peritoneum attached to the caecum, ascending colon and hepatic flexure is divided after ligation of the mesentery of the last 20 cm of ileum and the mesocolon as far as the proximal third of the transverse colon. The greater omentum is divided up to the point of intended division of the transverse colon. When it is clear that there is an adequate blood supply at the resection margins, the right colon is resected, and an anastomosis is fashioned between the ileum and the transverse colon using the surgeon’s preferred technique. If the tumour is at the hepatic flexure, the resection must be extended further along the transverse colon and will involve dividing the right branch of the middle colic artery.
Extended right hemicolectomy
Carcinomas of the transverse colon and splenic flexure are most commonly treated by an extended right hemicolectomy. The extent of the resection is from right colon to descending colon. The mobilisation is as for a right hemicolectomy, but dissection continues to take down the splenic flexure and the whole transverse mesocolon is ligated. Some surgeons will perform a left hemicolectomy for a splenic flexure cancer.

Left hemicolectomy
This is the operation of choice for descending colon and sigmoid cancers (Figure 69.29). The left half of the colon is mobilised completely along the 'white line' that marks the lateral attachment of the mesocolon. As the sigmoid mesentery is mobilised, the left ureter and gonadals must be identified and protected. The splenic flexure must be mobilised by extending the dissection from below and from the transverse colon side by entering the lesser sac. The inferior mesenteric artery below its left colic branch, together with the related paraocolic lymph nodes, are included in the resection by ligating the inferior mesenteric artery close to its origin – 'high-tie'. For full mobility, the inferior mesenteric vein is also ligated and divided at the lower border of the pancreas. The bowel and mesentery can now be resected to allow a tension-free anastomosis, which can be stapled with an end–end stapling device or hand-sewn. Where there are technical difficulties or concern about the anastomosis, a temporary diverting stoma may be fashioned upstream, usually by formation of a loop ileostomy.

Laparoscopic surgery
Laparoscopic surgery for colonic cancer has now been shown to have equivalent overall and cancer-related outcomes to open surgery. Lymph node harvests are equivalent to open surgery and initial concerns about reports of port site recurrence have been dispelled as the world experience has grown. In the UK, the National Institute for Health and Clinical Excellence (NICE) has endorsed laparoscopic colorectal surgery and has stated it should be offered to suitable patients. Operative times are longer but wound infection rates, blood loss and postoperative pain scores are lower than for open surgery. It is hoped that these factors will lead to shorter hospital stay and faster return to full activity, but this has yet to be firmly demonstrated. The costs of laparoscopic surgery are generally higher and this may be particularly relevant where funds are limited.

It is not possible to palpate lesions, so if laparoscopic surgery is planned, it is ideal to tattoo the lesion. Different surgeons advocate different port positions. The laparoscopic operation has particular advantages if performed in a medial to lateral manner – that is, starting the dissection by controlling and dividing the major vascular pedicles and only taking the lateral peritoneal reflection once the mesocolon is completely free. Specimen retrieval and bowel anastomosis can then be performed via small incisions. Training in laparoscopic surgery is important, as there is a steep learning curve and in the UK is currently part of a national training programme.

Emergency surgery
In the UK, 20 per cent of patients with colonic cancer will present as an emergency, the majority with obstruction, but occasionally with haemorrhage or perforation. If the lesion is right sided, it is usually possible to perform a right hemicolectomy and anastomosis in the usual manner; this can be facilitated by decompressing the bowel at the start of the operation. If there has been perforation with substantial contamination or if the patient is unstable, it may be advisable to bring out an ileostomy rather than anastomosing bowel in these circumstances. For a left-sided lesion, the decision-making process is similar to that in diverticular disease between a Hartmann’s procedure and resection and anastomosis. Where facilities are present, an obstructing left-sided lesion can be treated with an expanding metal stent (Figure 69.30). This has the great advantage of converting an emergency operation with a high chance of a stoma to a situation which can be managed semi-electively with a resection and anastomosis. It is currently unclear whether

Figure 69.29 Schematic showing left hemicolectomy.

Figure 69.30 Abdominal radiograph demonstrating a colonic stent in position (courtesy of Dr D Kasir, Hope Hospital, Salford, UK).
the overall morbidity and mortality of staged management of an obstructing colorectal cancer by initial stenting and later surgery are lower than primary emergency surgery. Results from two European trials have so far failed to demonstrate a benefit and the patients in whom stenting proved impossible seemed to have a higher morbidity and mortality, possibly because of the inherent delay in undertaking definitive surgical treatment. A larger multicentre trial is currently in progress.

**Postoperative care**

After colonic surgery, patients should be closely monitored, as there is a small incidence of postoperative bleeding. Antithrombosis measures prophylaxis against venous thromboembolism should be continued as discussed above under Preoperative preparation. There is no advantage to placing intra-abdominal drains after colonic surgery. Wound infections are sadly common after colonic surgery and may well be more frequent than the quoted 10 per cent. The most feared postoperative complication of anastomotic breakdown or leak occurs in 4–8 per cent of ileocolic or colocolic anastomoses. It should be kept in mind for any patient not progressing as expected or who is developing temperatures and worsening abdominal pain. Early investigation with contrast-enhanced CT scan is appropriate. In the presence of sepsis or peritonitis, early return to theatre and taking down the leaking anastomosis with the formation of stomas is advised.

Traditional practices after bowel surgery were prolonged nasogastric drainage and very cautious introduction of oral fluid and then diet. There is increasing interest after bowel surgery in enhanced recovery programmes (ERPs) which have been shown to reduce length of hospital stay from the traditional 10–14 days, to as little as 2–3 days by modulating the surgical stress response and reducing postoperative ileus. It is important to appreciate that these programmes require multiple interventions to be instituted and considerable time, effort and education from the surgical, anaesthetic and ward teams (Summary box 69.14).

### Summary box 69.14

**Key elements of an enhanced recovery programme**

- Pre-admission counselling
- Avoidance of mechanical bowel preparation
- Preoperative carbohydrate loading
- Avoidance of preoperative dehydration
- No nasogastric tubes
- Short, transverse incisions (or laparoscopic procedure)
- Short-acting anaesthetic drugs
- Avoidance of perioperative fluid/salt overload
- Thoracic epidurals
- Avoidance of opiate analgesia
- Maintenance of perioperative temperature
- Prevention of postoperative nausea and vomiting
- Early mobilisation
- Early introduction of oral fluids/diets/supplements
- Early removal of urinary catheters
- Continual audit of outcomes

**Adjuvant therapy**

This is discussed in more detail in Chapter 72 under rectal cancer. In colonic cancer, there is no current role for preoperative chemotherapy although a trial is underway. There is evidence of improved outcome after surgery with 5-fluorouracil (5-FU)-based chemotherapy in node-positive disease (Dukes’ C/N1,2).

**Metastatic disease**

Hepatic metastases can be resected and series have demonstrated five-year survival of over 30 per cent in resectable disease. Liver surgeons are increasingly aggressive in treatment and the only absolute limitation on what can be resected is in terms of leaving enough functional liver behind, although this clearly has to be moderated in terms of patient factors. It is important not to biopsy potentially resectable hepatic metastases as this may cause tumour dissemination. Imaging will usually correctly identify colorectal metastases and assess patients’ suitability for liver resection (Figure 69.31). The role of chemotherapy and the timing of colonic and hepatic surgery in synchronous metastases is still a matter of debate and such cases should be carefully discussed by a multidisciplinary team. Isolated lung metastases may also in occasional cases be suitable for resection, but generally they are accompanied by metastases elsewhere. In patients with widespread disease, palliative chemotherapy can be offered alongside symptomatic treatment and support by a palliative care team.

**Prognosis**

Overall five-year survival for colorectal cancer is approximately 50 per cent. The most important determinant of prognosis is tumour stage and, in particular, lymph node status. Patients with disease confined to the bowel wall (Dukes’ stage A) will...
usually be cured by surgical resection alone and 90 per cent of such patients will have disease-free survival at five years. Spread beyond the bowel wall reduces five-year survival to approximately 60–70 per cent. Patients with lymph node metastases have a five-year survival of 30 per cent, while fewer than 10 per cent of patients presenting with metastatic disease at outset will be alive five years later.

**Colorectal cancer follow up**

Since the advent of safe liver resection for metastases, the outcome benefit of follow up has become evident and has been demonstrated by meta-analysis. Follow up aims to identify synchronous bowel tumours that were not picked up at original diagnosis due to emergency presentation or incomplete assessment (3 per cent of patients will have a second bowel cancer at diagnosis). Similarly, 3 per cent of patients will develop a metachronous (at a different time) colonic cancer and surveillance colonoscopy is designed to diagnose these. Up to a half of patients with colorectal cancer will have liver metastases at some point and regular imaging of the liver (ultrasound and CT scan) and measurement of carcinoembryonic antigen (CEA) is designed to diagnose this early, in order to allow the possibility of curative metastectomy. Trials of the optimum follow-up pathway are ongoing.

**INTESTINAL DIVERTICULA**

Diverticula (hollow out-pouchings) are a common structural abnormality that can occur from the oesophagus to the rectosigmoid junction (but not usually in the rectum). They can be classified as:

- **Congenital.** All three coats of the bowel are present in the wall of the diverticulum, e.g. Meckel’s diverticulum.
- **Acquired.** There is no muscularis layer present in the diverticulum, e.g. sigmoid diverticula.

**Jejunal diverticula**

These arise from the mesenteric side of the bowel as a result of mucosal herniation at the point of entry of the blood vessels. They can vary in size and are often multiple. They are most often asymptomatic and an incidental finding at surgery or on radiological imaging (Figure 69.32); however, they can result in malabsorption, as a result of bacterial stasis, or present as an acute abdominal emergency if they become inflamed or perforate. Bleeding from a jejunal diverticulum is a rare complication. Elective resection of an affected small bowel segment that is causing malabsorption can be effective. If perforated jejunal diverticulitis is found at emergency laparotomy, a small bowel resection should be performed and a decision made between anastomosis and stoma formation. This will depend on degree of contamination, physiological stability and local resource for managing a patient with a high output jejunostomy. Extensive jejunal diverticulosis can be very difficult to treat. In severe cases, much of the proximal small intestine may be involved, effectively precluding resection. In addition, limited resection, while feasible, may fail to deal adequately with recurrent attacks of inflammation or bleeding.

**Meckel’s diverticulum**

A Meckel’s diverticulum is a persistent remnant of the vitellointestinal duct and is present in about 2 per cent of the population. It is found on the antimesenteric side of the ileum, commonly at 60 cm from the ileocaecal valve and is classically 5 cm long (Figure 69.33). A Meckel’s diverticulum contains all three coats of the bowel wall and has its own blood supply. It is vulnerable to obstruction and inflammation in the same way as the appendix; indeed, when a normal appendix is found at surgery for suspected appendicitis, a Meckel’s diverticulum should be looked for by examining the small bowel particularly if free fluid or pus is found (Summary box 69.15).

**Figure 69.32** Jejunal diverticula.

**Figure 69.33** Meckel’s diverticulum.
PART 11 | ABDOMINAL

THE SMALL AND LARGE INTESTINES

Summary box 69.15

Features of Meckel’s diverticulum

- Remnant of vitellointestinal duct
- Occurs in 2 per cent of patients, 2 inches (5 cm long), 2 feet (60 cm) from the ileocaecal valve, 20 per cent heterotopic epithelium
- Should be looked for when a normal appendix is found at surgery for suspected appendicitis
- If a Meckel’s is found incidentally at surgery, it can be left provided it has a wide mouth and is not thickened
- Can be source of gastrointestinal bleeding if it contains ectopic gastric mucosa

In around 20 per cent of cases, the mucosa of a Meckel’s diverticulum contains heterotopic epithelium of gastric, colonic or pancreatic type. A Meckel’s diverticulum can present clinically in the following ways:

- **Haemorrhage.** If gastric mucosa is present, peptic ulceration can occur and present as painless maroon rectal bleeding or melaena. If the stomach, duodenum and colon are cleared by endoscopy, radioisotope scanning with technetium-99m may demonstrate a Meckel’s. (A Meckel’s is notoriously difficult to see with contrast radiology.)
- **Diverticulitis.** Meckel’s diverticulitis presents like appendicitis, although if perforation occurs the presentation may resemble a perforated duodenal ulcer.
- **Intussusception.** A Meckel’s can be the lead point for ileoileal or ileocolic intussusception.
- **Chronic ulceration.** Pain is felt around the umbilicus, as the site of the diverticulum is mid Gut in origin.
- **Intestinal obstruction.** A band between the apex of the diverticulum and the umbilicus (also part of the vitellointestinal duct) may cause obstruction directly or by a volvulus around it.
- **Perforation.** (Figure 69.34).

The vast majority of Meckel’s are asymptomatic. When found in the course of abdominal surgery, a Meckel’s can safely be left alone provided it has a wide mouth and is not thickened. When there is doubt, it can be resected. The finding of a Meckel’s diverticulum in an inguinal or femoral hernia has been described as Littre’s hernia.

**Meckel’s diverticulectomy**

A broad-based Meckel’s diverticulum should not be amputated at its base and invaginated (as for an appendix), as there is the risk of stricture and of leaving heterotopic epithelium behind. It is safer simply to excise the diverticulum, either by resecting it and suturing the defect at its base, or with a linear stapler-cutter. If the base of the diverticulum is indurated, it is on balance more logical to perform a limited small bowel resection of the involved segment followed by an anastomosis.

**Diverticular disease of the large intestine**

Diverticula are found in the left colon in around 75 per cent of over 70 year olds in the Western world. The condition is overwhelmingly found in the sigmoid, but diverticula are found in the caecum and can affect the whole colon (but not the rectum). Interestingly, in South-East Asia, right-sided diverticular disease is more common. Diverticula are most often asymptomatic (diverticulosis) and found incidentally, but can present clinically with sepsis or haemorrhage.

**Aetiology**

Epidemiology supports the widely held view that diverticular disease is a consequence of a refined Western diet deficient in dietary fibre. The combination of altered collagen structure with ageing, disordered motility and increased intraluminal pressure most notably in the narrow sigmoid colon results in herniation of mucosa, protruding through the circular muscle at the points where blood vessels penetrate the bowel wall. The rectum has a complete muscular coat and a wider lumen and is thus very rarely affected. Diverticular disease is rare in Africa and Asia where the diet is high in natural fibre.

**Complications of diverticular disease**

The majority of patients with diverticula are asymptomatic; historical studies suggest somewhere between 10 and 30 per cent will have symptomatic complications (Summary box 69.16). These complications are:

- **Pain and inflammation** (diverticulitis).
- **Perforation:** most often contained leading to pericolic abscess formation, but occasionally free leading to generalised peritonitis.
- **Intestinal obstruction:** progressive fibrosis can cause stenosis of the sigmoid and large bowel obstruction or loops of small intestine can adhere to an inflamed sigmoid resulting in small bowel obstruction.
- **Haemorrhage:** diverticulitis may present with profuse colonic haemorrhage.
- **Fistula formation:** (colovesical, colovaginal, entero colic, colocutaneous) occurs in 5 per cent of cases, colovesical fistulation is most common.

---

Figure 69.34 Gangrenous Meckel’s diverticulitis.

Alexis Littre, 1658–1726, surgeon and lecturer in Anatomy, Paris, France. Described Meckel’s diverticulum in a hernial sac in 1700, 81 years before Meckel was born.
Summary box 69.16

Complications of diverticular disease
- Diverticulitis
- Abscess
- Peritonitis
- Intestinal obstruction
- Haemorrhage
- Fistula formation

Clinical features

In mild cases, symptoms such as distension, flatulence and a sensation of heaviness in the lower abdomen may be indistinguishable from those of irritable bowel syndrome. These symptoms are thought to result from a combination of increased luminal pressure affecting wall tension and increased visceral hypersensitivity. The difficulty in distinguishing between otherwise uncomplicated diverticular disease and irritable bowel syndrome is such that surgical treatment is rarely, if ever, appropriate for diverticular disease in the absence of complications.

Diverticulitis typically presents as persistent lower abdominal pain, usually in the left iliac fossa accompanied by loose stools or indeed constipation. Fever, malaise and leukocytosis can differentiate diverticulitis from painful diverticulosis. The lower abdomen is tender, especially on the left, but occasionally also in the right iliac fossa, if the sigmoid loop lies across the midline. The sigmoid colon may be tender and thickened on palpation and rectal examination may reveal a tender mass if an abscess has formed. Distinguishing between diverticulitis and abscess formation is difficult on clinical grounds alone and radiological imaging assessment is important. Generalised peritonitis as a result of free perforation presents in the typical manner with systemic upset and generalised tenderness, guarding and rebound. Similarly, large and/or small bowel obstruction due to diverticular disease has the same clinical features as other causes (see Chapter 69) and the aetiology is likely to be discovered only by imaging or at laparotomy.

Haemorrhage from colonic diverticula is typically painless and profuse. When from the sigmoid, it will be bright red with clots, whereas right-sided bleeding will be darker. Torrential bleeding is fortunately rare and in fact more commonly due to angiodysplasia but diverticular bleeding may persist or recur requiring transfusion and indeed resection. The presentation of a fistula resulting from diverticular disease depends on the site. The most common colovesical fistula results in recurrent urinary tract infections and pneumaturia (flatus in the urine) or even faeces in the urine. Colovaginal fistulae are more common in patients who have had a hysterectomy. Colocutaneous fistulation is rare in the absence of prior intervention (e.g. radiological drainage). Rarely, diverticular disease may perforate into the retroperitoneum leading to a psoas abscess, and then presenting in the groin with fistulation.

Classification of contamination

The degree of sepsis has a major impact on outcome in acute diverticulitis. Those with inflammatory masses have a lower mortality than those with perforation (3 versus 33 per cent).

Classification systems have been developed for acute diverticulitis to try and rationalise the literature, the most commonly used is the Hinchey classification (Table 69.3).

Table 69.3 Hinchey classification of complicated diverticulitis.

Radiology

Plain chest and abdominal radiographs can demonstrate a pneumoperitoneum. Where available, spiral CT has excellent sensitivity and specificity for identifying bowel wall thickening, abscess formation and extraluminal disease and has revolutionised the assessment of complicated diverticular disease (Figure 69.35). On identification of abscesses in stable patients, drainage may be carried out percutaneously, avoiding the need for laparotomy/laparoscopy. If access to CT is limited, a watersoluble contrast enema can demonstrate intraluminal inflammation and contrast extravasation. This investigation also has a role in large bowel obstruction to distinguish mechanical blockage from pseudo-obstruction, however distinguishing between a malignant and a diverticular stricture may be difficult.

Barium enemas (and colonoscopy/flexible sigmoidoscopy) are usually avoided in the acute setting for fear of causing perforation or peritonitis. However, they are used after an attack has settled to exclude a coexisting carcinoma and assess...
the extent of diverticular disease (Figure 69.36). Colovesical fistulae should be evaluated with cystoscopy and biopsy in addition. Contrast examinations or CT may demonstrate the fistula clearly. The differential diagnosis for colovesical fistula includes cancer, radiation injury, Crohn’s disease, tuberculosis and actinomycosis.

**Colonoscopy**

Colonoscopy is normally deferred until 6 weeks after an acute attack of diverticulitis. It may demonstrate the necks of diverticula within the bowel lumen (Figure 69.37). A narrowed area of diverticular disease may be impassable because of the severity of disease and there is a significant risk of endoscopic perforation. Colonoscopy in these circumstances requires judgement and experience. The differential diagnosis from a carcinoma can be impossible if a tight stenosis prevents colonoscopy. Biopsies may be taken if possible and corroborated with barium enema or CT virtual colonoscopy is required.

**Management**

Patients are frequently recommended to take a high-fibre diet and bulk-forming laxatives, although the evidence for the effectiveness of these in diverticulosis or after an attack of diverticulitis is limited. Antispasmodics may have a role if recurrent pain is a problem. Acute diverticulitis is treated by intravenous antibiotics (to cover Gram-negative bacilli and anaerobes) alongside appropriate resuscitation and analgesia. Nil by mouth to ‘rest the bowel’ and catheterisation to reduce the risk of colovesical fistula are often advocated, but there is little evidence to support these practices. A CT scan can confirm the diagnosis and assess for complications. After the acute attack has subsided and if CT has not already confirmed the diagnosis, the bowel should be investigated by endoscopy, barium enema or CT virtual colonoscopy. An abscess can be drained percutaneously, 5 cm is frequently regarded as a cut off between an abscess likely to settle with antibiotics and one likely to require intervention.

**Operative procedures for diverticular disease**

The aim of emergency surgery is to control peritoneal sepsis; indications are generalised peritonitis and failure to respond to best medical management (Summary box 69.17). Laparotomy for diverticular disease in the acute setting has considerable risk with mortality in most series around 15 per cent and in the case of faecal peritonitis mortality approaches 50 per cent. Alongside operative technique, resuscitation, anaesthesia and postoperative management should be optimised.

**Summary box 69.17**

**Principles of surgical management of diverticular disease**

- Hartmann’s procedure is the safest option in emergency surgery
- Primary anastomosis can be considered in selected patients
- Elective resection may be offered for recurrent attacks
- Definitive treatment of colovesical fistula will require resection

It is logical to perform a rigid sigmoidoscopy to avoid missing a rectal carcinoma. Laparotomy and thorough washout of contamination are performed and then a choice has to be made between a Hartmann’s procedure (sigmoid resection with formation of left iliac fossa colostomy and closure of the rectal stump) and resection with colonic washout and anastomosis (± defunctioning loop ileostomy). Primary anastomosis should be used selectively but is appealing in a young fit patient without...
gross contamination or overwhelming sepsis. However, this is a relatively rare scenario and the majority of emergency operations for perforated diverticular disease are Hartmann's procedures (Figure 69.38). There is good evidence that simple defunctioning with a proximal stoma is associated with higher mortality than a resection. There may be an emerging role for emergency laparoscopy in diverticular disease with washout if there is no faecal contamination (i.e. Hinchey grade III or less), avoiding sigmoid resection. At present, this remains in the domain of the experienced laparoscopic surgeon.

Indications for surgery in an elective setting are controversial. There are undoubtedly a small number of patients with recurrent attacks who should be offered an elective sigmoid colectomy (with anastomosis). This could be performed laparoscopically in experienced hands with a likely but not clearly proven swifter recovery, as well as improved cosmesis. Cohort series studies suggest that of younger patients (under 50 years old) admitted with diverticulitis, 25 per cent will get a further episode. This is used as an argument for offering elective resection, but equally suggests 75 per cent will not have another severe attack. Many surgeons would discuss the pros and cons of elective surgery after two emergency admissions, although general health must be carefully considered. There has been an increasing tendency, in recent years, to treat even patients with recurrent attacks of diverticulitis conservatively in the absence of complications.

Diverticular fistulae can only be cured by resection of the affected bowel, although a defunctioning stoma can ameliorate symptoms. In the most common scenario of a colovesical fistula, the sigmoid can often be pinched off the bladder and the sigmoid resected. If an anastomosis is performed, it is wise to place an omental pedicle to prevent recurrent fistulation. There will be occasions when a bladder resection is required and it is ideal to involve a urologist or general surgeon experienced in bladder surgery.

Haemorrhage from diverticular disease should be distinguished from angiodysplasia. It usually responds to conservative management and only occasionally requires resection. Where available angiography is helpful to localise bleeding points. On-table lavage and colonoscopy may be necessary to localise the bleeding site. If the source cannot be located, then subtotal colectomy and ileostomy is the safest option.

### Vascular anomalies of the intestine

#### Mesenteric ischaemia

Mesenteric vascular disease may be classified as acute intestinal ischaemia – with or without occlusion – venous, chronic arterial, central or peripheral. The superior mesenteric vessels are the visceral vessels most likely to be affected by embolisation or thrombosis, with the former being most common. Occlusion at the origin of the superior mesenteric artery (SMA) is almost invariably the result of thrombosis, whereas emboli lodge at the origin of the middle colic artery. Inferior mesenteric involvement is usually clinically silent because of a better collateral circulation.

Possible sources for the embolisation of the SMA include a left atrium associated with fibrillation, a mural myocardial infarction, an atheromatous plaque from an aortic aneurysm and a mitral valve vegetation associated with endocarditis.

Primary thrombosis is associated with atherosclerosis and thromboangiitis obliterans. Primary thrombosis of the superior mesenteric veins may occur in association with factor V Leiden, portal hypertension, portal pyaemia and sickle cell disease and in women taking the contraceptive pill.

Irrespective of whether the occlusion is arterial or venous, haemorrhagic infarction occurs. The mucosa is the only layer of the intestinal wall to have little resistance to ischaemic injury. The intestine and its mesentry become swollen and oedematous. Blood-stained fluid exudes into the peritoneal cavity and bowel lumen. If the main trunk of the SMA is involved, the infarction covers an area from just distal to the duodenojejunal flexure to the splenic flexure. Usually, a branch of the main trunk is implicated and the area of infarction is less.

#### Clinical features

The most important clue to an early diagnosis of acute mesenteric ischaemia is the sudden onset of severe abdominal pain in a patient with atrial fibrillation or atherosclerosis. The pain is typically central and out of all proportion to physical findings. Persistent vomiting and defaecation occur early, with the subsequent passage of altered blood. Hypovolaemic shock rapidly ensues. Abdominal tenderness may be mild initially with rigidity being a late feature.
Investigation will usually reveal a profound neutrophil leukocytosis with an absence of gas in the thickened small intestine on abdominal radiographs. The presence of gas bubbles in the mesenteric veins is rare but pathognomonic.

Treatment needs to be tailored to the individual. In conjunction with full resuscitation, embolectomy via the ileocolic artery or revascularisation of the SMA may be considered in early embolic cases. The majority of cases, however, are diagnosed late. In the young, all affected bowel should be resected, whereas in the elderly or infirm the situation may be deemed incurable. Anticoagulation should be implemented early in the postoperative period.

After extensive enterectomy, it is usual for patients to require intravenous alimentation. The young, however, may sometimes develop sufficient intestinal digestive and absorptive function to lead relatively normal lives. In selected cases, consideration may be given to small bowel transplantation.

Infarction of the large intestine alone is relatively rare. Involvement of the middle colic artery territory should be treated by transverse colectomy and exteriorisation of both ends, with an extended right hemicolectomy in selected cases.

Ischaemic colitis describes the structural changes that occur in the colon as a result of the deprivation of blood. They are most common in the splenic flexure, whose blood supply is particularly tenuous. They have been classified by Marston into gangrenous, transient and stricturing forms; only stricturing forms cause obstruction and only a few such patients require resection.

**Angiodysplasia**

Angiodysplasia is a vascular malformation that is a cause of haemorrhage from the colon, typically in patients over 60 years. The lesions are also called angiomas, haemangiomas and arteriovenous malformations. Angiodysplasias occur particularly in the ascending colon and caecum of elderly patients. The malformations consist of dilated tortuous submucosal veins and in severe cases the mucosa is replaced by massive dilated deformed vessels.

**Clinical features**

In the majority, the symptoms are subtle and patients can present with anaemia. About 10–15 per cent of patients have brisk bleeds, which may present as melaena or significant rectal bleeding. It is likely that in many patients in whom rectal bleeding has been attributed to diverticular disease, bleeding was in fact from angiodysplasia. There is an association with aortic stenosis (Heyde’s syndrome).

**Investigation**

If the bleeding is not too brisk, colonoscopy may show the characteristic lesion in the right colon. The lesions are only a few millimetres in size and appear as reddish, raised areas at endoscopy. Capsule endoscopy is a relatively new technology that may detect small bowel lesions. Selective superior and inferior mesenteric angiography shows the site and extent of the lesion by a ‘blush’ of contrast provided bleeding is above 1 mL/min. If this fails, a technetium-99m (99mTc)-labelled red cell scan may confirm and localise the source of haemorrhage.

**Treatment**

The first principle is to stabilise the patient. Following this, the bleeding needs to be localised. Colonoscopy may allow cauterisation to be carried out. In severe uncontrolled bleeding, surgery becomes necessary. On-table colonoscopy is carried out to confirm the site of bleeding. Angiodysplastic lesions are sometimes demonstrated by transillumination through the caecum (Figure 69.39). If it is still not clear exactly which segment of the colon is involved, then a subtotal colectomy may be necessary.

**Ischaemic colitis**

Ischaemia of the colon typically results from thrombosis or embolism. Sudden embolic events present with severe pain out of proportion to the degree of peritonism, bloody diarrhoea, severe haemodynamic instability and acidosis. Resuscitation and laparotomy are required with resection of gangrenous bowel and exteriorisation of the bowel. Mortality is extremely high.

If the disease process is thrombotic in the context of global atherosclerosis, the presentation tends to be less dramatic with intermittent abdominal pain and rectal bleeding. Abdominal radiographs may show ‘thumbprinting’ and endoscopy may demonstrate haemorrhagic oedema. The left colon and, in particular, the splenic flexure are usually the worst affected. Angioplasty and bypass procedures can be performed in these circumstances, but are rarely required as symptoms usually settle spontaneously. In some cases, ulceration at the splenic flexure associated with ischaemic colitis may heal with stricturing and present with subsequent large bowel obstruction.

**STOMAS**

A colostomy (or ileostomy) stoma is an artificial opening made in the colon (or small intestine) to divert faeces and flatus outside the abdomen where they can be collected in an external appliance. Depending on the purpose for which the diversion has been necessary, a stoma may be temporary or permanent (Summary box 69.18).

![Figure 69.39 Angiodysplasia of the caecum demonstrated by transillumination with a colonoscope intraoperatively.](image)
Loose colostomy

A transverse loose colostomy has in the past been used to defunction an anastomosis after an anterior resection. It is now less commonly employed, as it is difficult to manage and potentially disrupts the marginal arterial supply to the anastomosis. Loose transverse colostomies are also particularly prone to prolapse. A loop ileostomy is now more commonly used.

A loop left iliac fossa colostomy is still sometimes used to prevent faecal peritonitis developing following traumatic injury to the rectum, to facilitate the operative treatment of a high fistula in ano, for incontinence and to defunction a near obstructing rectal cancer prior to long course chemoradiotherapy (see Chapter 72).

A temporary loop colostomy is made by bringing a mobilised loop of colon to the surface, where it is held in place by a plastic bridge passed through a mesenteric window created just at the junction with the colon. Once the abdomen has been closed, the colostomy is opened, and the edges of the colonic incision are sutured to the adjacent skin margin (Figure 69.40). When firm adhesion of the colostomy to the abdominal wall has taken place, the bridge can be removed.

Following healing of the distal lesion for which the temporary stoma was constructed, the colostomy can be closed. It is usual to perform a contrast examination (proctogram) to check that there is no distal obstruction or continuing problem at the site of previous surgery. Colostomy closure is most easily and safely accomplished if the stoma is mature, typically after the colostomy has been established for two months. Closure is usually possible with a circumstomal incision, which avoids a full laparotomy, but it is important for patient and surgeon to consider the risks of closure carefully as it does involve a bowel anastomosis. In some cases, a full laparotomy may be required for safe closure of the stoma.

End colostomy

This is formed after an abdominoperineal excision of the rectum or as part of a Hartmann’s procedure bringing the divided colon through a left iliac fossa trephine in rectus abdominis and skin. The colonic margin is then sutured to the adjoining skin.

The point at which the colon is brought to the surface must be carefully selected to allow a colostomy bag to be applied without impinging on the bony prominence of the anterosuperior iliac spine. The best site is usually through the lateral edge of the rectus sheath, above and medial to the bony prominence (Figure 69.41).

Closure of the lateral space between the intraperitoneal segment of the sigmoid colon and the peritoneum of the pelvic wall, to prevent internal herniation or strangulation of loops of small bowel through the deficiency, has been practiced, but there is no good evidence that it is effective.

Loop ileostomy

A loop ileostomy is often used for defunctioning a low rectal anastomosis or an ileal pouch. A knuckle of ileum is pulled out through a skin trephine in the right iliac fossa. An incision is made in the distal part of the knuckle, and this is then pulled...
over the top of the more proximal part to create a spout on the proximal side of the loop with a flush distal side still in continuity. This allows near perfect defunction, but also the possibility of restoration of continuity by taking down the spout and reanastomosing the partially divided ileum.

The advantages of a loop ileostomy over a loop colostomy are the ease with which the bowel can be brought to the surface and the absence of odour. Care is needed when the ileostomy is closed, so that suture line obstruction does not occur. Closure of a loop ileostomy can be a technically challenging procedure, particularly if there are dense adhesions resulting from previous surgery.

**End ileostomy**

An end ileostomy is formed after a subtotal colectomy without anastomosis when it may later be reversed or may be permanent after a panproctocolectomy. The ileum is normally brought through the rectus abdominis muscle. Careful attention to the terminal ileal mesentery should be taken to ensure that it is not too bulky. The use of a spout was originally described by Bryan Brooke; this should project some 4 cm from the skin surface (Figure 69.42). A disposable appliance is placed over the ileostomy so that it is a snug fit at skin level.

There may be an ‘ileostomy flux’ while the ileum adapts to the loss of the colon. While ileostomy output can amount to 4 or 5 litres per day, losses of 1–2 litres are more common. A consistent ileostomy output in excess of 1.5 litres is usually associated with dehydration and sodium depletion in the absence of intravenous therapy. The stools thicken in a few weeks and are semisolid in a few months. The help, skill and advice of the stoma care nurse specialist are essential. Modern appliances have transformed stoma care, and skin problems are unusual (Figure 69.43). Complications of an ileostomy include prolapse, retraction, stenosis, bleeding, fistula and parastomal hernia.

**Stoma bags and appliances**

Stoma output is collected in disposable adhesive bags. Ileostomy appliances tend to be drainable bags, which are left in place for 48 hours, while colostomy appliances are simply changed two or three times each day. A wide range of such bags is currently available. Many now incorporate an adhesive backing, which can be left in place for several days. In most hospitals, a stoma care service is available to offer advice to patients, to acquaint them with the latest appliances and to provide the appropriate psychological and practical help.

**Caecostomy**

In unstable patients with advanced obstruction, a caecostomy may be useful. In late cases of obstruction, the caecum may become so distended and ischaemic that rupture of the caecal wall may be anticipated. This can occur spontaneously, giving rise to faecal peritonitis, or at operation, when an incision in the abdominal wall reduces its supportive role and allows the caecum to expand. In such a situation, it should be decompressed by suction as soon as the abdomen is opened. In thin patients, it may then be possible to carry out direct suture of the incised or perforated caecal wall to the abdominal skin of the right iliac fossa, although resection of this area is really the best treatment preferable. Following on-table lavage, via the appendix stump, the irrigating catheter can be left in place as a tube caecostomy.

**Complications of stomas**

Stoma complications are underestimated and common (Summary box 69.19). On occasion, these complications require surgical revision. Sometimes, this can be achieved with an incision immediately around the stoma, but on occasion reopening the abdomen and freeing up the stoma may be necessary. Repair of parastomal hernias is particularly technically challenging and the recurrence rate is high. Simple suture of the parastomal hernia is associated with an almost 100 per cent risk of recurrence and transfer to the opposite side of the abdomen, or insertion of a piece of prosthetic material within the abdominal wall around the stoma may be necessary.
**CONDITIONS CAUSING MALABSORPTION**

**Coeliac disease**
Coeliac disease is the most common cause of malabsorption in the UK with a stated prevalence of 1:1800, although this may be an underestimate. It is characterised by a hypertrophic small bowel mucosa with atrophic villi and deep crypts. It is thought that loss of surface area and brush border enzymes results in malabsorption.

Coeliac disease is caused by gluten, a cereal protein although the exact mechanism remains unclear. There is a genetic component as the disease is more common in first-degree relatives and has an association with HLA B8. In children, coeliac disease presents with steatorrhoea and growth retardation. In adults, it results in diarrhoea, weight loss and anaemia.

The diagnosis is made after an endoscopic duodenal biopsy allows pathological examination of mucosa. The antiendomysial antibody tests have a very high sensitivity and specificity for coeliac disease, but many gastroenterologists would still want a biopsy to be entirely certain of the diagnosis.

Patients with coeliac disease have an increased risk of small bowel lymphoma and adenocarcinoma. Extraintestinal complications are dermatitis herpetiformis and neurological problems.

The key treatment for coeliac disease is withdrawal of gluten from the diet by avoiding wheat, rye and barley. Surgery is reserved for malignancy.

**Bacterial overgrowth**
The small intestine can become colonised with bacteria normally confined to the colon if there is stasis resulting in delayed bacterial clearance (blind loop syndrome, Figure 69.44). If this occurs in the upper intestine, the defect is chiefly of fat absorption; if in the lower intestine, there is vitamin B12 deficiency. There is relatively little effect on carbohydrate or protein metabolism.

Essentially, the stasis produces an abnormal bacterial flora, which prevents proper breakdown of fat and mops up the vitamins that are present. Sometimes, the only manifestation is anaemia, resulting from vitamin B12 deficiency but, if steatorrhoea occurs, other serious malabsorption features may follow including glossitis, osteomalacia, paraesthesia and peripheral neuropathy.

Improvement normally follows after intermittent therapy with oral antibiotics; metronidazole, ciprofloxacin and tetracycline are commonly used. Definitive treatment is surgical to remove the ‘blind loop’, but this is not always feasible.

**FUNCTIONAL ABNORMALITIES**

**Constipation**
There is no single definition of constipation; however, a bowel frequency of less than one every 3 days is commonly considered to be abnormal. Although constipation is often regarded as a trivial symptom, some patients are greatly disabled by abdominal pain, distension, reliance on laxatives and difficulty with defaecation. It is an extremely prevalent complaint in western society. Some reports have put the annual prescription sales for laxatives in the UK at around £50 million. These are usually otherwise healthy individuals who seek help for constipation, but eat a normal diet and have a normal colon on endoscopy and barium enema. Constipation can be divided into:

- megacolon:
  - Hirschsprung’s disease;
  - non-Hirschsprung’s megacolon and megarectum;
- non-megacolon:
  - secondary to drugs or illness;
  - primary colonic problem.

**Hirschsprung’s disease**
The nature and treatment of Hirschsprung’s disease is discussed with other congenital disorders in Chapter 70.

**Idiopathic megacolon and megarectum**
This is a rare condition and the cause is not known, although in some it may result from poor toilet training during infancy and in others from a congenital abnormality of the intestinal myenteric plexus. In South America, Chagas disease is a common cause of megacolon resulting from infection with Trypanosoma cruzi. Volvulus and perforation can occur and treatment may require surgical resection.

---

**Harald Hirschsprung, 1830–1916, physician, The Queen Louise Hospital for Children, Copenhagen, Denmark described congenital megacolon in 1887.**

**Sir Frederick Treves, 1823–1953, surgeon, The London Hospital, attributed Hirschsprung’s disease to congenital spasm of the distal segment, thus preceding the rediscovery of this concept by 50 years.**

---

**Figure 69.44 Common types of blind loop.**
(a) Self-filling: deficiency occurs; (b) self-emptying: no deficiency occurs; (c) long afferent loop stasis in Pólya gastrectomy; (d) jejunal diverticula; (e) intestinal stricture causing stasis; (f) ‘stenosis–anastomosis loop’ syndrome.
Clinical features
Idiopathic megacolon usually presents with severe constipation before the age of 20. Patients with idiopathic megarectum often present with faecal incontinence due to rectal faecal loading that requires manual evacuation. Patients with megacolon are more likely to present with abdominal distension and pain. On clinical examination, there may be a hard faecal mass arising out of the pelvis and, on rectal examination, there is a large faecal mass in the lumen. The anus is usually patulous, perianal soiling is common, and sigmoidoscopy is usually impossible but may show melanosis coli if the patient has been taking laxatives over many years.

Investigation
Anorectal physiology tests demonstrate delayed sensation and raised maximum tolerated volume. Full-thickness rectal biopsy shows normal ganglion cells, a finding that definitively distinguishes this condition from Hirschsprung’s disease. Radiology studies will show gross faecal loading of the enlarged rectum and colon and an enlarged colon (Figure 69.45).

Medical treatment
This is directed at emptying the rectum and keeping it empty with enemas, washouts and occasionally, manual evacuation under anaesthesia. Thereafter, the patient is encouraged to develop a regular daily bowel habit, with the use of osmotic laxatives to help the passage of semiformed stool. Rectal evacuation with suppositories and biofeedback therapy may be useful in resistant cases.

Surgical treatment
Surgical treatment is sometimes necessary if medical therapy fails. Options that are available include:
- resection of the dilated rectum and colon (Figure 69.46) back to normal-diameter colon followed by reconstruction with a coloanal anastomosis;
- colectomy with the formation of an ileorectal anastomosis if the rectum is spared;
- restorative proctocolectomy;
- vertical reduction rectoplasty, which is a procedure designed to reduce the volume of the rectum by at least 50 per cent;
- stoma formation, which may be used either as a salvage operation for failure of previous surgery or as a primary intervention.

Non-megacolon constipation
Drugs and a range of illnesses can result in constipation (see Summary boxes 69.20 and 69.21). Altering medication or addition of laxatives can be helpful for drug-related constipation, correction of underlying illness is clearly ideal where possible for the conditions in Summary box 69.21.

Summary box 69.20
Drugs that can cause constipation
- Benzodiazepines
- Carbamazepine
- Chlorpromazine
- Cholestyramine
- Iron
- Opiates, particularly codeine and morphine
- Tricyclic antidepressants
- Statins
There remain a group of patients with significant constipation who do not have any structural, pharmacological or other pathology to explain their symptoms. Some will have obstructed defaecation and this is discussed in Chapter 72. Others will have slow colonic transit, a disorder usually seen in women, which may have been present since childhood or may suddenly follow abdominal or pelvic surgery. Marker studies will reveal delayed transit, and the patient may or may not be able to empty the rectum normally.

**Investigation**

Whole-gut transit time can be measured by asking the patient to stop all laxatives and take a capsule containing radio-opaque markers (Figure 69.47). Retention of more than 80 per cent of the shapes, 120 hours after ingestion, is abnormal.

Defaecating proctography will demonstrate intussusception and rectocoele if they are causing obstructed defaecation (Chapter 72).

**Treatment of slow colonic transit**

- **Dietary fibre.** This is the first-line treatment for people with mild constipation. Constipation only resolves after several weeks of therapy and usually needs to be continued in the long term.
- **Laxatives.** It is important that patients do not fall into a cycle of laxative abuse. A number of types are available which include bulk, osmotic and stimulant agents.
- **Biofeedback.** This involves conditioning and coordination of the abdominal and pelvic compartments. It has been shown to be effective in those with a rectal evacuation problem and has also been used in slow transit with some benefit.
- **Surgery.** This is a difficult condition to treat medically; dietary measures are usually unsuccessful, and surgical treatment is justified after careful studies and when medical treatment has been exhausted. Total colectomy and ileorectal anastomosis is the preferred procedure, but the results are unpredictable. Studies show complications of intermittent small bowel obstruction (60 per cent), further surgery (30 per cent), constipation (25 per cent), diarrhoea (25 per cent) and incontinence (10 per cent). This may be explained in part by the argument that colectomy does not address the functional problem of the remaining bowel. Patients need to be carefully selected for surgery and psychological evaluation may be of benefit. Other types of surgery performed for slow transit constipation include stoma creation and segmental resection, but results are variable.

**Irritable bowel syndrome**

The term ‘irritable bowel syndrome’ (IBS) covers a range of symptom patterns that have a functional basis, i.e. no anatomical abnormality has been found. The clinical features are therefore variable but abdominal pain, bloating, irregularity of bowel habit and passage of mucus are common. Colonic investigations are typically performed to rule out organic disease (colonoscopy, barium enema or CT virtual colonoscopy).

Treatment is difficult by its nature. Many patients benefit from reassurance that there is no sinister pathology and symptomatic treatment; fibre or Fybogel for constipation, loperamide for diarrhoea. Reduction of caffeine intake and nicotine intake may be helpful. Antispasmodic agents are commonly prescribed, but the evidence base for this is poor. There is evidence of benefit for low-dose tricyclic antidepressants, but some patients are reluctant to use them because of a perceived stigma. Psychological treatments have been shown to be beneficial including hypnotherapy and cognitive behavioural therapy.

**ENTEROCUTANEOUS FISTULA**

An abnormal connection between small bowel and skin can occur in fistulating Crohn’s disease or as a result of radiotherapy or abdominal trauma, but most commonly follows a surgical

---

complication – either a leak from an anastomosis or an inadvertent enterotomy during dissection. This can be very challenging to manage in patients with a high-output fistula (>500 mL/day). Low-output fistulae (<500 mL/day) can be expected to heal spontaneously, provided there is no distal obstruction. Reasons for failure of spontaneous healing also include:

- epithelial continuity between the gut and the skin;
- the presence of active disease where, for example, there is Crohn’s disease or carcinoma at the site of the anastomosis or in the fistula track;
- an associated complex abscess.

The management of high output fistulae is based on well-established principles (‘SNAP’, see Summary box 69.22), as an early return to theatre to try and fix the problem in a septic, malnourished patient is doomed to failure.

### Summary box 69.22

**Principles of management of enterocutaneous fistulae (SNAP)**

- **S**, elimination of Sepsis and skin protection
- **N**, Nutrition – a period of parenteral nutrition may well be required
- **A**, Anatomical assessment
- **P**, definitive Planned surgery

Infected collections are best identified at CT (Figure 69.48) and can be drained percutaneously. Skin protection is important, as small bowel effluent is caustic. Nutritional support must include fluid and electrolytes, which can be lost in high quantities from a proximal fistula as well as carbohydrates, protein, fat and vitamins. Judgements have to be made between enteral and parenteral feeding – enteral feeding has advantages but if the fistula is proximal or high output, total parenteral nutrition (TPN) will be required. Defining anatomy is best done after careful discussion with the radiologist – a sequence of contrast studies (follow-through, fistulogram and enema) may well be required to define bowel length and plan a surgical strategy. The surgery can on occasion be extremely technically demanding, and an anastomosis should not be fashioned in the presence of continuing intra-abdominal sepsis or when the patient is hypoproteinaemic.

### FURTHER READING

Intestinal obstruction may be classified into two types:

- **Dynamic**, in which peristalsis is working against a mechanical obstruction. It may occur in an acute or a chronic form (Figure 70.1 and Summary box 70.1).
- **Adynamic**, in which there is no mechanical obstruction; peristalsis is absent or inadequate (e.g. paralytic ileus or pseudo-obstruction).

### Summary box 70.1

**Causes of intestinal obstruction**

**Dynamic**
- Intraluminal
  - Faecal impaction
  - Foreign bodies
  - Bezoars
  - Gallstones
- Intramural
  - Stricture
  - Malignancy
  - Intussusception
  - Volvulus
- Extramural
  - Bands/adhesions
  - Hernia

**Adynamic**
- Paralytic ileus
- Pseudo-obstruction

### Pathophysiology

Irrespective of aetiology or acuteness of onset, in dynamic (mechanical) obstruction the bowel proximal to the obstruction dilates and the bowel below the obstruction exhibits normal peristalsis and absorption until it becomes empty and collapses. Initially, proximal peristalsis is increased in an attempt to overcome the obstruction. If the obstruction is not relieved, the bowel continues to dilate, ultimately there is a reduction in peristaltic strength, resulting in flaccidity and paralysis.

The distension proximal to an obstruction is caused by two factors:

- **Gas**: there is a significant overgrowth of both aerobic and anaerobic organisms, resulting in considerable gas production. Following the reabsorption of oxygen and carbon dioxide, the majority is made up of nitrogen (90 per cent) and hydrogen sulphide.
- **Fluid**: this is made up of the various digestive juices (saliva 500 mL, bile 500 mL, pancreatic secretions 500 mL, gastric secretions 1 litre – all per 24 hours). This accumulates in the gut lumen as absorption by the obstructed gut is retarded. Dehydration and electrolyte loss are therefore due to:
  - reduced oral intake;
— defective intestinal absorption;
— losses as a result of vomiting;
— sequestration in the bowel lumen;
— transudation of fluid into the peritoneal cavity.

**STRANGULATION**

It is important to appreciate that the consequences of intestinal obstruction are not immediately life-threatening unless there is superimposed strangulation. When strangulation occurs, the blood supply is compromised and the bowel becomes ischaemic (Summary box 70.2).

### Summary box 70.2

**Causes of strangulation**

- Direct pressure on the bowel wall
  - Hernial orifices
  - Adhesions/bands
- Interrupted mesenteric blood flow
  - Volvulus
  - Intussusception
- Increased intraluminal pressure
  - Closed-loop obstruction

Ischaemia from direct pressure on the bowel wall from a constricting band, such as a hernial orifice, is easy to understand.

Distention of the obstructed segment of bowel results in high pressure within the bowel wall. This can happen when only part of the bowel wall is obstructed as seen in Richter’s hernias. Venous return is compromised before the arterial supply. The resultant increase in capillary pressure leads to impaired local perfusion and once the arterial supply is impaired, haemorrhagic infarction occurs. As the viability of the bowel is compromised, translocation and systemic exposure to anaerobic organisms and endotoxin occurs.

The morbidity and mortality associated with strangulation are largely dependent on the duration of the ischaemia and its extent. Elderly patients and those with comorbidities are more vulnerable to its effects. Although in strangulated external hernias the segment involved is often short, any length of ischaemic bowel can cause significant systemic effects secondary to sepsis and obstruction proximal to the obstruction can result in significant dehydration. When bowel involvement is extensive circulatory failure is common.

**Closed-loop obstruction**

This occurs when the bowel is obstructed at both the proximal and distal points (Figure 70.2). The distention is principally confined to the closed loop, distention proximal to the obstructed segment is not typically marked.

A classic form of closed-loop obstruction is seen in the presence of a malignant stricture of the colon with a competent ileocaecal valve (present in up to one-third of individuals). This can occur with lesions as far distally as the rectum. The inability of the distended colon to decompress itself into the small bowel results in an increase in luminal pressure, which is greatest at the caecum, with subsequent impairment of blood flow in the wall. Unrelieved, this results in necrosis and perforation (Figure 70.3).

**SPECIAL TYPES OF MECHANICAL INTESTINAL OBSTRUCTION**

**Internal hernia**

Internal herniation occurs when a portion of the small intestine becomes entrapped in one of the retroperitoneal fossae or in a congenital mesenteric defect.

The following are potential sites of internal herniation (all are rare):

- the foramen of Winslow;
- a defect in the mesentery;
- a defect in the transverse mesocolon;
- defects in the broad ligament;
- congenital or acquired diaphragmatic hernia;
- duodenal retroperitoneal fossae – left paraduodenal and right duodenojejunal;

*Jacob Benignus Winslow, 1669–1760, Professor of Anatomy, Physic and Surgery, Paris, France.*
Special types of mechanical intestinal obstruction

Trychobezoars and phytozoars
These are firm masses of undigested hair ball and fruit/vegetable fibre, respectively. The former is due to persistent hair chewing or sucking, and may be associated with an underlying psychiatric abnormality. Predisposition to phytozoars results from a high fibre intake, inadequate chewing, previous gastric surgery, hypochlorhydria and loss of the gastric pump mechanism. When possible, the lesion may be kneaded into the caecum, otherwise open removal is required. A peroperative diagnosis is difficult even with high resolution computed tomography (CT) scanning.

Stercoliths
These are usually found in the small bowel in association with a jejunal diverticulum or ileal stricture. Presentation and management are identical to that of gallstones.

Worms
Ascaris lumbricoides may cause low small bowel obstruction, particularly in children, the institutionalised and those near the tropics (Figure 70.4). An attack may follow the initiation of antihelminthic therapy. Debility is frequently out of proportion to that produced by the obstruction. If worms are not seen in the stool or vomitus, the diagnosis may be indicated by eosinophilia or the sight of worms within gas-filled small bowel loops on a plain radiograph (Naik). At laparotomy, it may be possible to knead the tangled mass into the caecum; if not it should be removed. Occasionally, worms may cause a perforation and peritonitis, especially if the enteric wall is weakened by such conditions as amebiasis.

Obstruction by adhesions and bands

Adhesions
In Western countries where abdominal operations are common, adhesions and bands are the most common cause of intestinal obstruction. The lifetime risk of requiring an admission to hospital for adhesional small bowel obstruction subsequent to abdominal surgery is around 4 per cent and the risk of requiring a laparotomy around 2 per cent. Adhesions start to form within

Food
Bolus obstruction may occur after partial or total gastrectomy when unchewed articles can pass directly into the small bowel. Fruit and vegetables are particularly liable to cause obstruction. The management is similar to that for gallstone, with intraluminal crushing usually being successful.

Vinod C Naik, a doctor from Navsari, India.
ABDOMINAL INTESTINAL OBSTRUCTION

hours of abdominal surgery. In the early postoperative period, the onset of such a mechanical obstruction may be difficult to differentiate from paralytic ileus.

The causes of intraperitoneal adhesions are shown in Table 70.1. Any source of peritoneal irritation results in local fibrin production, which produces adhesions between apposed surfaces. Early fibrinous adhesions may disappear when the cause is removed or they may become vascularised and be replaced by mature fibrous tissue.

There are several factors that may limit adhesion formation (Summary box 70.3).

### Summary box 70.3

**Prevention of adhesions**

Factors that may limit adhesion formation include:
- Good surgical technique
- Washing of the peritoneal cavity with saline to remove clots
- Minimising contact with gauze
- Covering anastomosis and raw peritoneal surfaces

Numerous substances have been instilled in the peritoneal cavity to prevent adhesion formation, including hyaluronidase, hydrocortisone, silicone, dextran, polyvinylpropylene (PVP), chondroitin and streptomycin, anticoagulants, antihistamines, non-steroidal anti-inflammatory drugs and streptokinase. Currently, no single agent or combination of agents has been convincingly shown to be effective. It is hoped that with the more widespread use of laparoscopic surgery, the incidence of intra-abdominal adhesions will reduce.

Adhesions may be classified into various types by virtue of whether they are early (fibrinous) or late (fibrous) or by underlying aetiology. From a practical perspective, there are only two types – ‘easy’ flimsy ones and ‘difficult’ dense ones.

Postoperative adhesions giving rise to intestinal obstruction usually involve the lower small bowel and almost never involve the large bowel.

**Bands**

Usually only one band is culpable. This may be:
- congenital, e.g. obliterated vitellointestinal duct;
- a string band following previous bacterial peritonitis;
- a portion of greater omentum, usually adherent to the parietes.

**Acute intussusception**

This occurs when one portion of the gut invaginates into an immediately adjacent segment; almost invariably, it is the proximal into the distal.

The condition is encountered most commonly in children, with a peak incidence between five and ten months of age. About 90 per cent of cases are idiopathic, but an associated upper respiratory tract infection or gastroenteritis may precede the condition. It is believed that hyperplasia of Peyer’s patches in the terminal ileum may be the initiating event. Weaning, loss of passively acquired maternal immunity and common viral pathogens have all been implicated in the pathogenesis of intussusception in infancy.

Children with intussusception associated with a pathological lead point such as Meckel’s diverticulum, polyp, duplication, Henoch–Schönlein purpura or appendix are usually older than those with idiopathic disease. After the age of two years, a pathological lead point is found in at least one-third of affected children. Adult cases are invariably associated with a lead point, which is usually a polyp (e.g. Peutz–Jeghers syndrome), a submucosal lipoma or other tumour.

**Pathology**

An intussusception is composed of three parts (Figure 70.5):
- the entering or inner tube (intussusceptum);
- the returning or middle tube;
- the sheath or outer tube (intussuscipiens).

The part that advances is the apex, the mass is the intussusception and the neck is the junction of the entering layer with the mass.

Intussusception may be anatomically defined according to the site and extent of invagination (Table 70.2). In most children, the intussusception is ileocolic (see Chapter 8, Figure 6.16). In adults, colocolic intussusception is more common (Summary box 70.4). The degree of ischaemia is dependent on the tightness of the invagination, which is usually greatest as it passes through the ileocaecal valve. On CT scanning, the target sign may be evident and if present is pathognomonic. It is worth noting that rarely, intussusception has been noted on CT scanning in asymptomatic adults.

**Figure 70.5** Mechanism and nomenclature of intussusception.

**Summary box 70.4**

**Intussusception**

- Most common in children
- Adult cases are secondary to intestinal pathology, e.g. polyp, Meckel’s diverticulum
- Ileocolic is the most common variety
- Can lead to an ischaemic segment
- Radiological reduction is indicated in most paediatric cases
- Adults require surgery

**Volvulus**

A volvulus is a twisting or axial rotation of a portion of bowel about its mesentery. The rotation causes obstruction to the lumen (>180° torsion) and if tight enough also causes vascular occlusion in the mesentery (>360° torsion). Bacterial fermentation adds to the distention and increasing intraluminal pressure impairs capillary perfusion. Mesenteric veins become obstructed as a result of the mechanical twisting and thrombosis results and contributes to the ischaemia.

Volvuli may be primary or secondary. The primary form occurs secondary to congenital malrotation of the gut, abnormal mesenteric attachments or congenital bands. Examples include volvulus neonatorum, caecal volvulus and sigmoid volvulus. A secondary volvulus, which is the more common variety, is due to rotation of a segment of bowel around an acquired adhesion or stoma (Summary box 70.5).

**Summary box 70.5**

**Volvulus**

- May involve the small intestine, caecum or sigmoid colon; neonatal midgut volvulus secondary to midgut malrotation is life-threatening
- The most common spontaneous type in adults is sigmoid
- Sigmoid volvulus can be relieved by decompression per anum
- Surgery is required to prevent or relieve ischaemia

**Special types of mechanical intestinal obstruction**

**Volvulus neonatorum**

This occurs secondary to intestinal malrotation (see Chapter 8) and is potentially catastrophic.

**Sigmoid volvulus**

This is uncommon in Europe and the United States, but more common in Eastern Europe and Africa. Indeed, it is the most common cause of large bowel obstruction in the indigenous Black African population. Rotation nearly always occurs in the anticlockwise direction. The predisposing causes are summarised in Figure 70.6. Other predisposing factors include a high residue diet and constipation. In Western populations, the condition is seen most often in elderly patients with chronic constipation; comorbidities are common and chronic psychotropic drug use is associated with this condition. Younger patients present earlier and the prognosis is inversely related to the duration of symptoms. Presentation can be classified as:

- **Fulminant**: sudden onset, severe pain, early vomiting, rapidly deteriorating clinical course;
- **Indolent**: insidious onset, slow progressive course, less pain, late vomiting.

**Compound volvulus**

This is a rare condition also known as ileosigmoid knotting. The long pelvic mesocolon allows the ileum to twist around the sigmoid colon, resulting in gangrene of either or both segments of bowel. The patient presents with acute intestinal obstruction, but distension is comparatively mild. Plain radiography reveals distended ileal loops in a distended sigmoid colon. At operation, decompression, resection and anastomosis are required.

**Figure 70.6** Causes predisposing to volvulus of the sigmoid colon. Idiopathic megacolon usually precedes the volvulus in African people.
The underlying mechanisms are shown in Summary box 70.2 and their relative frequencies are shown in Figure 70.1. The common causes of intestinal obstruction in Western countries and their relative frequencies are shown in Figure 70.1. The underlying mechanisms are shown in Summary box 70.2.

**Dynamic obstruction**

The diagnosis of dynamic intestinal obstruction is based on the classic quartet of pain, distension, vomiting and absolute constipation. Obstruction may be classified clinically into two types:

- small bowel obstruction – high or low;
- large bowel obstruction (Summary box 70.6).

**Summary box 70.6**

**Features of obstruction**

- In high small bowel obstruction, vomiting occurs early, is profuse and causes rapid dehydration. Distension is minimal with little evidence of dilated small bowel loops on abdominal radiography.
- In low small bowel obstruction, pain is predominant with central distension. Vomiting is delayed. Multiple dilated small bowel loops are seen on radiography.
- In large bowel obstruction, distension and pronounced pain is less severe and vomiting and dehydration are later features. The colon proximal to the obstruction is distended on abdominal radiography. The small bowel will be dilated if the ileocaecal valve is incompetent.

The nature of the presentation will also be influenced by whether the obstruction is:

- complete;
- incomplete.

A complete small bowel obstruction has all the cardinal features (Summary box 70.7). In cases of complete large bowel obstruction, there is often a surprising lack of preceding symptoms. Both small and large bowel obstruction can present with more chronic symptoms in which the symptoms are intermittent or the obstruction is incomplete. Incomplete obstruction is also referred to as partial or subacute.

**Summary box 70.7**

**Cardinal clinical features of acute obstruction**

- Abdominal pain
- Distension
- Vomiting
- Absolute constipation

Presentation will be further influenced by whether the obstruction is:

- simple – in which the blood supply is intact;
- strangulating/strangulated – in which there is interference to blood flow.

The clinical features vary according to:

- the location of the obstruction;
- the duration of the obstruction;
- the underlying pathology;
- the presence or absence of intestinal ischaemia.

Late manifestations of intestinal obstruction that may be encountered include dehydration, oliguria, hypovolaemic shock, pyrexia, septicaemia, respiratory embarrassment and peritonism.

In all cases of suspected intestinal obstruction, the hernial orifices must be examined.

**Pain**

Pain is the first symptom encountered; it occurs suddenly and is usually severe. It is colicky in nature and usually centred on the umbilicus (small bowel) or lower abdomen (large bowel). Pain coincides with increased peristaltic activity. With increasing distension, the colicky pain is replaced by a mild and more constant diffuse pain. If there is no ischaemia and the obstruction persists over several days, pain reduces and can disappear.

The development of severe pain is suggestive of the presence of strangulation, especially if that severe pain is continuous. Beware the patient whose pain is not controlled with intravenous opiates. Colicky pain may not be a significant feature in postoperative simple mechanical obstruction and pain does not usually occur in paralytic ileus.

**Vomiting**

The more distal the obstruction, the longer the interval between the onset of symptoms and the appearance of nausea and vomiting. As obstruction progresses, the character of the vomitus alters from digested food to faeculent material, as a result of the presence of enteric bacterial overgrowth.

**Distension**

In the small bowel, the degree of distension is dependent on the site of the obstruction and is greater the more distal the lesion. Visible peristalsis may be present (Figure 70.7). This can sometimes be provoked by ‘flicking’ the abdominal wall. Distension is a later feature in colonic obstruction.

**Constipation**

This may be classified as absolute (i.e. neither faeces nor flatus is passed) or relative (where only flatus is passed). Absolute constipation is a cardinal feature of complete intestinal obstruction. Some patients may pass flatus or faeces after the onset of obstruction as a result of the evacuation of the distal bowel contents. The administration of enemas should be avoided in cases of suspected obstruction. This merely stimulates evacuation of bowel contents distal to the obstruction and confuses the clinical picture.

The rule that absolute constipation is present in intestinal obstruction does not apply in:

- Richter’s hernia;
- gallstone ileus;
- mesenteric vascular occlusion;
- functional obstruction associated with pelvic abscess;
- all cases of partial obstruction (in which diarrhoea may occur).

---

August Gottlieb Richter, 1742–1812, lecturer in surgery, Göttingen, Germany, described this form of hernia in 1777.
Clinical features of intestinal obstruction

**Other manifestations**

**Dehydration**

Dehydration is most commonly in small bowel obstruction because of repeated vomiting and fluid sequestration. It results in dry skin and tongue, poor venous filling and sunken eyes with oliguria. The blood urea level and haematocrit rise, giving a secondary polycythaemia.

**Hypokalaemia**

Hypokalaemia is not a common feature in simple mechanical obstruction. An increase in serum potassium, amylase or lactate dehydrogenase may be associated with the presence of strangulation, as may leukocytosis or leukopenia.

**Pyrexia**

Pyrexia in the presence of obstruction is rare and may indicate:
- the onset of ischaemia;
- intestinal perforation;
- inflammation or abscess associated with the obstructing disease.

Hypothermia indicates septicaemic shock or neglected cases of long duration.

**Abdominal tenderness**

Localised tenderness indicates impending or established ischaemia. The development of peritonitis or peritonitis indicates impending or overt infarction and/or perforation. In cases of large bowel obstruction, it is important to elicit these findings in the right iliac fossa as the caecum is most vulnerable to ischaemia.

---

**Bowel sounds**

High-pitched bowel sounds are present in the vast majority of patients with intestinal obstruction. Normal bowel sounds are of negative predictive value. Bowel sounds may be scanty or absent if the obstruction is long-standing and the small bowel has become inactive.

**Clinical features of strangulation**

It is vital to distinguish strangulating from non-strangulating intestinal obstruction because the former is a surgical emergency. The diagnosis is almost entirely clinical; the clinical features are shown in Summary box 70.8.

**Summary box 70.8**

**Clinical features of strangulation**

- Constant pain, severe pain
- Tenderness with rigidity and peritonism
- Shock

In addition to the features above, it should be noted that:
- The presence of shock suggests underlying ischaemia especially if the shock is resistant to simple fluid resuscitation.
- In impending or established strangulation, pain is never completely absent.
- The presence and character of any local tenderness are of great significance and, however mild, tenderness requires frequent reassessment.
- Generalised tenderness and the presence of rigidity indicate the need for early laparotomy.
- In cases of intestinal obstruction in which pain persists despite conservative management, even in the absence of the above signs, strangulation should be presumed.
- When strangulation occurs in an external hernia, the lump is tense, tender and irreducible and there is no expansile cough impulse. Skin changes with erythema or purplish discolouration are associated with underlying ischaemia (Figures 70.8 and 70.9).

**Clinical features of intussusception**

The classical presentation of intussusception is with episodes of screaming and drawing up of the legs in a previously well male infant. The attacks last for a few minutes and recur repeatedly. During attacks the child appears pale; between episodes he may be listless. Vomiting may or may not occur at the outset but becomes conspicuous and bile-stained with time. Initially, the passage of stool may be normal, whereas, later, blood and mucus are evacuated – the ‘redcurrant jelly’ stool.

Whenever possible, examination should be undertaken between episodes of colic, without disturbing the child. Classically, the abdomen is not initially distended; a lump that hardens on palpation may be discerned but this is present in only 60 per cent of cases (Figure 70.10). There may be an associated feeling of emptiness in the right iliac fossa (the sign of Dance). On rectal examination, blood-stained mucus may be found on the finger. Occasionally, in extensive ileocolic or colocolic

---

Jean Baptiste Hippolyte Dance, 1797–1832, physician, Hôpital Cochin, Paris, France.
intussusception, the apex may be palpable or even protrude from the anus.

Unrelieved, progressive dehydration and abdominal distension from small bowel obstruction will occur, followed by peritonitis secondary to gangrene. Rarely, natural cure may occur as a result of sloughing of the intussusception.

Differential diagnosis

Acute gastroenteritis
Although abdominal pain and vomiting are common in acute gastroenteritis, with occasional blood and mucus in the stool, diarrhoea is a leading symptom and faecal matter or bile is always present in the stool.

Henoch–Schönlein purpura
Henoch–Schönlein purpura is associated with a characteristic rash and abdominal pain; intussusception may occur.

Rectal prolapse
This may be easily differentiated by the fact that the projecting mucosa can be felt in continuity with the perianal skin whereas in intussusception the finger may pass indefinitely into the depths of a sulcus.

Clinical features of volvulus

Volvulus of the small intestine
This may be primary or secondary and usually occurs in the lower ileum. It may occur spontaneously in African people, particularly following the consumption of a large volume of vegetable matter, whereas in the West, it is usually secondary to adhesions passing to the parietes or female pelvic organs.

Caecal volvulus
This may occur as part of volvulus neonatorum or de novo and is usually a clockwise twist. It is more common in females in the fourth and fifth decades and usually presents acutely with the classic features of obstruction. Ischaemia is common. At first the obstruction may be partial, with the passage of flatus and faeces. In 25 per cent of cases, examination may reveal a palpable tympanic swelling in the midline or left side of the abdomen. The volvulus typically results in the caecum lying in the left upper quadrant. The diagnosis is not usually made preoperatively.

Sigmoid volvulus
The symptoms are of large bowel obstruction. Presentation varies in severity and acuteness, with younger patients appearing to develop the more acute form. Abdominal distension is an early and progressive sign, which may be associated with hiccough and retching. Constipation is absolute. In the elderly, a more chronic form may be seen. In some patients, the grossly distended torted left colon is visible through the abdominal wall.
Erect abdominal films are no longer routinely obtained and the radiological diagnosis is based on a supine abdominal film (Figure 70.11). An erect film may subsequently be requested when further doubt exists.

When distended with gas, the jejunum, ileum, caecum and remaining colon have a characteristic appearance in adults and older children that allows them to be distinguished radiologically (Summary box 70.9).

In intestinal obstruction, fluid levels appear later than gas shadows as it takes time for gas and fluid to separate (Figure 70.12). These are most prominent on an erect film. In adults, two inconstant fluid levels – one at the duodenal cap and the other in the terminal ileum – may be regarded as normal. In infants (less than one year old), a few fluid levels in the small bowel may be physiological. In this age group, it is difficult to distinguish large from small bowel in the presence of obstruction, because the characteristic features seen in adults are not present or are unreliable.

During the obstructive process, fluid levels become more conspicuous and more numerous when paralysis has occurred. When fluid levels are pronounced, the obstruction is advanced. In the small bowel, the number of fluid levels is directly proportional to the degree of obstruction and to its site, the number increasing the more distal the lesion.

In patients without evidence of strangulation, there is a role for other imaging modalities. A recent systematic review and meta-analysis of the diagnostic and therapeutic role of 50–100 mL water-soluble contrast agent in adhesive small bowel obstruction included 14 prospective studies. The appearance of contrast in the colon 4–24 hours after administration had a sensitivity of 96 per cent and a specificity of 98 per cent in predicting resolution of small bowel obstruction. If contrast does not reach the colon, surgery is required in about 90 per cent of patients. Administration of a water-soluble agent was also effective in reducing the need for surgery (OR 0.62; \( p = 0.007 \)) and shortening hospital stay.

In contrast, low colonic obstruction does not commonly give rise to small bowel fluid levels unless advanced, whereas high colonic obstruction may do so in the presence of an incompetent ileocaecal valve. Colonic obstruction is usually associated with a large amount of gas in the caecum. A limited water-soluble enema should be undertaken to differentiate large bowel obstruction from pseudo-obstruction. A barium follow-through is contraindicated in the presence of acute obstruction and may be life-threatening.

**Summary box 70.9**

**Radiological features of obstruction (on plain x-ray)**

- The obstructed small bowel is characterised by straight segments that are generally central and lie transversely. No/minimal gas is seen in the colon
- The jejunum is characterised by its valvulae conniventes, which completely pass across the width of the bowel and are regularly spaced, giving a ‘concertina’ or ladder effect
- Ileum – the distal ileum has been piquantly described by Wangensteen as featureless
- Caecum – a distended caecum is shown by a rounded gas shadow in the right iliac fossa
- Large bowel, except for the caecum, shows haustral folds, which, unlike valvulae conniventes, are spaced irregularly, do not cross the whole diameter of the bowel and do not have indentations placed opposite one another

---

Owen Harding Wangensteen, 1898–1981, Professor of Surgery, The University of Minnesota, Minneapolis, MN, USA.
The CT scan is now used very widely to investigate all forms of intestinal obstruction. It is highly accurate and its only limitations are in diagnosing ischaemia. It is important to remember that even with the best imaging techniques, the diagnosis of strangulation remains a clinical one.

Impacted foreign bodies may be seen on abdominal radiographs. It is noteworthy that gas-filled loops and fluid levels in the small and large bowel can also be seen in established paralytic ileus and pseudo-obstruction. The former can, however, normally be distinguished on clinical grounds, whereas the latter can be confirmed radiologically. Fluid levels may also be seen in non-obstructing conditions such as gastroenteritis, acute pancreatitis and intra-abdominal sepsis.

**Imaging in intussusception**

A plain abdominal field usually reveals evidence of small or large bowel obstruction with an absent caecal gas shadow in ileocolic cases. A soft tissue opacity is often visible in children. A barium enema may be used to diagnose the presence of an ileocolic intussusception (the claw sign) (Figure 70.13), but does not demonstrate small bowel intussusception. An abdominal ultrasound scan has a high diagnostic sensitivity in children, demonstrating the typical doughnut appearance of concentric rings in transverse section. CT scan is currently considered the most sensitive radiologic method to confirm intussusception, with a reported diagnostic accuracy of 58–100 per cent. The characteristic features of CT scan include a ‘target’ or ‘sausage’-shaped soft-tissue mass with a layering effect, mesenteric vessels within the bowel lumen are also typical.

**Imaging in volvulus**

- In caecal volvulus, radiological abnormalities are identifiable in nearly all patients, but are often non-specific, with caecal dilatation (98–100 per cent), single air-fluid level (72–88 per cent), small bowel dilatation (42–55 per cent) and absence of gas in distal colon (82 per cent) reported as the most common abnormalities. A barium enema may be used to confirm the diagnosis if there are no concerns about ischaemia, with an absence of barium in the caecum and a bird beak deformity. CT scanning is replacing barium enema as the imaging of choice in these less urgent cases.
- In sigmoid volvulus, a plain radiograph shows massive colonic distension. The classic appearance is of a dilated loop of bowel, the two limbs are seen running diagonally across the abdomen from right to left, with two fluid levels seen, one within each loop of bowel (if an erect film is taken).
- In volvulus neonatorum, the abdominal radiograph shows a variable appearance. Initially, it may appear normal or show evidence of duodenal obstruction but, as the intestinal strangulation progresses, the abdomen becomes relatively gasless.

**Supportive management**

Nasogastric decompression is achieved by the passage of a non-vented (Ryle) or vented (Salem) tube. The tubes are normally placed on free drainage with 4-hourly aspiration, but may be placed on continuous or intermittent suction. As well as facilitating decompression proximal to the obstruction, they are essential to reduce the risk of subsequent aspiration during induction of anaesthesia and post-extubation.
The basic biochemical abnormality in intestinal obstruction is sodium and water loss, and therefore the appropriate replacement is Hartmann’s solution or normal saline. The volume required varies and should be determined by clinical haematological and biochemical criteria.

Antibiotics are not mandatory but many clinicians initiate broad-spectrum antibiotics early in therapy because of bacterial overgrowth. Antibiotic therapy is mandatory for all patients undergoing surgery for intestinal obstruction.

**Surgical treatment**

The timing of surgical intervention is dependent on the clinical picture. There are several indications for early surgical intervention (Summary box 70.12).

The classic clinical advice that ‘the sun should not both rise and set’ on a case of unrelieved acute intestinal obstruction was based on the concern that intestinal ischaemia would develop while the patient was waiting for surgery. If there is complete obstruction, but no evidence of intestinal ischaemia, it is reasonable to defer surgery until the patient has been adequately resuscitated. Where obstruction is likely to be secondary to adhesions, conservative management may be continued for up to 72 hours in the hope of spontaneous resolution.

If the site of obstruction is unknown, adequate exposure is best achieved by a midline incision. Assessment is directed to:

- the site of obstruction;
- the nature of the obstruction;
- the viability of the gut.

In cases of small bowel obstruction, the first manoeuvre is to deliver the distended small bowel into the wound. This permits access to the site of obstruction. The small bowel should be covered with moist swabs and the weight of the fluid-filled bowel supported such that the blood supply to the mesentery is not impaired.

**Operative decompression** should be performed whenever possible. This reduces pressure on the abdominal wall reducing pain and improving diaphragmatic movement. The simplest and safest method is to insert a large bore orogastric tube and to milk the small bowel contents in a retrograde manner to the stomach for aspiration. All volumes of fluid removed should be accurately measured and appropriately replaced. It is important to ensure that the stomach is empty at the end of the procedure to prevent postoperative aspiration.

Rarely, decompression using Savage’s decompressor within a seromuscular purse-string suture may be required. Its benefits should be balanced against the potential risk of septic complications from spillage and the risk of leakage from the suture line postoperatively. The type of surgical procedure required will depend upon the cause of obstruction – division of adhesions (enterolysis), excision, bypass or proximal decompression.

Following relief of obstruction, the viability of the involved bowel should be carefully assessed (Table 70.3). Although frankly infarcted bowel is obvious, the viability status in many cases may be difficult to discern. If in doubt, the bowel should be wrapped in hot packs for 10 minutes with increased oxygenation and then reassessed. The state of the mesenteric vessels and pulsation in adjacent arcades should be sought. Viability is also confirmed by colour, sheen and peristalsis. If at the end of this period, there is still uncertainty about gut viability, the gut should be resected if this does not result in short bowel syndrome. If the patient is septic such that they require inotropic therapy or would require postoperative level 3 intensive care treatment following resection, consideration should be given to raising both ends of the bowel as stomas. This is not only safe, but also allows regular assessment of the bowel.

Intestinal ischaemia/reperfusion injury has been described following reperfusion of ischaemic bowel with remote lung injury resulting from the release of inflammatory mediators. This should be borne in mind when dealing with ischaemic bowel. For example, if there is a volvulus with established infarction, detorsion should be avoided until the affected mesentery has been clamped and thus reperfusion injury prevented. When no resection has been undertaken or there are multiple ischaemic areas (mesenteric vascular occlusion), a second-look laparotomy at 24–48 hours may be required.

Special attention should always be paid to the sites of constriction at each end of an obstructed segment. If of doubtful viability they should be infolded by the use of a seromuscular suture and can also be covered with omentum (Figures 70.14 and 70.15).

The surgical management of massive infarction is dependent on the patient’s overall prognostic criteria. In the elderly, infarction of the small bowel from the duodenojejunal flexure to the right colon may be considered incurable, whereas in the young, with the potential for long-term intravenous alimentation and small bowel transplantation, a policy of excision may be justified.

Whenever the small bowel is resected, the exact site of resection, the length of the resected segment and that of the residual bowel should be recorded.

| Table 70.3 Differentiation between viable and non-viable intestine. |
|-------------------|-------------------|-------------------|
| **Circulation**    | Viable            | Non-viable        |
| Dark colour becomes lighter | Dark colour remains lighter |
| **Visible pulsation in mesenteric arteries** | No detectable pulsation |
| **General appearance** | Shiny             | Dull and lustreless |
| **Intestinal musculature** | Firm              | Flabby, thin and friable |
| **Peristalsis may be observed** | No peristalsis |

Paul Thwaites Savage, formerly surgeon, The Whittington Hospital, London, UK.
As laparoscopic surgery is now so common, it is important to note that small bowel obstruction and strangulation occur in relation to port site hernias. The risk of port site herniation is related to older age, higher body mass, trocar diameter and extension of the port site for tissue extraction. For laparoscopic cholecystectomy, the hernia rate is reported to be around 2 per cent. Obstruction and strangulation have even been reported through 5-mm port sites. Complications from these hernias may present in the early postoperative period and as a Richter’s hernia. They can be easily overlooked and careful examination of port sites in patients with small bowel obstruction is essential.

**Treatment of adhesions**

Initial management is based on intravenous rehydration and nasogastric decompression; occasionally, this treatment is curative. Although an initial conservative regimen is considered appropriate, regular assessment is mandatory to ensure that strangulation does not occur. Conservative treatment should not usually be prolonged beyond 72 hours.

When laparotomy is required, although multiple adhesions may be found, only one may be causative. If there is absolute certainty that this is the cause of the obstruction, this should be divided and the remaining adhesions can be left in situ unless severe angulation is present. Division of these adhesions will only cause further adhesion formation.

When obstruction is caused by an area of multiple adhesions, the adhesions should be freed by sharp dissection from the duodeno-jejunal junction to the caecum. Following the release of band obstruction, the constriction sites that have suffered direct compression should be carefully assessed and, if they show residual colour changes, invaginated with a seromuscular suture (Figure 70.15).

Laparoscopic adhesiolysis may be considered in highly selected cases of small bowel obstruction (Summary box 70.13). This is classed as an advanced laparoscopic procedure and should only be undertaken by surgeons with advanced laparoscopic skills.

**Summary box 70.13**

**Treatment of adhesive obstruction**

- Initially treat conservatively provided there are no signs of strangulation; should rarely continue conservative treatment for longer than 72 hours
- At operation, divide only the causative adhesion(s) and limit dissection
- Repair serosal tears; invaginate (or resect) areas of doubtful viability
- Laparoscopic adhesiolysis in the hands of advanced laparoscopic practitioners
Treatment of recurrent intestinal obstruction caused by adhesions

Several procedures may be considered in the presence of recurrent obstruction including:

- repeat adhesiolysis (enterolysis) alone;
- Noble’s plication operation;
- Charles–Phillips transmesenteric plication;
- intestinal intubation.

The latter three operations are now very rarely performed and can probably be consigned to the history books (they have never been required by the author).

Postoperative intestinal obstruction

Differentiation between persistent paralytic ileus and early mechanical obstruction may be difficult in the early postoperative period. Mechanical obstruction is more likely if the patient has regained bowel function postoperatively which subsequently stops. Obstruction is usually incomplete and the majority settle with continued conservative management. Postoperative intra-abdominal sepsis is a potent cause of postoperative obstruction; CT scanning with oral contrast is of particular value in the assessment of the postoperative abdomen. A water-soluble contrast agent (50–100 mL) by mouth with a delayed plain abdominal x-ray is also of value (see p. 1189).

Treatment of intussusception

In the infant with ileocolic intussusception, after resuscitation with intravenous fluids, broad-spectrum antibiotics and nasogastric drainage, non-operative reduction can be attempted using an air or barium enema (see Chapter 8, Figure 6.17). Successful reduction can only be accepted if there is free reflux of air or barium into the small bowel, together with resolution of symptoms and signs in the patient. Non-operative reduction is contraindicated if there are signs of peritonitis or perforation, there is a known pathological lead point or in the presence of profound shock. In experienced units, more than 70 per cent of intussusceptions can be reduced non-operatively. Strangulated bowel and pathological lead points are unlikely to reduce. Perforation of the colon during pneumatic or hydrostatic reduction is a recognised hazard, but is rare. Recurrent intussusception occurs in up to 10 per cent of patients after non-operative reduction.

Surgery is required when radiological reduction has failed or is contraindicated. After resuscitation, a transverse right-sided abdominal incision provides good access. Reduction is achieved by gently compressing the most distal part of the intussusception toward its origin (Figure 70.16), making sure not to pull. The last part of the reduction is the most difficult (Figure 70.17). After reduction, the terminal part of the small bowel and the appendix will be seen to be bruised and oedematous. The viability of the whole bowel should be checked carefully. An irreducible intussusception or one complicated by infarction or a pathological lead point requires resection and primary anastomosis.

Acute intestinal obstruction of the newborn

Neonatal intestinal obstruction has many potential causes. Congenital atresia and stenosis are the most common. Intestinal malrotation with midgut volvulus, meconium ileus, Hirschsprung’s disease, imperforate anus, necrotising enterocolitis and an incarcerated inguinal hernia may also be responsible. Many of these conditions are discussed in Chapter 8.

Intestinal atresia

Duodenal atresia and stenosis are the most common forms of intestinal obstruction in the newborn (see Chapter 8). Jejunal or ileal atresias are next in frequency, whereas colonic atresia is rare. The possibility of multiple atresias makes intraoperative assessment of the whole small and large bowel mandatory. As with all congenital anomalies, associated malformations are common and should be excluded. There are four main types of jejunal/ileal atresia, ranging from an obstructing membrane with continuity of the bowel wall, through blind-ended segments of bowel separated by a fibrous cord or V-shaped mesenteric defect (including the so-called apple-peel atresia) (Figure 70.18), to multiple atresias (‘string of sausages’). The obstructed proximal bowel is at risk of perforation, which may happen prenatally causing meconium peritonitis in the fetus.

Small bowel atresias present with intestinal obstruction soon after birth. Bilious vomiting is the dominant feature in jejunal atresia, whereas abdominal distension is more prominent with
ileal atresia. A small amount of pale meconium may be passed despite the atresia.

Plain abdominal radiographs show a variable number of dilated loops of bowel and fluid levels according to the level of obstruction. In a stable infant, a contrast enema may be required to clarify the cause of a distal bowel obstruction.

**Surgery**

Duodenal atresia is corrected by a duodenoduodenostomy. In most cases of jejunal/ileal atresia, the distal end of the dilated proximal small bowel is resected and a primary end-to-end anastomosis is possible. If the proximal bowel is extremely dilated it may need to be tapered to the distal bowel before anastomosis. Occasionally, a temporary stoma is required before definitive repair.

**Meconium ileus**

Cystic fibrosis is almost always the underlying cause of this condition. Meconium is normally kept fluid by the action of pancreatic enzymes. In meconium ileus, the terminal ileum becomes filled with thick viscid meconium, resulting in progressive intestinal obstruction. A sterile meconium peritonitis may have occurred in utero.

Visibly dilated loops of bowel are often palpable in the newborn with meconium ileus. An abdominal radiograph may show a dilated small intestine with motting. Fluid levels are generally not seen. Unlike ileal atresia there is no abrupt termination of the gas-filled intestine. A contrast enema shows an unused microcolon. As the condition is caused by an autosomal recessive genetic defect, a family history may not be present. Further assessment includes gene mutation analysis and, beyond the neonatal period, a sweat test, which shows elevated sodium and chloride levels (>70 mmol/L).

Uncomplicated meconium ileus may respond to treatment with a hyperosmolar gastrografin enema. This draws fluid into the gut lumen and also has detergent properties, which help to liquefy the meconium. Infants treated in this way need extra intravenous fluids to compensate for fluid shifts. Meconium ileus complicated by intestinal perforation, volvulus or atresia, or unresponsive to enemas, demands surgery. Various surgical procedures are used including intestinal resection and temporary stoma formation, resection and primary anastomosis, and, in uncomplicated cases, enterotomy and irrigation of the bowel. The Bishop–Koop operation (Figure 70.19) with its irrigating stoma is now only rarely used.

**TREATMENT OF ACUTE LARGE BOWEL OBSTRUCTION**

Large bowel obstruction is usually caused by an underlying carcinoma or occasionally diverticular disease, and presents in an acute or chronic form. The condition of pseudo-obstruction should always be considered and excluded by a limited contrast study or CT scan to confirm organic obstruction.

After full resuscitation, the abdomen should be opened through a midline incision. Care should be taken to ensure that the loss of tamponade of the abdominal wall does not lead to increased caecal distension and rupture (this starts with splitting along the line of the taenia coli on the antimesenteric border). Distension of the caecum will confirm large bowel involvement. Identification of a collapsed distal segment of the large bowel and its sequential proximal assessment will readily lead to identification of the cause. As surgery for malignant bowel cancer is technically challenging, wherever possible a suitably trained surgeon should perform the procedure. When a removable lesion is found in the caecum, ascending colon, hepatic flexure or proximal transverse colon, an emergency right hemicolectomy should be performed. A primary anastomosis is safe if the patient’s general condition is reasonable. If the lesion is irremovable (this is rarely the case), a proximal stoma (colostomy or ileosotomy if the ileocaecal valve is incompetent) or ileotransverse bypass should be considered. Obstructing lesions at the splenic flexure should be treated by an extended right hemicolectomy with ileo-descending colonic anastomosis.
For obstructing lesions of the left colon or rectosigmoid junction, immediate resection should be considered unless there are clear contraindications (Summary box 70.14).

**Summary box 70.14**

**Management of left-sided large bowel obstruction**

Contraindications to immediate resection include:
- Inexperienced surgeon
- Moribund patient
- Advanced disease

In rare instances, or when caecal perforation is imminent, additional time to improve the patient's clinical condition can be bought by performing an emergency caecostomy (or ileostomy in the presence of an incompetent ileocaecal valve).

In the absence of senior clinical staff, it is safest to bring the proximal colon to the surface as a colostomy. When possible, the distal bowel should be brought out at the same time (Paul–Mikulicz procedure) to facilitate subsequent closure. In the majority of cases, the distal bowel will not reach and is closed and returned to the abdomen (Hartmann's procedure). A second-stage colorectal anastomosis can be planned when the patient is fit.

If an anastomosis is to be considered using the proximal colon, in the presence of obstruction, it must be decompressed and cleaned by an on-table colonic lavage.

Decompression of the obstructed left colon using endoscopically placed stents often as a bridge to surgery has been widely reported. However, as yet randomised trials have not shown improved outcomes compared to standard surgical treatment (Figure 70.20).

**Treatment of caecal volvulus**

At operation, the volvulus is usually found to be ischaemic and needs resection. If, viable, the volvulus should be reduced. Sometimes, this can only be achieved after decompression of the caecum using a needle. Further management consists of fixation of the caecum to the right iliac fossa (caecopexy) and/or a caecostomy. Recurrence of volvulus after caecopexy has been reported in up to 40 per cent of cases.

**Treatment of sigmoid volvulus**

Flexible sigmoidoscopy or rigid sigmoideoscopy and insertion of a flatus tube should be carried out to allow deflation of the gut. The tube should be secured in place with tape for 24 hours and a repeat x-ray taken to ensure that decompression has occurred. Successful deflation, as long as ischaemic bowel is excluded, will resolve the acute problem.

In young patients, an elective sigmoid colectomy is required. It is reasonable not to offer any further treatment following successful endoscopic decompression in the elderly as there is a high death rate (~80 per cent at two years) from causes other than recurrent volvulus. In elderly patients with comorbidities and recurrent episodes of volvulus, the options are resection or two point fixation with combined endoscopic/percutaneous tube insertion (gastrostomy tubes are frequently used for this purpose). Failure results in an early laparotomy, with untwisting of the loop and per anum decompression (Figure 70.21). When the bowel is viable, fixation of the sigmoid colon to the posterior abdominal wall may be a safer manoeuvre in inexperienced hands. Resection is preferable if it can be achieved.

![Figure 70.20 X-ray of stent inserted for malignant colonic obstruction.](image)

![Figure 70.21 Volvulus of the sigmoid colon (a) before and (b) after untwisting (courtesy of SU Rahman, Manchester, UK).](image)
safely. A Paul–Mikulicz procedure is useful, particularly if there is suspicion of impending gangrene (Figure 70.22); an alternative procedure is a sigmoid colectomy and, when anastomosis is considered unwise, a Hartmann’s procedure with subsequent reanastomosis can be carried out.

**CHRONIC LARGE BOWEL OBSTRUCTION**

The symptoms of chronic intestinal obstruction may arise from two sources – the cause and the subsequent obstruction.

The causes of obstruction may be organic:

- intraluminal (rare) – faecal impaction;
- intrinsic intramural – strictures (Crohn’s disease, ischaemia, diverticular), anastomotic stenosis;
- extrinsic intramural (rare) – metastatic deposits (ovarian), endometriosis, stomal stenosis;

or functional:

- Hirschsprung’s disease, idiopathic megacolon, pseudo-obstruction.

The symptoms of chronic obstruction differ in their predominance, timing and degree from acute obstruction. In functional cases, the symptoms may have been present for months or years. Constipation appears first. It is initially relative and then absolute, associated with distension. In the presence of large bowel disease, the point of greatest distension is in the caecum, and this is heralded by the onset of pain. Vomiting is a late feature and therefore dehydration is less severe. Examination is unremarkable, save for confirmation of distension (which can be profound) (Figure 70.23) and the onset of peritonism in late cases. Rectal examination may confirm the presence of faecal impaction or a tumour.

**Investigation**

Plain abdominal radiography confirms the presence of large bowel distension. All such cases should be investigated by a subsequent single-contrast water-soluble enema study, CT scan or endoscopic assessment to rule out functional disease (Summary box 70.15).

![Figure 70.22 The Paul–Mikulicz operation applied to volvulus of the pelvic colon.](image1)

![Figure 70.23 Gross functional distension.](image2)

![Figure 70.24 Stomal stenosis causing large bowel obstruction.](image3)

**Summary box 70.15**

**Principles of investigation of possible large bowel obstruction**

- In the presence of large bowel obstruction, a single contrast water-soluble enema or CT should be undertaken to exclude a functional cause

Organic disease requires decompression with either a laparotomy or stent. Stomal stenosis can usually be managed at the abdominal wall level (Figure 70.24). Surgical management after resuscitation depends on the underlying cause and the relevant chapters in this book should be consulted.

Frank Thomas Paul 1851–1941, surgeon, The Royal Infirmary, Liverpool, UK.

Johann von Mikulicz-Radecki 1850–1905, Professor of Surgery, Breslau, Germany (now Wroclaw, Poland).
Functional disease requires colonoscopic decompression in the first instance and conservative management. Intestinal perforation can occur in patients with functional obstruction. Those at risk have such gross distension that the abdomen is rigid on palpation (Figure 70.23).

ADYNAMIC OBSTRUCTION

Paralytic ileus

This may be defined as a state in which there is failure of transmission of peristaltic waves secondary to neuromuscular failure (i.e. in the myenteric (Auerbach’s) and submucous (Meissner’s) plexuses). The resultant stasis leads to accumulation of fluid and gas within the bowel, with associated distension, vomiting, absence of bowel sounds and absolute constipation.

Varieties

The following varieties are recognised:

- **Postoperative**. A degree of ileus usually occurs after any abdominal procedure and is self-limiting, with a variable duration of 24–72 hours. Postoperative ileus may be prolonged in the presence of hypoproteinaemia or metabolic abnormality (see below).
- **Infection**. Intra-abdominal sepsis may give rise to localised or generalised ileus.
- **Reflex ileus**. This may occur following fractures of the spine or ribs, retroperitoneal haemorrhage or even the application of a plaster jacket.
- **Metabolic**. Uraemia and hypokalaemia are the most common contributory factors.

Clinical features

Paralytic ileus takes on a clinical significance if, 72 hours after laparotomy:

- there has been no return of bowel sounds on auscultation;
- there has been no passage of flatus.

Abdominal distension becomes more marked and tympanitic. Colicky pain is not a feature. Distension increases pain from the abdominal wound. In the absence of gastric aspiration, effortless vomiting may occur. Radiologically, the abdomen shows gas-filled loops of intestine with multiple fluid levels (if an erect film is felt necessary).

Management

Nasogastric tubes are not required routinely after elective intra-abdominal surgery. Paralytic ileus is managed with the use of nasogastric suction and restriction of oral intake until bowel sounds and the passage of flatus return. Electrolyte balance must be maintained. The use of an enhanced recovery programme with early introduction of fluids and solids is, however, becoming increasingly popular.

Specific treatment is directed towards the cause, but the following general principles apply:

- If a primary cause is identified, this must be treated.
- Gastrointestinal distension must be relieved by decompression.
- Close attention to fluid and electrolyte balance is essential.
- There is no place for the routine use of peristaltic stimulants. Rarely, in resistant cases, medical therapy with a gastroprokinetic agent, such as domperidone or erythromycin may be used, provided that an intraperitoneal cause has been excluded.

- If paralytic ileus is prolonged, CT scanning is the most effective investigation; it will demonstrate any intra-abdominal sepsis or mechanical obstruction and therefore guide any requirement for laparotomy. Otherwise the decision to take a patient back to theatre in these circumstances is always difficult. The need for a laparotomy becomes increasingly likely the longer the bowel inactivity persists, particularly if it lasts for more than 7 days or if bowel activity recommences following surgery and then stops again.

Pseudo-obstruction

This condition describes an obstruction, usually of the colon, that occurs in the absence of a mechanical cause or acute intra-abdominal disease. It is associated with a variety of syndromes in which there is an underlying neuropathy and/or myopathy and a range of other factors (Summary box 70.16).

Small intestinal pseudo-obstruction

This condition may be primary (i.e. idiopathic or associated with familial visceral myopathy) or secondary. The clinical picture consists of recurrent subacute obstruction. The diagnosis is made by the exclusion of a mechanical cause. Treatment consists of initial correction of any underlying disorder. Metoclopramide and erythromycin may be of use.

Leopold Auerbach, 1828–1897, Professor of Neuropathology, Breslau, Germany (now Wroclaw, Poland), described the myenteric plexus in 1862.

Georg Meissner, 1829–1905, Professor of Physiology, Göttingen, Germany, described the submucous plexus of the alimentary tract in 1852.

Carlos Justiniano Ribeiro Chagas, 1879–1934, Director of The Oswald Cruz Institute, and Professor of Tropical Medicine, The University of Rio de Janeiro, Brazil.

Colonic pseudo-obstruction

This may occur in an acute or a chronic form. The former, also known as Ogilvie’s syndrome, presents as acute large bowel obstruction. Abdominal radiographs show evidence of colonic obstruction, with marked caecal distension being a common feature. Indeed, caecal perforation is a well-recognised complication. The absence of a mechanical cause requires urgent confirmation by colonoscopy or a single-contrast water-soluble barium enema or CT. Once confirmed, pseudo-obstruction requires treatment of any identifiable cause. If this is ineffective, intravenous neostigmine should be given (1 mg intravenously), with a further 1 mg given intravenously within a few minutes if the first dose is ineffective. During this procedure, it is best to sit the patient on a commode. ECG monitoring is required and atropine should be available. If neostigmine is not effective, colonoscopic decompression should be performed. Caecal perforation can occur in pseudo-obstruction. Abdominal examination should pay attention to tenderness and peritonism over the caecum and as with mechanical obstruction, caecal perforation is more likely if the caecal diameter is 14 cm or greater. Surgery is associated with high morbidity and mortality and should be reserved for those with impending perforation when other treatments have failed or perforation has occurred.

Rarely, an endoscopically placed tube colostomy is used as a vent for patients with those with a chronic unremitting condition.

FURTHER READING

INTRODUCTION

The vermiform appendix is considered by most to be a vestigial organ; its importance in surgery results only from its propensity for inflammation, which results in the clinical syndrome known as ‘acute appendicitis’. Acute appendicitis is the most common cause of an ‘acute abdomen’ in young adults and, as such, the associated symptoms and signs have become a paradigm for clinical teaching. Appendicitis is sufficiently common that appendicectomy (termed ‘appendectomy’ in North America) is the most frequently performed urgent abdominal operation and is often the first major procedure performed by a surgeon in training. Advances in modern radiographic imaging have improved diagnostic accuracy, however the diagnosis of appendicitis remains essentially clinical, requiring a mixture of observation, clinical acumen and surgical science and as such it remains an enigmatic challenge and a reminder of the art of surgical diagnosis.

ANATOMY

The vermiform appendix is present only in humans, certain anthropoid apes and the wombat. It is a blind muscular tube with mucosal, submucosal, muscular and serosal layers. Morphologically, it is the undeveloped distal end of the large caecum found in many lower animals. At birth, the appendix is short and broad at its junction with the caecum, but differential growth of the caecum produces the typical tubular structure by about the age of two years (Condon). During childhood, continued growth of the caecum commonly rotates the appendix into a retrocaecal but intraperitoneal position (Figure 71.1). In approximately one quarter of cases, rotation of the appendix does not occur, resulting in a pelvic, subcaecal or paracaecal position. Occasionally, the tip of the appendix becomes extraperitoneal, lying behind the caecum or ascending colon. Rarely, the caecum does not migrate during development to its normal position in the right lower quadrant of the abdomen. In these circumstances, the appendix can be found near the gall bladder or, in the case of intestinal malrotation, in the left iliac fossa, causing diagnostic difficulty if appendicitis develops (Figure 71.2).

The position of the base of the appendix is constant, being found at the confluence of the three taeniae coli of the caecum, which fuse to form the outer longitudinal muscle coat of the appendix. At operation, use can be made of this to find an elusive appendix, as gentle traction on the taeniae coli, particularly the anterior taenia, will lead the operator to the base of the appendix.

The mesentery of the appendix or mesoappendix arises from the lower surface of the mesentery or the terminal ileum and is itself subject to great variation. Sometimes, as much as the...
distal one-third of the appendix is bereft of mesoappendix. Especially in childhood, the mesoappendix is so transparent that the contained blood vessels can be seen (Figure 71.3). In many adults, it becomes laden with fat, which obscures these vessels. The appendicular artery, a branch of the lower division of the ileocolic artery, passes behind the terminal ileum to enter the mesoappendix a short distance from the base of the appendix. It then comes to lie in the free border of the mesoappendix. An accessory appendicular artery may be present but, in most people, the appendicular artery is an 'end-artery', thrombosis of which results in necrosis of the appendix (synonym: gangrenous appendicitis). Four, six or more lymphatic channels traverse the mesoappendix to empty into the ileocaecal lymph nodes.

**Microscopic anatomy**

The appendix varies considerably in length and circumference. The average length is between 7.5 and 10 cm. The lumen is irregular, being encroached upon by multiple longitudinal folds of mucous membrane lined by columnar cell intestinal mucosa of colonic type (Figure 71.4). Crypts are present, but are not numerous. In the base of the crypts lie argentaffin cells (Kulchitsky cells), which may give rise to carcinoid tumours (see below under Carcinoid tumours). The appendix is the most frequent site for carcinoid tumours, which may present with appendicitis due to occlusion of the appendiceal lumen. The submucosa contains numerous lymphatic aggregations or follicles. While no discernible change in immune function results from appendicectomy, the prominence of lymphatic tissue in the appendix of young adults seems to be important in the aetiology of appendicitis (see below under Aetiology).

**ACUTE APPENDICITIS**

While there are isolated reports of perityphlitis (fatal inflammation of the caecal region) from the late 1500s, recognition of acute appendicitis as a clinical entity is attributed to Reginald Fitz, who presented a paper to the first meeting of the Association of American Physicians in 1886 entitled 'Perforating inflammation of the vermiform appendix'. Soon afterwards, Charles McBurney described the clinical manifestations of acute appendicitis including the point of maximum tenderness in the right iliac fossa that now bears his name. The incidence of appendicitis seems to have risen greatly in the first half of the twentieth century, particularly in Europe, America and Australasia, with up to 16 per cent of the population undergoing appendicectomy. In the past 30 years, the

---

**Nicolai Kulchitsky**, 1856–1925, Professor of Histology, Krakow, Ukraine, who left Russia after the revolution of 1917, and later worked at University College, London. He described these cells in 1897.
Acute appendicitis is relatively rare in infants, and becomes increasingly common in childhood and early adult life, reaching a peak incidence in the teens and early 20s. After middle age, the risk of developing appendicitis is quite small. The incidence of appendicitis is equal among males and females before puberty. In teenagers and young adults, the male–female ratio increases to 3:2 at age 25; thereafter, the greater incidence in males declines.

**Aetiology**

There is no unifying hypothesis regarding the aetiology of acute appendicitis. Decreased dietary fibre and increased consumption of refined carbohydrates may be important. As with colonic diverticulitis, the incidence of appendicitis is lowest in societies with a high dietary fibre intake. In developing countries that are adopting a more refined western-type diet, the incidence continues to rise. This is in contrast to the dramatic decrease in the incidence of appendicitis in western countries observed in the past 30 years. No reason has been established for these paradoxical changes; however, improved hygiene and a change in the pattern of childhood gastrointestinal infection related to the increased use of antibiotics may be responsible.

While appendicitis is clearly associated with bacterial proliferation within the appendix, no single organism is responsible. A mixed growth of aerobic and anaerobic organisms is usual. The initiating event causing bacterial proliferation is controversial. Obstruction of the appendix lumen has been widely held to be important, and some form of luminal obstruction, either by a faecolith or a stricture, is found in the majority of cases.

A faecolith (sometimes referred to as an ‘appendicolith’) is composed of inspissated faecal material, calcium phosphates, bacteria and epithelial debris (Figure 71.5). Rarely, a foreign body is incorporated into the mass. The incidental finding of a faecolith is a relative indication for prophylactic appendicectomy or an interval appendicectomy in a patient treated conservatively (see below) (Figure 71.6). A fibrotic stricture of the appendix usually indicates previous appendicitis that resolved without surgical intervention (Figure 71.7). Obstruction of the appendiceal orifice by tumour, particularly carcinoma of the caecum, is an occasional cause of acute appendicitis in middle-aged and elderly patients. Intestinal parasites, particularly Oxyuris vermicularis (pinworm), can proliferate in the appendix and occlude the lumen.

**Pathology**

Obstruction of the appendiceal lumen seems to be essential for the development of appendiceal gangrene and perforation. Yet, in many cases of early appendicitis, the appendix lumen is patent despite the presence of mucosal inflammation and lymphoid hyperplasia. Occasional clustering of cases among children and young adults suggests an infective agent, possibly viral, which initiates an inflammatory response. Seasonal variation in the incidence is also observed, with more cases occurring between May and August in Northern Europe than at other times of the year.
Lymphoid hyperplasia narrows the lumen of the appendix, leading to luminal obstruction. Once obstruction occurs, continued mucus secretion and inflammatory exudation increase intraluminal pressure, obstructing lymphatic drainage. Oedema and mucosal ulceration develop with bacterial translocation to the submucosa. Resolution may occur at this point either spontaneously or in response to antibiotic therapy. If the condition progresses, further distension of the appendix may cause venous obstruction and ischaemia of the appendix wall. With ischaemia, bacterial invasion occurs through the muscularis propria and submucosa, producing acute appendicitis (Figure 71.8). Finally, ischaemic necrosis of the appendix wall produces gangrenous appendicitis, with free bacterial contamination of the peritoneal cavity. Alternatively, the greater omentum and loops of small bowel become adherent to the inflamed appendix, walling off the spread of peritoneal contamination, and resulting in a phlegmonous mass or para-caecal abscess. Rarely, appendiceal inflammation resolves, leaving a distended mucus-filled organ termed a ‘mucocoele’ of the appendix (Figure 71.9).

It is the potential for diffuse peritonitis that is the great threat of acute appendicitis. Peritonitis occurs as a result of free migration of bacteria through an ischaemic appendicular wall, frank perforation of a gangrenous appendix or delayed perforation of an appendix abscess. Factors that promote this process include extremes of age, immunosuppression, diabetes mellitus and faecolith obstruction of the appendix lumen, a free-lying pelvic appendix and previous abdominal surgery that limits the ability of the greater omentum to wall off the spread of peritoneal contamination. In these situations, a rapidly deteriorating clinical course is accompanied by signs of diffuse peritonitis and systemic sepsis syndrome (Summary box 71.1).

**Clinical diagnosis**

**History**

The classical features of acute appendicitis begin with poorly localised colicky abdominal pain. This is due to midgut visceral
discomfort in response to appendical inflammation and obstruction. The pain is frequently first noticed in the periumbilical region and is similar to, but less intense than, the colic of small bowel obstruction. Central abdominal pain is associated with anorexia, nausea and usually one or two episodes of vomiting that follow the onset of pain (Murphy). Anorexia is a useful and constant clinical feature, particularly in children. The patient often gives a history of similar discomfort that settled spontaneously. A family history is also useful as up to one-third of children with appendicitis have a first-degree relative with a similar history (Summary box 71.2).

### Summary box 71.2

**Symptoms of appendicitis**
- Periumbilical colic
- Pain shifting to the right iliac fossa
- Anorexia
- Nausea

With progressive inflammation of the appendix, the parietal peritoneum in the right iliac fossa becomes irritated, producing more intense, constant and localised somatic pain that begins to predominate. Patients often report this as an abdominal pain that has shifted and changed in character. Typically, coughing or sudden movement exacerbates the right iliac fossa pain.

The classic visceral–somatic sequence of pain is present in only about half of those patients subsequently proven to have acute appendicitis. Atypical presentations include pain that is predominantly somatic or visceral and poorly localised. Atypical pain is more common in the elderly, in whom localisation to the right iliac fossa is unusual. An inflamed appendix in the pelvis may never produce somatic pain involving the anterior abdominal wall, but may instead cause suprapubic discomfort and tenesmus. In this circumstance, tenderness may be elicited only on rectal examination and is the basis for the recommendation that a rectal examination should be performed on every patient who presents with acute lower abdominal pain.

During the first 6 hours, there is rarely any alteration in temperature or pulse rate. After that time, slight pyrexia (37.2–37.7°C) with a corresponding increase in the pulse rate to 80 or 90 is usual. However, in 20 per cent of patients, there is no pyrexia or tachycardia in the early stages. In children, a temperature greater than 38.5°C suggests other causes, e.g. mesenteric adenitis (see below under Children).

Typically, two clinical syndromes of acute appendicitis can be discerned, acute catarrhal (non-obstructive) appendicitis and acute obstructive appendicitis, the latter characterised by a more acute course. The onset of symptoms is abrupt, and there may be generalised abdominal pain from the start. The temperature may be normal and vomiting is common, so that the clinical picture may mimic acute intestinal obstruction.

### Signs

The diagnosis of appendicitis rests more on thorough clinical examination of the abdomen than on any aspect of the history or laboratory investigation. The cardinal features are those of an unwell patient with low-grade pyrexia, localised abdominal tenderness, muscle guarding and rebound tenderness. Inspection of the abdomen may show limitation of respiratory movement in the lower abdomen. The patient is then asked to point to where the pain began and where it moved (the pointing sign). Gentle superficial palpation of the abdomen, beginning in the left iliac fossa moving anticlockwise to the right iliac fossa will detect muscle guarding over the point of maximum tenderness, classically McBurney’s point. Asking the patient to cough or gentle percussion over the site of maximum tenderness will elicit rebound tenderness (Summary box 71.3).

### Summary box 71.3

**Clinical signs in appendicitis**
- Pyrexia
- Localised tenderness in the right iliac fossa
- Muscle guarding
- Rebound tenderness

Deep palpation of the left iliac fossa may cause pain in the right iliac fossa, Rovsing’s sign, which is helpful in supporting a clinical diagnosis of appendicitis. Occasionally, an inflamed appendix lies on the psoas muscle, and the patient, often a young adult, will lie with the right hip flexed for pain relief (the psoas sign). Spasm of the obturator internus is sometimes demonstrable when the hip is flexed and internally rotated. If an inflamed appendix is in contact with the obturator internus, this manoeuvre will cause pain in the hypogastrium (the obturator test; Zachary Cope). Cutaneous hyperaesthesia may be demonstrable in the right iliac fossa, but is rarely of diagnostic value (Summary box 71.4).

### Summary box 71.4

**Signs to elicit in appendicitis**
- Pointing sign
- Rovsing’s sign
- Psoas sign
- Obturator sign

Charles McBurney, 1854–1913, Professor of Surgery, Columbia College of Physicians and Surgeons, New York, NY, USA. In 1889, McBurney published a paper on appendicitis in which he stated ‘I believe in every case the seat of greatest pain determined by the pressure of one finger has been very exactly between an inch and a half and two inches from the anterior spinous process of the ilium on a straight line drawn from that process to the umbilicus.’

Sir Vincent Zachary Cope, 1881–1975, surgeon, St Mary’s Hospital, London, UK. He was a poet who wrote a poetry book under a pseudonym ‘Zeta’ describing the acute abdomen: ‘The Acute Abdomen in Rhyme’. He described the differential diagnosis of acute appendicitis as:

- Distension, rigidity, vomiting, pain,
- Are actors abdominal which often deign
- To act on behalf of the chest, spine or brain,
- Or general ills of which typhoid’s the main.

[John Benjamin Murphy, 1857–1916, Professor of Surgery, Northwestern University, Chicago, IL, USA, described his sign in 1903. In 1896, he was the first person to successfully suture a severed femoral artery; in 1898, he was the first person to successfully perform an operation to drain a pneumothorax for pulmonary tuberculosis and pioneered bone grafting techniques. William Mayo said of him, ‘the surgical genius of our generation.’]

[Thorkild Rosing, 1862–1937, Professor of Surgery, Copenhagen, Denmark.]
Special features, according to position of the appendix

Retrocaecal

Rigidity is often absent, and even application of deep pressure may fail to elicit tenderness (silent appendix), the reason being that the caecum, distended with gas, prevents the pressure exerted by the hand from reaching the inflamed structure. However, deep tenderness is often present in the loin, and rigidity of the quadratus lumborum may be in evidence. Psoas spasm, due to the inflamed appendix being in contact with that muscle, may be sufficient to cause flexion of the hip joint. Hyperextension of the hip joint may induce abdominal pain when the degree of psoas spasm is insufficient to cause flexion of the hip.

Pelvic

Occasionally, early diarrhoea results from an inflamed appendix being in contact with the rectum. When the appendix lies entirely within the pelvis, there is usually complete absence of abdominal rigidity, and often tenderness over McBurney’s point is also lacking. In some instances, deep tenderness can be made out just above and to the right of the symphysis pubis. In either event, a rectal examination reveals tenderness in the rectovesical pouch or the pouch of Douglas, especially on the right side. Spasm of the psoas and obturator internus muscles may be present when the appendix is in this position. An inflamed appendix in contact with the bladder may cause frequency of micturition. This is more common in children.

Postileal

In this case, the inflamed appendix lies behind the terminal ileum. It presents the greatest difficulty in diagnosis because the pain may not shift, diarrhoea is a feature and marked retching may occur. Tenderness, if any, is ill defined, although it may be present immediately to the right of the umbilicus.

Special features, according to age

Infants

Appendicitis is relatively rare in infants under 36 months of age and, for obvious reasons, the patient is unable to give a history. Because of this, diagnosis is often delayed, and thus the incidence of perforation and postoperative morbidity is considerably higher than in older children. Diffuse peritonitis can develop rapidly because of the underdeveloped greater omentum, which is unable to give much assistance in localising the infection.

Children

It is rare to find a child with appendicitis who has not vomited. Children with appendicitis usually have complete aversion to food.

The elderly

Gangrene and perforation occur much more frequently in elderly patients. Elderly patients with lax abdominal walls or obesity may harbour a gangrenous appendix with little evidence of it, and the clinical picture may simulate subacute intestinal obstruction. These features, coupled with coincident medical conditions, produce a much higher mortality for acute appendicitis in the elderly.

The obese

Obesity can obscure and diminish all the local signs of acute appendicitis. Delay in diagnosis, coupled with the technical difficulty of operating in the obese, makes it wiser to consider operating through a midline abdominal incision. Laparoscopy is particularly useful in the obese as it may obviate the need for a large abdominal incision.

Pregnancy

Appendicitis is the most common extrauterine acute abdominal condition in pregnancy, with a frequency of 1:1500–2000 pregnancies. Diagnosis is complicated by delay in presentation as early non-specific symptoms are often attributed to the pregnancy. Obstetric teaching has been that the caecum and appendix are progressively pushed to the right upper quadrant of the abdomen as pregnancy develops during the second and third trimesters. However, pain in the right lower quadrant of the abdomen remains the cardinal feature of appendicitis in pregnancy. Fetal loss occurs in 3–5 per cent of cases, increasing to 20 per cent if perforation is found at operation.

Differential diagnosis

Although acute appendicitis is the most common abdominal surgical emergency, the diagnosis can be extremely difficult at times. There are a number of common conditions that it is wise to consider carefully and, if possible, exclude. The differential diagnosis differs in patients of different ages; in women, additional differential diagnoses are diseases of the female genital tract (Table 71.1).

Children

The diseases most commonly mistaken for acute appendicitis are acute gastroenteritis and mesenteric lymphadenitis. In mesenteric lymphadenitis, the pain is colicky in nature and cervical lymph nodes may be enlarged. It may be impossible to clinically distinguish Meckel’s diverticulitis from acute appendicitis. The pain is similar; however, signs may be central or left sided. Occasionally, there is a history of antecedent abdominal pain or intermittent lower gastrointestinal bleeding.

It is important to distinguish between acute appendicitis and intussusception. Appendicitis is uncommon before the age of two years, whereas the median age for intussusception is 18 months. A mass may be palpable in the right lower quadrant, and the preferred treatment of intussusception is reduction by careful barium enema.

Henoch–Schönlein purpura is often preceded by a sore throat or respiratory infection. Abdominal pain can be severe and can be confused with intussusception or appendicitis. There is nearly always an ecchymotic rash, typically affecting the extensor surfaces of the limbs and on the buttocks. The face is usually spared. The platelet count and bleeding time are within normal limits. Microscopic haematuria is common.

Lobar pneumonia and pleurisy, especially at the right base, may give rise to right-sided abdominal pain and mimic appendicitis. Abdominal tenderness is minimal, pyrexia is marked,
and chest examination may reveal a pleural friction rub or altered breath sounds on auscultation. A chest radiograph is diagnostic.

**Adults**

Terminal ileitis in its acute form may be indistinguishable from acute appendicitis unless a doughy mass of inflamed ileum can be felt. An antecedent history of abdominal cramping, weight loss and diarrhoea suggests regional ileitis rather than appendicitis. The ileitis may be non-specific, due to Crohn's disease or *Yersinia* infection. *Yersinia enterocolitica* causes inflammation of the terminal ileum, appendix and caecum with mesenteric adenopathy. If suspected, serum antibody titres are diagnostic, and treatment with intravenous tetracycline is appropriate. If *Yersinia* infection is suspected at operation, a mesenteric lymph node should be excised and divided, with half submitted for microbiological culture (including tuberculosis) and half for histological examination.

Ureteric colic does not commonly cause diagnostic difficulty, as the character and radiation of pain differs from that of appendicitis. Urinalysis should always be performed, and the presence of red cells should prompt a supine abdominal radiograph. Renal ultrasound or intravenous urogram is diagnostic.

Right-sided acute pancreatitis is accompanied and often preceded by increased frequency of micturition. It may cause difficulty in diagnosis, especially in women. The leading features are tenderness confined to the loin, fever (temperature 39°C) and possibly rigors and pyuria.

In perforated peptic ulcer, the duodenal contents pass along the paracolic gutter to the right iliac fossa. As a rule, there is a history of dyspepsia and a very sudden onset of pain that starts in the epigastrium and passes down the right paracolic gutter. In appendicitis, the pain starts classically in the umbilical region. Rigidity and tenderness in the right iliac fossa are present in both conditions but, in perforated duodenal ulcer, the rigidity is usually greater in the right hypochondrium. An erect chest radiograph will show gas under the diaphragm in 70 per cent of patients. An abdominal computed tomography (CT) examination is valuable when there is diagnostic difficulty.

Testicular torsion in a teenage or young adult male is easily missed. Pain can be referred to the right iliac fossa, and shyness on the part of the patient may lead the unwary to suspect appendicitis unless the scrotum is examined in all cases.

Acute pancreatitis should be considered in the differential diagnosis of all adults suspected of having acute appendicitis and, when appropriate, should be excluded by serum or urinary amylase measurement.

Rectus sheath haematoma is a relatively rare but easily missed differential diagnosis. It usually presents with acute pain and localised tenderness in the right iliac fossa, often after an episode of strenuous physical exercise. Localised pain without gastrointestinal upset is the rule. Occasionally, in an elderly patient, particularly one taking anticoagulant therapy, a rectus sheath haematoma may present as a mass and tenderness in the right iliac fossa after minor trauma.

**Adult female**

It is in women of childbearing age that pelvic disease most often mimics acute appendicitis. A careful gynaecological history should be taken in all women with suspected appendicitis, concentrating on menstrual cycle, vaginal discharge and possible pregnancy (see also Chapter 80). The most common diagnostic mimics are pelvic inflammatory disease (PID), Mittelschmerz, torsion or haemorrhage of an ovarian cyst and ectopic pregnancy.

**Pelvic inflammatory disease**

PID comprises a spectrum of diseases that include salpingitis, endometritis and tubo-ovarian sepsis. The incidence of these conditions is increasing and the diagnosis should be considered in every young adult female. Typically, the pain is lower than in appendicitis and is bilateral. A history of vaginal discharge, dysmenorrhoea and burning pain on micturition is a helpful differential diagnostic point. The physical findings include adnexal and cervical tenderness on vaginal examination. When suspected, a high vaginal swab should be taken for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* culture, and the opinion of a gynaecologist should be obtained. Treatment is usually a combination of ofloxacin and metronidazole for 14 days. Transvaginal ultrasound can be particularly helpful in establishing the diagnosis. When serious diagnostic uncertainty persists, diagnostic laparoscopy should be undertaken.

**Mittelschmerz**

Midcycle rupture of a follicular cyst with bleeding produces lower abdominal and pelvic pain, typically midcycle. Systemic upset is rare, a pregnancy test is negative, and symptoms usu-

ally subside within hours. Occasionally, diagnostic laparoscopy is required. Retrograde menstruation may cause similar symptoms.

**Torsion/haemorrhage of an ovarian cyst**

This can prove a difficult differential diagnosis. When suspected, pelvic ultrasound and a gynaecological opinion should be sought. If encountered at operation in women of childbearing years, untwisting of the involved adnexa and ovarian cystectomy should be performed, if necessary. Documented visualisation of the contralateral ovary is an essential medicolegal precaution prior to oophorectomy for any reason.

**Ectopic pregnancy**

It is unlikely that a ruptured ectopic pregnancy, with its well-defined signs of haemoperitoneum, will be mistaken for acute appendicitis, but the same cannot be said for a right-sided tubal abortion, or still more for a right-sided unruptured tubal pregnancy. In the latter, the signs are very similar to those of acute appendicitis, except that the pain commences on the right side and stays there. The pain is severe and continues unabated until operation. Usually, there is a history of a missed menstrual period, and a urinary pregnancy test may be positive. Severe pain is felt when the cervix is moved on vaginal examination. Signs of intraperitoneal bleeding usually become apparent, and the patient should be questioned specifically regarding referred pain in the shoulder. Pelvic ultrasonography should be carried out in all cases in which an ectopic pregnancy is a possible diagnosis.

**Elderly**

**Diverticulitis**

In some patients with a long sigmoid loop, the colon lies to the right of the midline, and it may be impossible to differentiate between diverticulitis and appendicitis. Abdominal CT scanning is particularly useful in this setting and should be considered in the management of all patients over the age of 60 years. A trial of conservative management with intravenous fluids and antibiotics is often appropriate, with a low threshold for laparoscopy or exploratory laparotomy in the face of deterioration or lack of clinical response. Right-sided diverticulitis is unusual and may be clinically indistinguishable from appendicitis. Abdominal CT scanning is particularly useful in making the distinction. As with left-sided diverticulitis, treatment should be conservative with intravenous antibiotics with recourse to laparoscopy or laparotomy in the face of deterioration.

**Intestinal obstruction**

The diagnosis of intestinal obstruction is usually clear; the subtlety lies in recognising acute appendicitis as the occasional cause in the elderly. As with diverticulitis, intravenous fluids, antibiotics and nasogastric decompression should be instigated, with early resort to laparotomy.

**Carcinoma of the caecum**

When obstructed or locally perforated, carcinoma of the caecum may mimic or cause obstructive appendicitis in adults. A history of antecedent discomfort, altered bowel habit or unexplained anaemia should raise suspicion. A mass may be palpable (see below under Carcinoid tumour) and an abdominal CT scan diagnostic.

**Rare differential diagnoses**

Preherpetic pain of the right 10th and 11th dorsal nerves is localised over the same area as that of appendicitis. It does not shift and is associated with marked hyperaesthesia. There is no intestinal upset or rigidity. The herpetic eruption may be delayed for 3–8 hours.

**Tabetic crises** are now rare. Severe abdominal pain and vomiting usher in the crisis. Other signs of tabes confirm the diagnosis.

**Spinal conditions** are sometimes associated with acute abdominal pain especially in children and the elderly. These may include tuberculosis of the spine, metastatic carcinoma, osteoporotic vertebral collapse and multiple myeloma. The pain is due to compression of nerve roots and may be aggravated by movement. There is rigidity of the lumbar spine and intestinal symptoms are absent.

The abdominal crises of **porphyria** and **diabetes mellitus** need to be remembered. A urinalysis should be undertaken in every abdominal emergency. In cyclical vomiting of infants or young children, there is a history of previous similar attacks and abdominal rigidity is absent. Acetone is found in the urine but is not diagnostic as it may accompany starvation.

**Typhilitis** or leukaemic ileocaecal syndrome is a rare but potentially fatal enterocolitis occurring in immunosuppressed patients. Gram-negative or **clostridial septicaemia** (especially **Clostridium septicum**) can be rapidly progressive. Treatment is with appropriate antibiotics and haematopoietic factors. Surgical intervention is rarely indicated.

**Investigation**

The diagnosis of acute appendicitis is essentially clinical; however, a decision to operate based on clinical suspicion alone can lead to the removal of a normal appendix in 15–30 per cent of cases. The premise that it is better to remove a normal appendix than to delay diagnosis does not stand up to close scrutiny, particularly in the elderly. A number of clinical and laboratory-based scoring systems have been devised to assist diagnosis. The most widely used is the Alvarado score (Table 71.2). A score of 7 or more is strongly predictive of acute appendicitis.

In patients with an equivocal score (5–6), abdominal ultrasound or contrast-enhanced CT examination further reduces the rate of negative appendicectomy. Abdominal ultrasound examination is more useful in children and thin adults, particularly if gynaecological pathology is suspected, with a diagnostic accuracy in excess of 90 per cent (Figure 71.10). Contrast-enhanced CT scan (Figure 71.11) is most useful in patients in whom there is diagnostic uncertainty, particularly older patients, in whom acute diverticulitis, intestinal obstruction and neoplasm are likely differential diagnoses. Selective use of CT scanning may be cost-effective by reducing both the negative appendicectomy rate and the length of hospital stay (Summary box 71.5).

**Treatment**

The traditional treatment for acute appendicitis is appendicectomy. While this remains standard teaching, there is an

---

Alfredo Alvarado, trained in medicine in Bogota, Columbia, contemporary, surgeon, Plantation, FL, USA, described his scoring system in 1986.
emerging body of literature to support a trial of conservative management in those thought not to have obstructive appendicitis. Treatment is bowel rest and intravenous antibiotics, usually metronidazole and third-generation cephalosporin. The available data indicate successful outcomes in 80–90 per cent of patients, however there is an approximately 15 per cent recurrence rate within one year. This approach should be considered in patients with high operative risk (multiple comorbidities). As with conservative treatment of an appendix mass, patients over the age of 40 should be followed up to ensure there is no underlying malignancy (see below under Management of an appendix mass).

With regard to appendicectomy, there is a perception that emergency, often out of hours, operation is essential to prevent the increased morbidity and mortality of peritonitis. While there should be no unnecessary delay, all patients, particularly those most at risk of serious morbidity, benefit by a short period of intensive preoperative preparation. Intravenous fluids, sufficient to establish adequate urine output (catheterisation is needed only in the very ill), and appropriate antibiotics should be given. There is ample evidence that in the absence of purulent peritonitis, a single preoperative dose of antibiotics reduces the incidence of postoperative wound infection. When peritonitis is suspected, therapeutic intravenous antibiotics to cover Gram-negative bacilli, as well as anaerobic cocci, should be given. Hyperpyrexia in children should be treated with salicylates in addition to antibiotics and intravenous fluids. With appropriate use of intravenous fluids and parenteral antibiotics, a policy of deferring appendicectomy after midnight to the first case on the following morning does not increase morbidity. However, when acute obstructive appendicitis is recognised, operation should not be deferred longer than it takes to optimise the patient’s condition.

Appendicectomy
Claudius Amyand successfully removed an acutely inflamed appendix from the hernial sac of a boy in 1736. The first surgeon to perform deliberate appendicectomy for acute appendicitis was Lawson Tait in May 1880. The patient recovered; however, the case was not reported until 1890. Meanwhile, Thomas Morton was the first to diagnose appendicitis, drain the abscess and remove the appendix with recovery, publishing his findings in 1887.

Claudius Amyand, 1685–1740, surgeon, St George’s Hospital, London, UK.

RIF, right iliac fossa.

Figure 71.10 Abdominal ultrasound examination showing features of acute appendicitis, distended oedematous appendix (open arrows), longitudinal scan (left) and transverse scan (right). A faecolith is seen (closed arrow) (courtesy of Dr M Behan, FRCR, Dublin, Ireland).

Figure 71.11 Abdominal contrast-enhanced computed tomography scan showing a faecolith (open arrow) at the base of a distended (>0.6 cm) appendix with intramural gas (white arrows) (courtesy of Professor H Fenlon, FRCR, Dublin, Ireland).
Appendicectomy should be performed under general anaesthetic with the patient supine on the operating table. When a laparoscopic technique is to be used, the bladder must be empty (ensure that the patient has voided before leaving the ward). Prior to preparing the entire abdomen with an appropriate antiseptic solution, the right iliac fossa should be palpated for a mass. If a mass is felt, it may, on occasion, be preferable to adopt a conservative approach (see below under Management of an appendix mass). Draping of the abdomen is in accordance with the planned operative technique, taking account of any requirement to extend the incision or convert a laparoscopic technique to an open operation.

**Conventional appendicectomy**

When the preoperative diagnosis is considered reasonably certain, the incision that is widely used for appendicectomy is the so-called gridiron incision *(gridiron*: a frame of cross-beams to support a ship during repairs). The gridiron incision (described first by McArthur) is made at right angles to a line joining the anterior superior iliac spine to the umbilicus, its centre being along the line at McBurney’s point (Figure 71.12). If better access is required, it is possible to convert the gridiron to a Rutherford Morison incision (see below) by cutting the internal oblique and transversus muscles in the line of the incision.

In recent years, a transverse skin crease (Lanz) incision has become more popular, as the exposure is better and extension, when needed, is easier. The incision, appropriate in length to the size and obesity of the patient, is made approximately 2 cm below the umbilicus centred on the midclavicular–midinguinal line (Figure 71.13). When necessary, the incision may be extended medially, with retraction or suitable division of the rectus abdominis muscle.

When the diagnosis is in doubt, particularly in the presence of intestinal obstruction, a lower midline abdominal incision is to be preferred over a right lower paramedian incision. The latter, although widely practised in the past, is difficult to extend, more difficult to close and provides poorer access to the pelvis and peritoneal cavity.

Rutherford Morison’s incision is useful if the appendix is para- or retrocaecal and fixed. It is essentially an oblique muscle-cutting incision with its lower end over McBurney’s point and extending obliquely upwards and laterally as necessary. All layers are divided in the line of the incision.

**Removal of the appendix**

The caecum is identified by the presence of taeniae coli and, using a finger or a swab, the caecum is withdrawn. A turgid appendix may be felt at the base of the caecum. Inflammatory adhesions must be gently broken with a finger, which is then hooked around the appendix to deliver it into the wound. The appendix is conveniently controlled using a Babcock or Lane’s forceps applied in such a way as to encircle the appendix and yet not damage it. The base of the mesoappendix is clamped in artery forceps, divided and ligated (Figure 71.14a). When the mesoappendix is broad, the procedure must be repeated with a second or, rarely, a third artery forceps. The appendix, now completely freed, is crushed near its junction with the caecum in artery forceps, which is removed and reapplied just distal to the crushed portion. An absorbable 2/0 ligature is tied around the crushed portion close to the caecum. The appendix is amputated between the artery forceps and the ligature (Figure 71.14b). An absorbable 2/0 or 3/0 purse-string or ‘Z’ suture may then be inserted into the caecum about 1.25 cm from the base (Figure 71.14c). The stitch should pass through the muscle

Robert Lawson Tait, 1845–1899, surgeon, The Hospital for Diseases of Women, Birmingham, UK.

Thomas George Morton, 1835–1903, surgeon, Philadelphia, PA, USA.

James Rutherford Morison, 1853–1939, Professor of Surgery, The University of Durham, Durham, UK.

Sir William Arbuthnot Lane, 1855–1943, surgeon, Guy’s Hospital, London, UK.
coat, picking up the taeniae coli. The stump of the appendix is invaginated (Figure 71.14d) while the purse-string or ‘Z’ suture is tied, thus burying the appendix stump. Many surgeons believe invagination of the appendiceal stump is unnecessary.

**Methods to be adopted in special circumstances**

When the caecal wall is oedematous, the purse-string suture is in danger of cutting out. If the oedema is of limited extent, this can be overcome by inserting the purse-string suture into more healthy caecal wall at a greater distance from the base of the appendix. Occasions may arise when, because of the extensive oedema of the caecal wall, it is better not to attempt invagination.

When the base of the appendix is inflamed, it should not be crushed, but ligated close to the caecal wall just tightly enough to occlude the lumen, after which the appendix is amputated and the stump invaginated. Should the base of the appendix be gangrenous, neither crushing nor ligation should be attempted. Two stitches are placed through the caecal wall close to the base of the gangrenous appendix, which is amputated flush with the caecal wall, after which these stitches are tied. Further closure is effected by means of a second layer of interrupted seromuscular sutures.

**Retrograde appendicectomy**

When the appendix is retrocaecal and adherent, it is an advantage to divide the base between artery forceps. The appendiceal vessels are then ligated, the stump ligated and invaginated, and gentle traction on the caecum will enable the surgeon to deliver the body of the appendix, which is then removed from base to tip. Occasionally, this manoeuvre requires division of the lateral peritoneal attachments of the caecum.

**Laparoscopic appendicectomy**

The most valuable aspect of laparoscopy in the management of suspected appendicitis is as a diagnostic tool, particularly in women of child-bearing age. The placement of operating ports may vary according to operator preference and previous abdominal scars. The operator stands to the patient’s left and faces a video monitor placed at the patient’s right foot (Figure 71.15). A moderate Trendelenburg tilt of the operating table assists delivery of loops of small bowel from the pelvis. The appendix is found in the conventional manner by identification of the caecal taeniae and is controlled using a laparoscopic tissue-holding forceps. By elevating the appendix, the mesoappendix is displayed (Figure 71.16a). A dissecting forceps is used to create a window in the mesoappendix to allow the appendicular vessels to be coagulated or ligated using a clip applicator. The appendix, free of its mesentery, can be ligated at its base with an absorbable loop ligature (Figure 71.16b), divided (Figure 71.16c) and removed through one of the operating ports. It is not usual to invert the stump of the appendix (Figure 71.16d). A single absorbable suture is used to close the linea alba at the
PART 11 | ABDOMINAL

THE VERMIFORM APPENDIX

1210

umbilicus, and the small skin incisions may be closed with subcuticular sutures.

Patients who undergo laparoscopic appendicectomy are likely to have less postoperative pain and to be discharged from hospital and return to activities of daily living sooner than those who have undergone open appendicectomy. While the incidence of postoperative wound infection is lower after the laparoscopic technique, the incidence of postoperative intra-abdominal sepsis may be higher in patients operated on for gangrenous or perforated appendicitis. There may be an advantage for laparoscopic over open appendicectomy in obese patients and early pregnancy. At present, there seems little, if any, benefit from single incision laparoscopic surgery (SILS) for acute appendicitis.

Problems encountered during appendicectomy

- A normal appendix is found. This demands careful exclusion of other possible diagnoses, particularly terminal ileitis, Meckel's diverticulitis and tubal or ovarian causes in women. It is usual to remove the appendix to avoid future diagnostic difficulties, even though the appendix

Figure 71.15 Position of surgeon, assistants and equipment for laparoscopic appendicectomy.

![Image](image1.png)

Figure 71.16 Laparoscopic appendicectomy. (a) Mesoappendix displayed; (b) ligation at the base of the appendix; (c) division of base; (d) appendicectomy complete (courtesy of Professor O McAnena, FRCSI, Galway, Ireland).
is macroscopically normal, particularly if a skin crease or gridiron incision has been made. A case can be made for preserving the macroscopically normal appendix seen at diagnostic laparoscopy, although approximately one-quarter of seemingly normal appendices show microscopic evidence of inflammation.

- The appendix cannot be found. The caecum should be mobilised, and the taeniae coli should be traced to their confluence on the caecum before the diagnosis of ‘absent appendix’ is made.

- An appendicular tumour is found. Small tumours (under 2.0 cm in diameter) can be removed by appendicectomy; larger tumours should be treated by a right hemicolectomy (see below).

- An appendix abscess is found and the appendix cannot be removed easily. This eventuality is rare in the era of modern diagnostic imaging. Percutaneous drainage of the abscess and intravenous antibiotic treatment is to be preferred. If found at operation, the abscess should be drained and intravenous antibiotics administered. Very rarely in the face of a frankly necrotic appendix, a caecectomy or partial right hemicolectomy is required. (The first recorded operation for an appendix abscess was by Henry Hancock of Charing Cross Hospital, London, in 1848.)

Appendicitis complicating Crohn’s disease
Occasionally, a patient undergoing surgery for acute appendicitis is found to have concomitant Crohn’s disease of the ileocaecal region. Providing that the caecal wall is healthy at the base of the appendix, appendicectomy can be performed without increasing the risk of an enterocutaneous fistula. Rarely, the appendix is involved with the Crohn’s disease. In this situation, a conservative approach may be warranted, and a trial of intravenous corticosteroids and systemic antibiotics can be used to resolve the acute inflammatory process.

Appendix abscess
Failure of resolution of an appendix mass or continued spiking pyrexia usually indicates that there is pus within the phlegmonous appendix mass. Ultrasound or abdominal CT scan may identify an area suitable for the insertion of a percutaneous drain. Rarely, this is unsuccessful and laparotomy through a midline incision is indicated.

Pelvic abscess
Pelvic abscess formation is an occasional complication of appendicitis and can occur irrespective of the position of the appendix within the peritoneal cavity. The most common presentation is a spiking pyrexia several days after appendicitis; indeed, the patient may already have been discharged from hospital. Pelvic pressure or discomfort associated with loose stool or tenesmus is common. Rectal examination reveals a boggy mass in the pelvis, anterior to the rectum, at the level of the peritoneal reflection (Figure 71.17). Pelvic ultrasound or CT scan will confirm. Traditionally, treatment has been through transrectal drainage under general anaesthetic, however increasing availability of radiologically guided percutaneous drainage has reduced the need considerably.

Management of an appendix mass
If an appendix mass is present and the condition of the patient is satisfactory, the standard approach is the conservative Ochsner–Sherren regimen. This strategy is based on the premise that the inflammatory process is already localised and that inadvertent surgery is difficult and may be dangerous. It may be impossible to find the appendix and, occasionally, a faecal fistula may form. For these reasons, it is wise to observe a non-operative programme but to be prepared to operate should clinical deterioration occur (Summary box 71.6).

### Summary box 71.6
Criteria for stopping conservative treatment of an appendix mass
- A rising pulse rate
- Increasing or spreading abdominal pain
- Increasing size of the mass

Careful recording of the patient’s condition and the extent of the mass should be made and the abdomen regularly re-examined. It is helpful to mark the limits of the mass on the abdominal wall using a skin pencil. A contrast-enhanced CT examination of the abdomen should be performed and antibiotic therapy instigated. An abscess, if present, should be drained radiologically. Temperature and pulse rate should be recorded 4-hourly and a fluid balance record maintained. Clinical deterioration or evidence of peritonitis is an indication for early...
laparotomy. Clinical improvement is usually evident within 24–48 hours. Failure of the mass to resolve should raise suspicion of a carcinoma or Crohn’s disease. Using this regimen, approximately 90 per cent of cases resolve without incident. The great majority of patients will not develop recurrence, and it is no longer considered necessary to remove the appendix after an interval of 6–8 weeks. Patients over the age of 40 should have colonoscopy and follow-up imaging to ensure resolution as a small minority (less than 5 per cent) may have an underlying appendicular or colonic malignancy.

Postoperative complications
Postoperative complications following appendicectomy are relatively uncommon and reflect the degree of peritonitis that was present at the time of operation and intercurrent diseases that may predispose to complications (Summary box 71.7).

\textbf{Wound infection}
Wound infection is the most common postoperative complication, occurring in 5–10 per cent of all patients. This usually presents with pain and erythema of the wound on the 4th or 5th postoperative day, often soon after hospital discharge. Treatment is by wound drainage and antibiotics when required. The organisms responsible are usually a mixture of Gram-negative bacilli and anaerobic bacteria, predominantly Bacteroides species and anaerobic streptococci.

\textbf{Intra-abdominal abscess}
Approximately 8 per cent of patients following appendicectomy will develop a postoperative intra-abdominal abscess. In an era of hospital discharge 24 to 48 hours following appendicectomy, patients should be advised prior to discharge that a spiking fever, malaise and anorexia developing 5–7 days after operation is suggestive of an intraperitoneal collection and that urgent medical advice should be obtained. Interloop, paracolic, pelvic and subphrenic sites should be considered. Abdominal ultrasonography and CT scanning greatly facilitate diagnosis and allow percutaneous drainage. Laparotomy should be considered in patients suspected of having intra-abdominal sepsis, but in whom imaging fails to show a collection, particularly those with continuing ileus.

\textbf{Ileus}
A period of adynamic ileus is to be expected after appendicectomy, and this may last a number of days following removal of a gangrenous appendix. Ileus persisting for more than 4 or 5 days, particularly in the presence of a fever, is indicative of continuing intra-abdominal sepsis and should prompt further investigation (see above). Rarely, early during postoperative recovery, a Richter’s type of hernia may occur at the site of a laparoscopic port insertion and may be confused with a postoperative ileus. A CT scan is usually definitive.

\textbf{Respiratory}
In the absence of concurrent pulmonary disease, respiratory complications are rare following appendicectomy. Adequate postoperative analgesia and physiotherapy, when appropriate, reduce the incidence.

\textbf{Venous thrombosis and embolism}
These conditions are rare after appendicectomy, except in the elderly and in women taking the oral contraceptive pill. Appropriate prophylactic measures should be taken in such cases.

\textbf{Portal pyaemia (pylephlebitis)}
This is a rare but very serious complication of gangrenous appendicitis associated with high fever, rigors and jaundice. It is caused by sepsicaemia in the portal venous system and leads to the development of intrahepatic abscesses (often multiple). Treatment is with systemic antibiotics and percutaneous drainage of hepatic abscesses as appropriate. A screen for underlying thrombophilia should be considered.

\textbf{Faecal fistula}
Leakage from the appendicular stump occurs rarely, but may follow if the encircling stitch has been put in too deeply or if the caecal wall was involved by oedema or inflammation. Occasionally, a fistula may result following appendicectomy in Crohn’s disease. Conservative management with low-residue enteral nutrition will usually result in closure.

\textbf{Adhesive intestinal obstruction}
This is the most common late complication of appendicectomy. At operation, a single band adhesion is often found to be responsible. Occasionally, chronic pain in the right iliac fossa is attributed to adhesion formation after appendicectomy. In such cases, laparoscopy is of value in confirming the presence of adhesions and allowing division.

\textbf{Recurrent acute appendicitis}
Appendicitis is notoriously recurrent. It is not uncommon for patients to attribute such attacks to ‘biliousness’ or dyspepsia. The attacks vary in intensity and may occur every few months, and the majority of cases ultimately culminate in severe acute appendicitis. If a careful history is taken from patients with acute appendicitis, many remember having had milder but similar attacks of pain. The appendix in these cases shows fibrosis indicative of previous inflammation (Figure 71.18). Chronic appendicitis, per se, does not exist; however, there is evidence of altered neuroimmune function in the myenteric nerves of patients with so-called recurrent appendicitis (Büchler).
Neoplasms of the appendix

Carcinoid tumours
Carcinoid tumours (synonym: argentaffinoma) arise in argentaffin tissue (Kulchitsky cells of the crypts of Lieberkühn) and are most common in the vermiform appendix. Carcinoid tumour is found once in every 300–400 appendices subjected to histological examination and is ten times more common than any other neoplasm of the appendix. In many instances, the appendix had been removed because of symptoms of subacute or recurrent appendicitis. The tumour can occur in any part of the appendix, but it is frequently found in the distal third. The neoplasm feels moderately hard and, on sectioning the appendix, it can be seen as a yellow tumour between the intact mucosa and the peritoneum. Microscopically, the tumour cells are small, arranged in small nests within the muscle and have a characteristic pattern using immunohistochemical stain for chromogranin B (Figure 71.19). Unlike carcinoid tumours arising in other parts of the intestinal tract, carcinoid tumour of the appendix rarely gives rise to metastases. Appendicectomy has been shown to be sufficient treatment, unless the caecal wall is involved, the tumour is 2 cm or more in size or involved lymph nodes are found, when right hemicolectomy is indicated.

Other appendiceal tumours
Goblet cell carcinoid tumour is an unusual variant, which exhibits a combination of endocrine and glandular differentiation. It has a more aggressive natural history and right hemicolectomy is indicated if the tumour is 2 cm or more in size, has greater than two mitoses per high power field, involved margins or lymphovascular invasion.

Primary adenocarcinoma of the appendix is extremely rare. It is usually of the colonic type and should be treated by right hemicolectomy (as a second-stage procedure if the condition is not recognised at the first operation).

Mucinous cystadenoma
A mucin-secreting adenoma of the appendix may rupture into the peritoneal cavity (Figure 71.20), seeding it with mucus-secreting cells. Presentation is often delayed until the patient has gross abdominal distension as a result of pseudomyxoma peritonei, which may mimic ascites (Figure 71.21). Treatment consists of radical resection of all involved parietal peritoneal surfaces and aggressive intraperitoneal chemotherapy (Sugarbaker). When diagnosed, patients should be referred to specialist centres that have the requisite facilities and experience to undertake the prolonged and complex surgery involved.

Figure 71.18 Excised appendix showing the point of luminal obstruction with distal fibrosis.

Figure 71.19 Carcinoid tumour. A small incidental carcinoid tumour of the appendix. The tumour cells infiltrate the muscle arranged in small nests and trabeculae (arrows). Tumour cells are small and have inconspicuous nuclei. Inset: higher magnification of an immunohistochemical stain for chromogranin B shows a strong positive reaction (brown) of tumour cells (courtesy of Dr P Kelly, FRCPath, Dublin, Ireland).

FURTHER READING

The rectum begins where the taenia coli of the sigmoid colon join to form a continuous outer longitudinal muscle layer at the level of the sacral promontory. The rectum follows the curve of the sacrum, and ends at the anorectal junction. The puborectalis muscle encircles the posterior and lateral aspects of the junction, creating the anorectal angle (normally 120°). The rectum has three lateral curvatures: the upper and lower are convex to the right, and the middle is convex to the left. On the luminal aspect, these three curves are marked by semicircular folds (Houston’s valves) (Figure 72.1).

The adult rectum is approximately 12–18 cm in length and is conventionally divided into three equal parts: the upper third, which is mobile and has a peritoneal covering anteriorly and laterally; the middle third, where the peritoneum covers only the anterior and part of the lateral surfaces; and the lowest third, which lies deep in the pelvis surrounded by fatty mesorectum and is separated from adjacent structures by fascial layers.

The lower third of the rectum is separated by a fascial condensation (Denonvilliers’ fascia) from the prostate/vagina in front, and behind by another fascial layer (Waldeyer’s fascia) from the coccyx and lower two sacral vertebrae (Table 72.1). These fascial layers are surgically important as they are a barrier to malignant invasion (Summary box 72.1).

Summary box 72.1

Anatomy of the rectum

- The rectum measures approximately 15 cm in length
- It is divided into lower, middle and upper thirds
- The blood supply consists of superior, middle and inferior rectal vessels
- Although the lymphatic drainage follows the blood supply, the principal route is upwards along the superior rectal vessels to the para-aortic nodes

Blood supply

The superior rectal artery is the direct continuation of the inferior mesenteric artery and is the main arterial supply of the rectum. The arteries and their accompanying lymphatics lie within the loose fatty tissue of the mesorectum, surrounded by a sheath of connective tissue (the mesorectal fascia).

The middle rectal artery arises on each side from the internal iliac artery (Figure 72.2) and passes to the rectum in the lateral ligaments. It is usually small (and often only present on one side) and breaks up into several terminal branches.

The inferior rectal artery arises on each side from the internal pudendal artery as it enters Alcock's canal. It hugs the inferior surface of the levator ani muscle as it crosses the roof of the ischiorectal fossa to enter the anal muscles (Figure 72.2).

Venous drainage

The superior haemorrhoidal veins draining the upper half of the anal canal above the dentate line pass upwards to become the rectal veins: these unite to form the superior rectal vein, which later becomes the inferior mesenteric vein. This forms part of the portal venous system and ultimately drains into the splenic vein. Middle rectal veins exist but are small, unimportant channels unless the normal paths are blocked.

Lymphatic drainage

The lymphatics of the mucosal lining of the rectum communicate freely with those of the muscular layers. The usual drainage flow is upwards, and only to a limited extent laterally and downwards. For this reason, surgical clearance of malignant disease concentrates mainly on achieving wide resection of proximal lymph nodes. However, if the usual upwards routes are blocked (for example, by carcinoma), flow can reverse, and it is then possible to find metastatic lymph nodes on the side walls of the pelvis (along the middle rectal vessels) or even in the inguinal region (along the inferior rectal artery).

CLINICAL FEATURES OF RECTAL DISEASE

Symptoms

Rectal diseases are common and serious and can occur at any age. The symptoms of many of them overlap. In general, the inflammations affect younger age groups, while the tumours occur in the middle-aged and elderly. The common symptoms of rectal disease are shown in Summary box 72.2.

Summary box 72.2

Main symptoms of rectal disease

- Bleeding per rectum
- Altered bowel habit
- Mucus discharge
- Tenesmus
- Prolapse

Bleeding

This is often bright red in colour but may be darker, and should be carefully investigated at any age.

Altered bowel habit

Early-morning stool frequency (‘spurious diarrhoea’) is a symptom of rectal carcinoma, while blood-stained frequent loose stools characterise the inflammatory diseases.

Discharge

Mucus and pus are associated with rectal pathology.

Tenesmus

Often described by the patient as ‘I feel I want to go, but nothing happens’, this is normally an ominous symptom of rectal cancer, but can occur with any rectal pathology.

Prolapse

This usually indicates either mucosal or full-thickness rectal wall descent.

Loss of weight

This usually indicates serious or advanced disease, e.g. hepatic metastases.

Charles Alexander Wells, 1898–1989, Professor of Surgery, University of Liverpool, Liverpool, UK.
Aubrey York Mason, 1910–1993, surgeon, St Helier Hospital, Carshalton, Surrey, UK.
Signs
Because the rectum is accessible via the anus, these can be elicited by systematic examination. The patient is either positioned in the left lateral (Sims) position or examined in the knee–elbow position (Figure 72.3).

Inspection
Visual examination of the anus precedes rectal examination to exclude the presence of anal disease, e.g. fissure or fistula.

Digital examination
The index finger used with gentleness and precision remains a valuable test for rectal disease (Figure 72.4). Tumours in the lower and middle thirds of the rectum can be felt and assessed; by asking the patient to strain, even some tumours in the upper third can be 'tipped' with the finger. After it is removed, the finger should be examined for tell-tale traces of mucus, pus or blood. It is always useful to note the normal, as well as the abnormal findings on digital examination, e.g. the prostate in the male. Digital findings can be recorded as intraluminal (e.g. blood, pus), intramural (e.g. tumours, granular areas, strictures) or extramural (e.g. enlarged prostate, uterine fibroids).

Proctoscopy
This procedure can be used to inspect the anus, anorectal junction and lower rectum (up to 10 cm) (Figure 72.5). Biopsy can be performed of any suspicious areas.

Sigmoidoscopy
In the past, the sigmoidoscope was a rigid stainless steel instrument of variable diameter and normally 25 cm in length (Figure 72.5). This has in the main been replaced by a disposable plastic instrument. The rectum must be empty for proper inspection with a sigmoidoscope. Gentleness and skill are required for its use, and perforations can occur if care is not taken.

Flexible sigmoidoscope
The ‘flexiscope’ can be used to supplement or replace rigid sigmoidoscopy (Figure 72.6). It requires skill and experience, and the lower bowel should be cleaned out with preliminary enemas. In addition to the rectum, the whole sigmoid colon is within visual reach of this instrument (Summary box 72.3).

Summary box 72.3
Examination of the rectum
- Visual inspection of the perineum
- Digital examination
- Proctoscopy
- Sigmoidoscopy – rigid or flexible

INJURIES
The rectum or anal canal may be injured in a number of ways, all uncommon:

James Marion Sims, 1813–1883, gynaecological surgeon, the State Hospital for Women, New York, NY, USA, introduced this position to give access to the anterior vaginal wall during operations for the closure of vaginovascular fistulae.

Charles Victor Mann, formerly surgeon, St Mark’s Hospital and Royal London Hospital, London, UK.
PART 11
ABDOMINAL

THE RECTUM

by falling in a sitting posture onto a pointed object: the upturned leg of a chair, handle of a broom, floor-mop, pitchfork or a broken shooting stick have all resulted in rectal impalement;

by penetrating injury (including gunshots) to the buttocks;

by sexual assault or sexual activity involving anal penetration;

by the fetal head during childbirth, especially forceps-assisted.

**Diagnosis**

The anus should be inspected and the abdomen palpated. If rigidity or tenderness is present, early laparotomy or laparoscopy is indicated. A water-soluble contrast enema or computed tomography (CT) scan with rectal contrast is useful to identify perforation. Prior to the operation, a urethral catheter is passed, but if there is any possibility of urethral injury (suggested by difficulty passing urine, haematuria or high prostate on digital examination), a urethrogram should be performed first (see Chapters 76 and 78).

**Treatment**

If perforation is suspected, the rectum is examined under general anaesthetic with a finger and a sigmoidoscope, particular attention being directed to the anterior wall. If penetrating injury is confirmed, laparotomy or laparoscopy is then performed. If an intraperitoneal rupture of the rectum is found, the perforation is closed with sutures. A defunctioning colostomy is usually required, constructed in the left iliac fossa. If the rectal injury is below the peritoneal reflection, wide drainage from below is indicated, with rectal washout and a defunctioning colostomy. If the defect in the rectum is very large, resection may have to be contemplated, usually in the form of a Hartmann’s procedure. Care must be taken to preserve sphincter function during debridement of the perineal wounds. Antibiotic cover must be provided against both aerobic and anaerobic organisms.

**FOREIGN BODIES IN THE RECTUM**

The variety of foreign bodies that have found their way into the rectum is hardly less remarkable than the ingenuity displayed in their removal (Figure 72.7). A turnip has been delivered per anum by the use of obstetric forceps. A large soft rubber sex toy has been withdrawn by inserting a myomectomy screw into its lower end. A tumbler, mouth open downwards, has been extracted by filling the interior with a wet plaster of Paris bandage, leaving the end of the bandage protruding and allowing the plaster to set.

If insurmountable difficulty is experienced in grasping any foreign body in the rectum, a laparotomy is usually necessary, which allows the object to be pushed from above into the assistant’s fingers in the rectum. If there is considerable laceration of the mucosa, a temporary colostomy is advisable (Summary box 72.4).
Summary box 72.4

**Injuries to the rectum are serious and invariably require surgery**

- A temporary colostomy is often necessary
- There is a serious risk of associated necrotising fasciitis, and broad-spectrum antibiotics are mandatory
- There may be associated bladder or urethral damage

**PROLAPSE**

**Mucosal prolapse**

The mucous membrane and submucosa of the rectum protrude outside the anus for approximately 1–4 cm. When the prolapsed mucosa is palpated between the finger and thumb, it is evident that it is composed of no more than a double layer of mucous membrane (see below under Full-thickness prolapse) (Summary box 72.5).
PART 11
ABDOMINAL

Summary box 72.5
Rectal prolapse
- It may be mucosal or full thickness
- If full thickness, the whole wall of the rectum is included
- It commences as a rectal intussusception
- In children, the prolapse is usually mucosal and should be treated conservatively
- In the adult, the prolapse is often full thickness and is frequently associated with incontinence
- Surgery is necessary for full-thickness rectal prolapse
- The operation is performed either via the perineum or via the abdomen

In infants
The direct downward course of the rectum, due to the as-yet undeveloped sacral curve (Figure 72.8), predisposes to this condition, as does the reduced resting anal tone, which offers diminished support to the mucosal lining of the anal canal.

In children
Mucosal prolapse often commences after an attack of diarrhoea, or from loss of weight and consequent loss of fat in the ischiorectal fossae. It may also be associated with cystic fibrosis, neurological causes and maldevelopment of the pelvis.

In adults
The condition in adults is often associated with third-degree haemorrhoids. In the female, a torn perineum, and in the male straining from urethral obstruction, predispose to mucosal prolapse. In old age, both mucosal and full-thickness prolapse are associated with weakness of the sphincter mechanism, but whether this is the cause of the problem or secondary to it is unknown.

Partial prolapse may follow an operation for fistula in ano where a large portion of muscle has been divided. Here, the prolapse is usually localised to the damaged quadrant and is seldom progressive.

Prolapsed mucous membrane is pink; prolapsed internal haemorrhoids are plum coloured and more pedunculated.

Treatment
In infants and young children
- Digital repositioning. The parents are taught to replace the protrusion, and any underlying causes are addressed.
- Submucosal injections. If digital repositioning fails after 6 weeks’ trial, injections of 5 per cent phenol in almond oil are carried out under general anaesthetic. As a result of the aseptic inflammation following these injections, the mucous membrane becomes tethered to the muscle coat.
- Surgery. Occasionally, surgery is required and, in such cases, the child is placed in the prone jack-knife position, the retrorectal space is entered, and the rectum is sutured to the sacrum.

In adults
- Local treatments. Submucosal injections of phenol in almond oil or the application of rubber bands are sometimes successful in cases of mucosal prolapse.
- Excision of the prolapsed mucosa. When the prolapse is unilateral, the redundant mucosa can be excised or, if circumferential, an endoluminal stapling technique can be used.

Full-thickness prolapse
Full-thickness prolapse (synonym: procidentia) is less common than the mucosal variety. The protrusion consists of all layers of the rectal wall and is usually associated with a weak pelvic floor. The prolapse is thought to commence as an intussusception of the rectum, which descends to protrude outside the anus. The process starts with the anterior wall of the rectum, where the supporting tissues are weakest, especially in women. It is more than 4 cm and commonly as much as 10–15 cm in length (Figure 72.9). On palpation between the finger and thumb, the prolapse feels much thicker than a mucosal prolapse, and obviously consists of a double thickness of the entire wall of the rectum. Any prolapse over 5 cm in length contains anteriorly between its layers a pouch of peritoneum (Figure 72.10). When large, the peritoneal pouch may contain small intestine, which returns to the general peritoneal cavity with a characteristic gurgle when the prolapse is reduced. The anal sphincter is characteristically patulous and gaps widely on straining to allow the rectum to prolapse. Complete prolapse is uncommon in children. In adults, it can occur at any age, but it is more common in the elderly. Women are affected six times more often than men.

Figure 72.8 The absence of the normal sacral curve predisposes to rectal prolapse in an infant.

Figure 72.9 Full-thickness rectal prolapse (courtesy of GD Adhia, Bombay, India).
PART 11

ABDOMINAL

Prolapse

men, and it is commonly associated with prolapse of the uterus. In approximately 50 per cent of adults, faecal incontinence is also a feature.

**Differential diagnosis**

In the case of a child with abdominal pain, prolapse of the rectum must be distinguished from ileocaecal intussusception protruding from the anus. Figures 72.11 and 72.12 make the differential diagnosis clear. In rectosigmoid intussusception in the adult, there is a deep groove (5 cm or more) between the emerging protruding mass and the margin of the anus, into which the finger can be placed.

**Treatment**

Surgery is required, and the operation can be performed via the perineal or the abdominal approaches. An abdominal rectopexy has a lower rate of recurrence but, when the patient is elderly and very frail, a perineal operation, sometimes performed under spinal anaesthetic, is usually safer. As an abdominal procedure risks damage to the pelvic autonomic nerves, resulting in possible sexual dysfunction, a perineal approach is often preferred in young men.

**Perineal approach**

These procedures have been used most commonly:

- **Thiersch operation.** This procedure, which aimed to place a steel wire or, more commonly, a silastic or nylon suture around the anal canal, has become obsolete. The reasons for its lack of popularity were that the suture would often break or cause chronic perineal sepsis, or both, or the anal stenosis so created would produce severe functional problems.

- **Delorme’s operation.** In this procedure, the rectal mucosa is removed circumferentially from the prolapsed rectum over its length (Figure 72.13). The underlying muscle is then plicated with a series of sutures, so that, when these are tied, the rectal muscle is concertinaed towards the anal canal. The anal canal mucosa is then sutured circumferentially to the rectal mucosa remaining at the tip of the prolapse. The prolapse is reduced, and a ring of muscle is created above the anal canal, which prevents recurrence.

- **Altemeier’s procedure.** This consists of excision of the prolapsed rectum and associated sigmoid colon from below, and construction of a coloanal anastomosis.

**Abdominal approach**

The principle of all abdominal operations for rectal prolapse is to fix the rectum in its proper position. Many variations have been described, including inserting a sheet of polypropylene mesh between the rectum and the sacrum, hitching up the rectosigmoid junction with a Teflon sling to the front of the sacrum (Figure 72.14) or simply suturing the mobilised rectum to the sacrum using four to six interrupted non-absorbable sutures – so-called ‘sutured rectopexy’. Recently, the technique has been performed laparoscopically, thus reducing the operative trauma and limiting the time in hospital.

As an abdominal rectopexy may lead to severe constipation, some surgeons recommend combining this procedure with resection of the sigmoid colon, so-called ‘resection rectopexy’. Recently, an anterior mesh rectopexy has gained favour. In this procedure, a piece of mesh is fixed to the upper sacrum. The plane between the rectum and vagina is dissected, and the mesh placed into it and sutured to the rectum. This has the advantage of fixing the rectum in place anteriorly, where the prolapse starts, and reinforcing the rectovaginal septum which can bulge forward as a rectocoele.

SOLITARY RECTAL ULCER

This is becoming a more commonly diagnosed problem. Classically, it takes the form of an ulcer on the anterior wall of the rectum. In this form, it can be mistaken for a rectal carcinoma or inflammatory bowel disease, particularly Crohn’s disease. It may heal, leaving a polypoid appearance. Proctographic studies indicate that it is due to a combination of internal intussusception or anterior rectal wall prolapse and an increase in intrarectal pressure, usually caused by chronic straining as a result of constipation. The histological appearances confirm the diagnosis and are similar to the appearance of biopsies from a full-thickness overt rectal prolapse. The condition, although benign, is difficult to treat. Symptomatic relief from bleeding and discharge may sometimes be achieved by preventing the internal prolapse by biofeedback, an intrarectal stapling procedure or an abdominal rectopexy. In rare cases, rectal excision may be required.

PROCTITIS

Inflammation is sometimes limited to the rectum; in other cases, it is associated with a similar condition in the colon (proctocolitis). The inflammation can be acute or chronic. The symptoms are tenesmus and the passage of blood and mucus and, in severe cases, of pus also. Although the patient has a frequent intense desire to defaecate, the amount of faeces passed at a time is small. Acute proctitis is usually accompanied by malaise and pyrexia. On rectal examination, the mucosa feels swollen and is often tender. Proctoscopy is seldom sufficient and sigmoidoscopy is the more valuable method of examination. If the diagnosis is confirmed, colonoscopy with multiple biopsies is mandatory to determine the extent of the inflammatory process. Skilled pathological assessment is required to establish or exclude the diagnosis of specific infection by bacteriological examination and culture of the stools, examination of scrapings or swabs from ulcers and serological tests.

Non-specific proctitis is an inflammatory condition affecting the mucosa and, to a lesser extent, the submucosa, confined to the distal rectum. In 10 per cent of cases, the condition extends to involve the whole colon (total ulcerative colitis) (Summary box 72.6).

Summary box 72.6

Proctitis

- May be non-specific or related to a specific infective agent
- Non-specific proctitis usually remains confined to the distal bowel, but can spread to the proximal colon
- Causes bleeding, diarrhoea and tenesmus
- Treatment is usually conservative

Aetiology

This is unknown. The concept that the condition is a mild and limited form of ulcerative colitis (although actual ulceration is often not present) is the most acceptable hypothesis.

Clinical features

The patient is usually middle-aged and complains of slight loss of blood in the motions. Often, the complaint is one of diarrhoea but, on closer questioning, it transpires that usually one relatively normal action of the bowels occurs each day, although it is accompanied by some blood. During the day, the patient attempts to defaecate, with the passage of flatus and a little blood-stained faecal matter, which is interpreted as diarrhoea. On rectal examination, the mucosa feels warm and smooth. Often, there is some blood on the examining finger. Proctoscopic and sigmoidoscopic examination shows inflamed mucosa of the rectum, but usually no ulceration. The inflammation usually extends for only 5–15 cm from the anus, with the mucosa above this level being normal.

Treatment

The condition is usually self-limiting, but treatment with topical 5-aminosalicylic acid (5-ASA) compounds (Asacol, Pentasa) in the form of suppositories or foam enemas is usually effective. Topical steroids are a less effective alternative. In very severe resistant cases, oral steroids may have to be used to obtain remission. Rarely, surgical treatment is required as a last resort when the patient is desperate for relief of symptoms.

Ulcerative proctocolitis

Proctitis is present in a high percentage of cases of ulcerative colitis, and the degree of severity of the rectal involvement may influence the type of operative procedure (see Chapter 69).

Proctitis due to Crohn’s disease

Crohn’s disease can occasionally affect the rectum, although classically it is spared. Sigmoidoscopic characteristics differ from those in non-specific proctitis. The inflammatory process tends to be patchy rather than confluent, and there may be fissuring, ulceration and even a cobblestone appearance. Rectal Crohn’s disease is often associated with severe perineal disease characterised by fistulation. Skip lesions are also often present in the rest of the colon or small bowel, or both.
Proctitis due to specific infections

*Clostridium difficile*
An acute form of proctocolitis caused by infection with *Clostridium difficile* can follow broad-spectrum antibiotic administration. A ‘membrane’ can sometimes be seen on proctoscopy (‘pseudomembranous’ colitis).

*Bacillary dysentery*
The appearance is that of an acute purulent proctitis with multiple small, shallow ulcers. The examination of a swab taken from the ulcerated mucous membrane is more certainly diagnostic than stool microscopy.

*Amoebic dysentery*
The infection is more liable to be chronic, and exacerbations after a long period of freedom from symptoms often occur. Proctoscopy and sigmoidoscopy are not painful. The appearance of an amoebic ulcer is described in Chapter 69. Scrapings from the ulcer should be immersed in warm isotonic saline solution and sent to the laboratory for immediate microscopic examination.

*Amoebic granuloma*
This presents as a soft mass, usually in the rectosigmoid region. This lesion is frequently mistaken for a carcinoma. Sigmoidoscopy shows an ulcerated surface, but the mass is less friable than a carcinoma. A scraping should be taken, preferably with a small, sharp spoon on a long handle, and the material sent for immediate microscopic examination, as detailed above. A biopsy can also help. Treatment is as described in Chapter 69. Amoebic granuloma of the rectum is encountered from time to time in a patient who has never visited a country in which the disease is endemic.

*Tuberculous proctitis*
This is nearly always associated with active pulmonary tuberculosis or tuberculous ulceration of the anus. Submucous rectal abscesses burst and leave ulcers with an undermined edge. A hypertrophic type of tuberculous proctitis occurs in association with tuberculous peritonitis, or tuberculous proctitis occurs in association with tuberculous peritonitis or tuberculous salpingitis. This type of tuberculous proctitis requires biopsy for confirmation of the diagnosis.

*Gonococcal proctitis*
Gonococcal proctitis occurs in both sexes as the result of rectal coitus and, in the female, from direct spread from the vulva. In the acute stage, the mucous membrane is hyperaemic, and thick pus can be expressed as the proctoscope is withdrawn. In the early stages, the diagnosis can be readily established by bacteriological examination but, later, when the infection is mixed, it is more difficult to recognise. Systemic treatment is so effective that local treatment is unnecessary.

*Lymphogranuloma venereum*
The modes of infection are similar to those of gonococcal proctitis but, in the female, chlamydial infection spreading from the cervix uteri via lymphatics to the pararectal lymph nodes is common. The proctological findings are similar to those of gonococcal proctitis. The diagnosis of lymphogranuloma venereum should be suspected when the inguinal lymph nodes are greatly enlarged, although the enlargement may be subsiding by the time proctitis commences.

Acquired immunodeficiency syndrome
Acquired immunodeficiency syndrome (AIDS) due to human immunodeficiency virus (HIV) may present with a particularly florid type of proctitis. In such patients, unusual organisms such as cytomegalovirus (CMV), herpes simplex virus and organisms such as *Cryptosporidium* are often found.

‘Strawberry’ lesion of the rectosigmoid
This results from an infection by *Spirochaeta vincenti* and *Bacillus fusiformis*. The leading symptom is diarrhoea, often scantily blood-stained. Occasionally, the diagnosis can be made by the demonstration of the specific organisms in the stools. More often, sigmoidoscopy is required. The characteristic lesion is thickened, somewhat raised mucosa with superficial ulceration in the region of the rectosigmoid. The inflamed mucous membrane oozes blood at numerous pinpoints, giving the appearance of an over-ripe strawberry. A swab should be taken from the lesion and examined for Vincent’s and fusiform organisms. Swabs from the gums and the throat are also advisable.

*Rectal bilharziasis*
Rectal bilharziasis is caused by *Schistosoma mansoni*, which is endemic in many tropical and subtropical countries, and particularly in the delta of the Nile.

In stage 1, a cutaneous lesion develops at the site of entrance of the cercariae (parasites of freshwater snails). Stage 2 is characterised by pyrexia, urticaria and a high eosinophilia. Both these stages are frequently overlooked. Stage 3 results from deposition of the ova in the rectum (much more rarely in the bladder; Chapter 76) and is manifested by bilateral dysentery. On examination in the later stages, papillomas are frequently present. The papillomas, which are sessile or pedunculated, contain the ova of the trematode, the life cycle of which resembles that of *Schistosoma haematobium*.

Untreated, the rectum becomes festooned, and prolapse of the diseased mucous membrane is usual. Multiple fistulae in ano are prone to develop.

Treatment
The primary treatment is systemic and should be undertaken by a specialist in tropical medicine. When the papillomas persist in spite of general treatment, they should be treated by local destruction.

Proctitis due to herbal enemas
This is a well-known clinical entity to those practising in tropical Africa. Following an enema consisting of a concoction of ginger, pepper and bark, administered by a witch doctor, a virulent proctitis sets in. Pelvic peritonitis frequently supervenes. Not infrequently, a complete gelatinous cast of the mucous membrane of the rectum is extruded. Very large doses of morphine, together with antibiotics, often prevent a fatal outcome if commenced early. Temporary colostomy is often advisable.
**BENIGN TUMOURS**

The rectum, along with the sigmoid colon, is the most frequent site of polyps (and cancers) in the gastrointestinal tract. Adenomatous polyps of the colon and rectum have the potential to become malignant. The chance of harbouring invasive cancer is enhanced if the polyp is more than 1 cm in diameter. Removal of all polyps is recommended to give complete histological examination and exclude (or confirm) carcinoma, and also to prevent local recurrence. This is best done using endoscopic hot biopsy or snare polypectomy techniques. If one or more rectal polyps are discovered on sigmoidoscopic examination, a colonoscopy must be performed, as further polyps are frequently found in the colon and treatment may be influenced. No rectal polyp should be removed until the possibility of a proximal carcinoma has been ruled out, otherwise local implantation of cancer cells may occur in the distally situated rectal wound.

The rectum shares substantially the same spectrum of polyps as the colon. Polyps are described chiefly in terms of their tissue organisation. Certain polyps that have features relevant to the rectum are now described.

**Polyps relevant to the rectum**

**Villous adenomas**

These have a characteristic frond-like appearance. They may be very large, and occasionally fill the entire rectum. These tumours have an enhanced tendency to become malignant — a change that can sometimes be detected by palpation with the finger; any hard area should be assumed to be malignant and should be biopsied. Rarely, the profuse mucous discharge from these tumours, which is rich in potassium, causes dangerous electrolyte and fluid losses (Figure 72.15).

Provided cancerous change has been excluded, these tumours can be removed by submucosal resection endoscopically, surgically per anum or by sleeve resection from above. Only very occasionally is rectal excision required. A technique known as transanal endoscopic microsurgery (TEM) has been developed, which has improved the endoanal approach for the local removal of villous adenomas. The method requires the insertion of a large operating sigmoidoscope. The rectum is distended by carbon dioxide insufflation, the operative field is magnified by a camera inserted via the sigmoidoscope, and the image is displayed on a monitor (Figure 72.16). The lesion is excised using specially designed instruments. The technique is highly specialised and takes a considerable amount of time to master.

**Familial adenomatous polyposis**

This autosomal dominantly inherited condition is characterised by the development of multiple rectal and colonic adenomas around puberty. It is due to mutation of the adenomatous polyposis coli (APC) gene, allowing genetic testing in the 75 per cent of families in which a mutation can be identified. A colonoscopy and biopsy will confirm the diagnosis. As this condition is premalignant, a total colectomy must be performed; often, the rectum can be preserved, but regular flexible endoscopy and removal of polyps before they develop carcinoma are required. The operation of restorative proctocolectomy with ileal pouch–anal anastomosis is an alternative if proctectomy is required: the rectum is replaced by a ‘pouch’ of folded ileum (Chapter 69). A pan-proctocolectomy with permanent ileostomy is necessary in some instances, especially when patient follow up may be impractical.

**Inflammatory pseudopolyps**

These are oedematous islands of mucosa. They are usually associated with colitis in the UK, but most inflammatory diseases (including tropical diseases) can cause them. They are more likely to cause radiological difficulty as the sigmoidoscopic appearances are usually associated with obvious signs of the inflammatory cause.

**Juvenile polyp**

This is a bright-red glistening pedunculated sphere (‘cherry tumour’), which is found in infants and children. Occasionally, it persists into adult life. It can cause bleeding, or pain if it prolapses during defaecation. It often separates itself, but can be removed easily with forceps or a snare. A solitary juvenile polyp has virtually no tendency to malignant change, but should be treated if it is causing symptoms. It has a unique histological structure of large mucus-filled spaces covered by a smooth surface of thin rectal cuboidal epithelium (Figure 72.17). The rare autosomal dominantly inherited syndrome juvenile polyposis does confer an increased risk of gastrointestinal cancers. It is characterised by multiple juvenile polyps and a positive family history (Summary box 72.7).
Benign tumours

Summary box 72.7

### Polyps in the rectum
- Are either single or multiple
- Adenomas are the most frequent histological type
- Villous adenomas may be extensive and undergo malignant change more commonly than tubular adenomas
- All adenomas must be removed to avoid carcinomatous change
- All patients must undergo colonoscopy to determine whether further polyps are present
- Most polyps can be removed by endoscopic techniques, but sometimes major surgery is required

### Endometrioma
Endometrioma is rare and may be misdiagnosed as a carcinoma. The focus of ectopic endometrial tissue produces either a constricting lesion of the rectosigmoid or a tumour invading the rectum from the rectovaginal septum. The latter variety gives rise to a very tender submucous elevation of the rectal wall. Endometrioma occurs usually between 20 and 40 years of age. Dysmenorrhoea and rectal bleeding (particularly coinciding with the menses) are the main symptoms. On sigmoidoscopy, endometriosis involving the rectosigmoid junction usually presents as a stricture, with the mucous membrane intact. Hormonal manipulation is the first line of therapy, but sometimes total abdominal hysterectomy and bilateral salpingo-oophorectomy and even bowel resection is required.

### Haemangioma
Haemangioma of the rectum is an uncommon cause of serious haemorrhage. When localised in the lower part of the rectum or...
anal canal, a haemangioma can be excised. When the lesion is
diffuse, or lying in the upper part of the rectum, the symptoms
simulate ulcerative colitis, and the diagnosis is often missed for
a long period, or it is mistakenly thought to be a carcinoma.
Selective angiography and embolisation may be helpful, but
excision of the rectum is sometimes required.

Gastrointestinal stromal tumour
Smooth muscle tumours of the rectum are rare. If the mitotic
rate is high, and if there is variation in nuclear number, size and
shape, hyperchromasia and frequent bizarre cells, these tumours
are likely to metastasise. In these circumstances, they should
be classified as malignant gastrointestinal stromal tumours (for-
merly leiomyosarcomas). The uncertainty in their behaviour
means that treatment should, whenever possible, be by radical
excision.

CARCINOMAS
Overall, colorectal cancer is the second most common malign-
nancy in western countries, with approximately 18 000 patients
dying per annum in the UK. The rectum is the most frequent
site involved.

Origin
It is now accepted that colorectal cancer arises from adenomas
in a stepwise progression in which increasing dysplasia in the
adenoma is due to an accumulation of genetic abnormali-
ties (the adenoma–carcinoma sequence). In approximately 5
per cent of cases, there is more than one carcinoma present.
Usually, these carcinomas present as an ulcer, but polypoid and
infiltrating types are also common.

Types of carcinoma spread
Local spread
Local spread occurs circumferentially rather than in a longitudi-
nal direction. After the muscular coat has been penetrated, the
growth spreads into the surrounding mesorectum, but is initially
limited by the mesorectal fascia. If penetration occurs anteriorly,
the prostate, seminal vesicles or bladder become involved in the
male; in the female, the vagina or the uterus is invaded.
In either sex, if the penetration is lateral, a ureter may become
involved, while posterior penetration may reach the sacrum and
the sacral plexus. Downward spread for more than a few centi-
metres is rare.

Lymphatic spread
Lymphatic spread from a carcinoma of the rectum above the
peritoneal reflection occurs almost exclusively in an upward
direction; below that level, the lymphatic spread is still upwards,
but when the neoplasm lies within the field of the middle rectal
artery, primary lateral spread along the lymphatics that accom-
pany it is not infrequent.
Downward spread is exceptional, with drainage along the
subcutaneous lymphatics to the groins being confined, for
practical purposes, to the lymph nodes draining the perianal
rosette and the epithelium lining the distal 1–2 cm of the
anal canal.

Metastasis at a higher level than the main trunk of the super-
ior rectal artery occurs only late in the disease. A radical oper-
ation should ensure that the high-lying lymph nodes are removed
by ligating the inferior mesenteric artery at a high level.
Atypical and widespread mesenteric artery at a high level.

Venous spread
The principal sites for blood-borne metastases are liver (34
per cent), lungs (22 per cent) and adrenals (11 per cent). The
remaining 33 per cent are divided among the many other loca-
tions where secondary carcinomatous deposits tend to lodge,
including the brain.

Peritoneal dissemination
This may follow penetration of the peritoneal coat by a high-
lymphating rectal carcinoma.

Stages of progression
Dukes classified carcinoma of the rectum into three stages
(Figure 72.18).

Dukes' staging
- A. The growth is limited to the rectal wall (15 per cent): prognosis excellent (90 per cent year survival).
- B. The growth is extended to the extrarectal tissues, but
  no metastasis to the regional lymph nodes (35 per cent): prognosis reasonable (70 per cent year survival).
- C. There are secondary deposits in the regional lymph nodes
  (50 per cent). These are subdivided into C1, in which the
  local pararectal lymph nodes alone are involved, and C2, in
  which the nodes accompanying the supplying blood vessels
  are implicated up to the point of division. This does not take
  into account cases that have metastasised beyond the regional
  lymph nodes or by way of the venous system: prognosis is poor
  (40 per cent year survival).

A stage D is often included, which was not described by Dukes.
This stage signifies the presence of widespread metastases, usu-
ally hepatic.

Figure 72.18 The three cardinal stages of progression of the neoplasm
(after C Dukes, FRCS).
Other staging systems have been developed (e.g. Astler–Coller, TNM) to improve prognostic accuracy, but the tumour–node–metastasis (TNM) classification is now recognised internationally as the optimum classification for staging.

**TNM staging**

T represents the extent of local spread and there are four grades:

- T1 tumour invasion through the muscularis mucosae, but not into the muscularis propria;
- T2 tumour invasion into, but not through the muscularis propria;
- T3 tumour invasion through the muscularis propria, but not through the serosa (on surfaces covered by peritoneum) or mesorectal fascia;
- T4 tumour invasion through the serosa or mesorectal fascia.

N describes nodal involvement:

- N0 no lymph node involvement;
- N1 between one and three involved lymph nodes;
- N2 four or more involved lymph nodes.

M indicates the presence of distant metastases:

- M0 no distant metastases;
- M1 distant metastases.

The prefix ‘p’ indicates that the staging is based on histopathological analysis, and ‘y’ that it is the stage after neoadjuvant treatment, which may have resulted in downstaging.

**Histological grading**

In the great majority of cases, carcinoma of the rectum is a columnar-celled adenocarcinoma. The more nearly the tumour cells approach normal shape and arrangement, the less aggressive the tumour is. Conversely, the greater the percentage of cells of an undifferentiated type, the more aggressive the tumour is:

- Low grade, well-differentiated 11 per cent prognosis good;
- Average grade, 64 per cent prognosis fair;
- High grade, undifferentiated tumours 25 per cent prognosis poor.

Vascular and perineural invasion are poor prognostic features, as is the presence of an infiltrating (rather than pushing) margin and tumour budding. In a small number of cases, the tumour is a primary mucoid carcinoma. The mucus lies within the cells, displacing the nucleus to the periphery, like the seal of a signet ring. Primary mucoid carcinoma gives rise to a rapidly growing bulky growth that metastasises very early and the prognosis of which is very poor (Summary box 72.8).

**Clinical features**

Carcinoma of the rectum can occur early in life, but the age of presentation is usually above 55 years, when the incidence rises rapidly. Often, the early symptoms are so insignificant that the patient does not seek advice for six months or more (Summary box 72.9), and the diagnosis is often delayed in younger patients as these symptoms are attributed to benign causes. Initial rectal examination and a low threshold for investigating persistent symptoms are essential to prevent this.

---

**Summary box 72.8**

**Pathology and staging of rectal cancer**

- Tumours are adenocarcinomas and are well, moderately or poorly differentiated
- They spread by local, lymphatic, venous and transperitoneal routes
- Circumferential local spread is the most important as this profoundly affects surgical treatment
- Although lymphatic spread follows the blood supply of the rectum, most occurs in an upwards direction via the superior rectal vessels to the para-aortic nodes
- The TNM classification is the internationally recognised staging system

**Summary box 72.9**

**Early symptoms of rectal cancer**

- Bleeding per rectum
- Tenesmus
- Early morning diarrhoea

---

**Bleeding**

Bleeding is the earliest and most common symptom. There is nothing characteristic about the time at which it occurs, nor is the colour or the amount of blood distinctive; often, the bleeding is slight in amount and occurs at the end of defaecation, or is noticed because it has stained underclothing. Indeed, more often than not, the bleeding in every respect simulates that of internal haemorrhoids (haemorrhoids and carcinoma sometimes coexist).

**Sense of incomplete defaecation**

The patient's bowels open, but there is the sensation that there are more faeces to be passed (tenesmus, a distressing straining to empty the bowels without resultant evacuation). This is a very important early symptom and is almost invariably present in tumours of the lower half of the rectum. The patient may endeavour to empty the rectum several times a day (spurious diarrhoea), often with the passage of flatus and a little blood-stained mucus ('bloody slime').

**Alteration in bowel habit**

This is the next most frequent symptom. The patient may find it necessary to start taking an aperient or to supplement the usual dose. A patient who has to get up early in order to defaecate, or one who passes blood and mucus in addition to faeces ('early-morning bloody diarrhoea'), is usually found to be suffering from carcinoma of the rectum. Often, it is the patient with an annular carcinoma at the rectosigmoid junction who suffers with increasing constipation, and the one with a growth in the ampulla of the rectum who has early-morning diarrhoea.

**Pain**

Pain is a late symptom, but pain of a colicky character may accompany advanced tumours of the rectosigmoid, and is caused by the pressure of an obstructing growth on the distal part of the bowel. It is also increased by straining to defaecate, and is frequently sufficient to render the patient an invalid; it is then that the proper treatment can be applied with the greatest success.
by some degree of intestinal obstruction. When a deep carcinomatous ulcer of the rectum erodes the prostate or bladder, there may be severe pain. Pain in the back, or sciatica, occurs when the cancer invades the sacral plexus.

Weight loss is suggestive of hepatic metastases.

Investigation

Abdominal examination

Abdominal examination is normal in early cases. Occasionally, when an advanced annular tumour is situated at the rectosigmoid junction, signs of obstruction of the large intestine are present. By the time the patient seeks advice, metastases in the liver may be palpable. When the peritoneum has become studied with secondary deposits, ascites usually results.

Rectal examination

In many cases, the neoplasm can be felt digitally: in early cases as a nodule with an indurated base. When the centre ulcerates, a shallow depression will be found, the edges of which are raised and everted. On bimanual examination, it may be possible to feel the lower extremity of a carcinoma situated in the rectosigmoid junction. After the finger has been withdrawn, if it has been in direct contact with a carcinoma, it is smeared with blood or mucopurulent material tinged with blood. When a carcinomatous ulcer is situated in the lower third of the rectum, involved lymph nodes can sometimes be felt as one or more hard, oval swellings in the mesorectum posteriorly or posterolaterally above the tumour. In females, a vaginal examination should be performed and, when the neoplasm is situated on the anterior wall of the rectum, with one finger in the vagina and another in the rectum, very accurate palpation can be carried out.

Proctosigmoidoscopy

Proctosigmoidoscopy will always show a carcinoma, if present, provided that the rectum is emptied of faeces beforehand.

Biopsy

Using biopsy forceps (Figure 72.19) via a sigmoidoscope, a portion of the edge of the tumour can be removed. If possible, another specimen from the more central part of the growth should also be obtained.

Colonoscopy

A colonoscopy is required if possible in all patients to exclude a synchronous tumour, be it an adenoma or a carcinoma. If a proximal adenoma is found, it can be conveniently snared and removed via the colonoscope. If a synchronous carcinoma is present, the operative strategy will need changing. If a full colonoscopy is not possible, a CT colonography or barium enema can be performed.

When a stenosing carcinoma is present, it may not be possible using these investigations, especially colonoscopy, to visualise the proximal colon. However, in view of the high incidence of synchronous tumours, it is imperative that a colonoscopy is always performed either before or within a few months of surgical resection.

Differential diagnosis

When an adenoma shows evidence of induration or unusual friability, it is almost certain that malignancy has occurred, even in spite of biopsy findings to the contrary. On the other hand, biopsy is invaluable in distinguishing carcinoma from an inflammatory stricture or an amoebic granuloma. The possibility of a neoplasm being an endometrioma should always be considered in patients with dysmenorrhoea. The possibility of a carcinoid tumour in atypical cases must be remembered. In the last four instances, biopsy should establish the correct diagnosis. The solitary ulcer syndrome has already been mentioned above (Summary box 72.10).

Summary box 72.10

Diagnosis and assessment of rectal cancer

All patients with suspected rectal cancer should undergo:
- Digital rectal examination
- Sigmoidoscopy and biopsy
- Colonoscopy if possible (or CT colonography or barium enema)

All patients with proven rectal cancer require staging by:
- Imaging of the liver and chest, preferably by CT
- Local pelvic imaging by magnetic resonance imaging and/or endoluminal ultrasound

Treatment

Some form of excision of the tumour remains the mainstay of treatment, if at all possible, because of the extreme suffering entailed if the neoplasm remains. However, the management of rectal cancer has become increasingly complex, because of the various surgical, neoadjuvant and adjuvant options available, and is best delivered in a multidisciplinary setting. Before treatment can be planned, it is necessary to assess:
- the fitness of the patient;
- the extent of spread of the tumour.

Assessment of spread should include CT of the chest and abdomen to exclude distant metastases (Figure 72.20). Ultrasonography of the liver and a chest radiograph are decreasingly used alternatives. Positron emission tomography (PET) scanning can be helpful in identifying metastases if imaging is otherwise equivocal.

Endoluminal ultrasound, performed using a probe placed in the rectal lumen, can be used to assess the local spread of the tumour (Figure 72.21), and is particularly accurate in staging the degree of penetration through the rectal wall in early tumours. CT is not particularly accurate in local staging, which is usually performed using magnetic resonance imaging (MRI), which allows assessment of the circumferential resection margin and adjacent structures (Figure 72.22).
Principles of surgical treatment

Radical excision of the rectum, together with the mesorectum and associated lymph nodes, should be the aim in most cases. Even in the presence of widespread metastases, a rectal excision should be considered, as this is often the best means of palliation. The presence of liver metastases does not necessarily rule out the feasibility of cure: the results of surgery for liver metastases have greatly improved, with long-term survival being achieved in over a third of patients.

When a tumour appears to be locally advanced (i.e. invading a neighbouring structure or threatening to breach the circumferential resection margin), the administration of a course of neoadjuvant (preoperative) chemoradiotherapy over approximately 6 weeks may reduce its size and make curative surgery possible. The administration of preoperative ‘short-course’ (5 days) neoadjuvant radiotherapy in resectable rectal cancer cases significantly reduces the incidence of local recurrence, but at the cost of some increase in complication rates.

For patients who are unfit for radical surgery, who have very early tumours or who have widespread metastases, a local procedure such as transanal excision, laser destruction or interstitial radiation should be considered.

When a rectal excision is possible, the aim should be to restore gastrointestinal continuity and continence by preserving the anal sphincter whenever feasible. A sphincter-saving operation (anterior resection) is usually possible for tumours whose lower margin is $\geq 2$ cm above the anal canal. Although removal of the rectum and anus with a permanent colostomy (abdominoperineal excision) was often required for tumours of the lower third of the rectum in the past, the introduction of the stapling gun has enabled many more of these patients to be treated by a sphincter-saving procedure. The principles of the operation involve radical excision of the neoplasm, removal of the mesorectum that surrounds it and high proximal ligation of the inferior mesenteric lymphovascular pedicle. Once the rectum has been adequately mobilised, it is removed, and the rectal stump is washed out. Restoration of continuity by direct end-to-end anastomosis (manually or by stapling) must be carried out by a meticulous technique to reduce the risks of anastomotic breakdown.

Rectosigmoid tumours and those in the upper third of the rectum are removed by ‘high anterior resection’, in which the rectum and mesorectum are taken to a margin 5 cm distal to the tumour, and a colorectal anastomosis is performed. This does not usually require defunctioning. The retention of at least a part of the rectum results in good postoperative function.

For tumours in the middle and lower thirds of the rectum, complete removal of the rectum and mesorectum is required, i.e. total mesorectal excision (TME). A temporary protecting stoma is usually formed after TME (see below under Anterior resection).

Preoperative preparation

Traditionally, the bowel was prepared by mechanical cleansing using a combination of diet, purgatives and enemas (e.g. senna,
This approach is now used more selectively, with many surgeons reserving full bowel preparation for those undergoing a low anterior resection, and clearing only the distal bowel using enemas in the rest. Prophylactic systemic antibiotics are given perioperatively. The antibiotic regimen must be active against both aerobic and anaerobic organisms. At present, a suitable prescription would be cefuroxime 750 mg plus metronidazole 500 mg given on induction of anaesthesia. If a patient comes to surgery with a loaded colon, on-table intraoperative irrigation can be performed.

All patients should see a stoma care nurse preoperatively and be sited for a temporary or permanent ileostomy or colostomy. They must also be counselled as to the complications of the procedure, and particularly about the risks of pelvic autonomic nerve damage causing bladder and sexual disturbance, especially impotence.

Blood and electrolyte deficiencies are corrected. Before commencing the operation, an indwelling catheter is inserted into the bladder (Summary box 72.11).

### Local operations

For small, low-grade T1 tumours, local removal should be curative in the vast majority; only a small percentage of these will have involved lymph nodes which are left undetected and unresolved by this approach. For these tumours, especially in the unfit or in patients who will not accept a colostomy, local removal has been used. This is usually done via the anus and the TEM technique is often used.

There is considerable controversy, however, as to whether such local techniques should be used for potentially curable lesions as they do not allow full histopathological staging or deal with the mesorectal or lymphatic spread of the tumour. Certainly the local recurrence rate (mostly due to lymph node metastases within the mesorectum) after local excision of T2 tumours is in the region of 20 per cent, which is unacceptable in all but those in whom radical surgery is associated with very high risk. Combined local excision with chemotherapy and radiotherapy has been suggested as a curative treatment for T1 and T2 tumours, but is not widely accepted.

### Anterior resection

In the last 30 years, there has been a move to extend sphinctersaving operations to treat most tumours of the middle third of the rectum, and indeed many in the lower third. Over the last five years it has become clear that this surgery can be performed laparoscopically with at least equivalent oncological outcomes. This is, however, technically challenging and should only be performed in this way by adequately trained and experienced surgeons.

Following a midline incision, the liver and the peritoneum are examined for metastases. The sigmoid and descending colon are freed by dividing the peritoneal reflection on the left side and mobilised to the midline on their mesentry. The splenic flexure is dissected and the left ureter and testicular or ovarian vessels are identified. The mesocolon is divided at the site of the proposed division of the colon and the trunk of the inferior mesenteric artery (Figure 72.23) is ligated and divided. Most surgeons divide the descending colon at this point.

The rectosigmoid mesentery is separated from the sacrum by sharp dissection with scissors or, more usually, diathermy. Great care is exercised to ensure that the hypogastric nerves are identified and preserved. It is essential that, as the distal dissection proceeds, the surgeon remains outside the mesorectal fascia and stays within the bloodless ‘holy’ plane outside it. The peritoneal incision is carried anteriorly around the rectum, and the seminal vesicles or the vaginal wall are identified so that Denonvilliers’ fascia behind them is cleared by a dissection leading down to the prostate or vagina. The condensations of fascia that attach the rectum to the pelvic side walls and are known as the lateral ligaments are dissected by diathermy. This tissue contains the middle rectal vessels, which sometimes require separate ligation and division.

The rectum is mobilised to the pelvic floor, and a right-angled clamp is placed at least 1 cm below the tumour. The rectum can then be stapled transversely. After the rectum and sigmoid colon have been excised, continuity is re-established by the method depicted in Figure 72.24. Although a single loop of colon is often used for the anastomosis, a short J-shaped colonic pouch may be

---

constructed with the aim of increasing neorectal capacity and thus reducing postoperative bowel frequency and urgency. Many surgeons believe that such a temporary defunctioning stoma is required for all colorectal and coloanal anastomoses that are constructed below the peritoneal reflection.

Occasionally, although the rectum, together with its tumour, can be removed adequately, continuity cannot be restored by a stapling technique. In such cases, it may still be possible to restore continuity by bringing the colon down to the anal canal and constructing a sutured coloanal anastomosis via the transanal route (Figure 72.25).

It is important to ensure that any free tumour cells released by mobilisation of the rectum are destroyed by irrigation of the rectal lumen with a cancercidal solution such as 1 per cent cetrimide. By so doing, the implantation of such cells and subsequent local recurrence is prevented. However, it should be realised that, although a small percentage of local recurrences are due to implantation of shed cells, the majority result from inadequate removal of the tumour at the time of the initial operation. It is now known that micrometastases are present in the mesorectum, and these are the most likely cause of local recurrence after rectal excision. It is essential to remove all the mesorectum during anterior resection or abdominoperineal

Figure 72.24 Low anterior resection by the double stapling method. The rectum has been excised, and the distal anorectal stump has been transected with a transverse stapling device. A circular stapling gun is used to construct (a) a straight low coloanal anastomosis or (b) a colonic pouch–anus anastomosis.

Figure 72.25 Abdominotransanal–coloanal anastomosis. (a) The rectum has been excised, and the mucosa from the distal anorectal stump has been removed, leaving the rectal muscle intact. The proximal colon has been brought down through the rectal muscular cuff to be anastomosed to the anal mucosa via the transanal route. (b) The completed coloanal anastomosis. A covering ileostomy has been performed to allow the anastomosis to heal.
Excision, the procedure known as TME. TME is now being practised worldwide and appears to reduce the risks of local recurrence substantially (Figure 72.26). This has been largely due to the work of Heald, who has shown that training in the technique improves local recurrence rates, and has been central to its widespread adoption. However, it is unlikely that surgery alone will deal adequately with all the micrometastases in the pelvis. Consequently, neoadjuvant radiotherapy may have added benefit (see below under Radiotherapy).

Hartmann’s operation

This is an excellent procedure in an old and frail patient in whom there is concern about anal sphincter function or the viability of an anastomosis. Through an abdominal incision, the rectum is excised, the anorectal stump is transected, usually with a stapler and an end colostomy is formed.

Abdominoperineal excision of the rectum

This operation is still required for some tumours of the lower third of the rectum, which are unsuitable for a sphincter-saving procedure. A large catheter is passed to allow easy identification of the urethra. Traditionally, the procedure was performed by two surgeons operating simultaneously, one via the abdomen and the other via the perineum with the patient in the Trendelenburg lithotomy position. More recently, there has been a shift to completing the abdominal procedure first (with the patient in the Lloyd-Davies position, in which the legs are in supports set lower than the lithotomy position), and then placing the patient prone and completing the operation via the perineum from behind (cylindrical or extra-levator abdominoperineal excision). There is evidence that this allows a wider dissection at the level of the pelvic floor, increasing complete resection rates and reducing local recurrence, although increasing morbidity.

The abdominal procedure is carried out laparoscopically or via a midline laparotomy, and is performed in the same way as an anterior resection, except that dissection stops before the pelvic floor is reached (at the level of the seminal vesicles in men or the cervix in women), to avoid ‘coning down’ onto the tumour at the level of the pelvic floor. The end colostomy is formed and the wounds closed.

The site for the colostomy in the left iliac fossa should have been marked preoperatively by the stoma care nurse in consultation with the patient. If this has not been possible, it should be sited equidistant from the umbilicus and the left anterior superior iliac spine at the linea semilunaris.

The perineal procedure is then carried out via an elliptical incision between the tip of the coccyx and the central perineal point around the anus. This is deepened until the pelvic floor is reached. This is divided as far laterally as possible, to maximise clearance of the tumour, which will be lying at this level (Figure 72.27). The dissection is extended posteriorly by incising Waldeyer’s fascia, which is a thick condensation of pelvic fascia lying between the rectum and the sacrum. Some surgeons routinely remove the coccyx to improve access and surgical margins. The dissection is deepened until the mobilisation performed via the abdomen is reached posteriorly and laterally. The plane between the rectum and the prostate in the male or between the rectum and the vagina in the female is developed, with particular care to avoid the membranous urethra in the male. The catheter within it should be palpated so that it can be avoided. The posterior wall of the vagina can be excised with the rectum if an advanced anterior tumour is present. The whole of the anus and rectum is drawn downwards and removed through the perineal wound.

Care of the colostomy

This is much the same as care of an ileostomy (Chapter 69). Within a very short time, the colostomy acts once or twice a day. Many patients are now taught to empty their lower colon by irrigation through the colostomy: this has many advantages for the patient who requires an inactive colostomy while at work.

Endoluminal stenting

An increasingly used alternative is placement of an endoluminal stent, which can be done endoscopically, often with fluoroscopic guidance. This can either be used as a palliative procedure, or to relieve obstruction and permit elective rather than emergency surgery to be undertaken. Only colonic and upper rectal tumours are suitable for stenting.

Palliative colostomy

This is indicated only in cases giving rise to intestinal obstruction, or where there is gross infiltration of the neoplasm. It is sometimes possible to resect the tumour later (e.g. after chemotherapy) and, in some cases, cure, rather than palliation, is achieved.
Other palliative procedures

Occasionally, a neodymium:yttrium–aluminium–garnet (Nd: YAG) laser can be used to deal with an obstructing or bleeding lesion, and intraluminal debulking has also been described.

More extensive operations

When the carcinoma of the rectum has spread to contiguous organs, the radical operation can often be extended to remove these structures. Thus, in the male, in whom spread is usually to the bladder, a cystectomy and resection of the rectum can be performed. In the female, the uterus acts as a barrier, usually preventing spread from the rectum to the bladder. Accordingly, a hysterectomy should be undertaken in addition to excision of the rectum. Pelvic evisceration for carcinoma of the rectum is justifiable only when the surgeon is confident that the growth can be completely removed.

Pelvic exenteration (Brunschwig’s operation)

The aim is to remove all the pelvic organs, together with the internal iliac and the obturator groups of lymph nodes (Figure 72.28). Ligation of both internal iliac arteries diminishes the blood loss. A rectus abdominis flap can be used to fill the empty pelvis. Special care must therefore be taken to suture the perineal skin accurately, and to avoid pressure necrosis of the perineal incision by nursing the patient on alternate sides. Some form of urinary diversion is necessary, usually an ileal conduit.

Liver resection

Single or several well-localised liver metastases can now be resected with relatively low mortality and morbidity. Provided the patients are carefully selected, a reasonable long-term

survival rate can be achieved (approximately 40 per cent in some series). Such surgery is usually carried out in a specialised liver unit, and it is generally advised that it takes place after the primary lesion has been dealt with (Summary box 72.12).

Summary box 72.12

Surgery for rectal cancer

- Surgery is the mainstay of curative therapy
- The primary resection consists of rectal excision with total mesorectal excision
- Most cases can be treated by anterior resection with the colorectal anastomosis being achieved with a circular stapling gun
- A smaller group of low, extensive tumours require an abdominoperineal excision with a permanent colostomy
- Preoperative radiotherapy can reduce local recurrence
- Adjuvant chemotherapy can improve survival in node-positive disease
- Liver resection in carefully selected patients offers the best chance of cure for single or well-localised liver metastases

Radiotherapy

Various trials have been performed to investigate the effect of adjuvant radiotherapy given either pre- or postoperatively. The overall results suggest that, provided an adequate dose is given, neoadjuvant radiotherapy can reduce the incidence of local recurrence; however, long-term survival is not affected. Recent studies have combined radiotherapy with chemotherapy in an attempt to shrink an extensive tumour prior to surgical excision. In some cases using this combined therapy, the results can be spectacular, and it has become the standard initial treatment for locally advanced tumours, allowing potentially curative resection in cases that would otherwise be inoperable. Indeed, in a few cases, the tumour appears to respond completely, making the approach to further management controversial.

Palliative irradiation can be given for inoperable primary tumours or local recurrence, especially when painful. Papillon refined a technique of intracavity radiation that applies the treatment direct to the tumour from the rectal lumen. In a selected series of early cases, the results were good (five-year survival rates of more than 70 per cent).

Chemotherapy

A variety of drugs has been tried both as an adjuvant therapy and for the treatment of disseminated disease. The most frequently used drug is 5-fluorouracil (5-FU) or its oral equivalent capecitabine. There is now good evidence that systemic 5-FU alone or in combination with oxaliplatin can improve survival by 10–15 per cent in node-positive disease. Similarly, studies in which 5-FU has been infused into the portal vein during and immediately after the primary operation have shown a small benefit. Such intraportal adjuvant therapy is thought to kill malignant cells, which are released into the circulation during operative manipulation of the tumour, and thus prevent the formation of metastases. Recently, some exciting new drugs have become available, the most notable being irinotecan and cetuximab. Both agents have been shown to have a moderate but beneficial effect in disseminated disease, but it remains to be seen whether they will be effective in an adjuvant setting.

Results of surgery for rectal cancer

In specialised centres, the resectability rate may be as high as 95 per cent, with an operative mortality of less than 5 per cent. Overall, the five-year survival rate is about 50 per cent.

Survival rates are influenced by TNM/Dukes’ stage, with node-positive patients doing worse than those with node-negative lesions (Figure 72.29). The bowel cancer screening programmes being introduced in many countries will result in earlier stage at presentation, and consequently improved outcome. The lower the tumour is in the rectum, the worse the outlook. Histological grade also influences outcome, with undifferentiated lesions having the worse prognosis.

Local recurrence

Local recurrence after rectal excision is a major problem. The patient often presents with persistent pelvic pain, which radiates down the legs if the sacral roots are involved. Bladder symptoms may occur. If recurrence develops after abdominoperineal excision, a swelling or induration may be present in the perineum, or an abscess or discharging sinus may develop. After sphincter-saving resection, there may be a change in bowel habit or the passage of blood per rectum. Sigmoidoscopic examination may reveal friable tissue at the anastomosis which, when biopsied, confirms the diagnosis. However, the recurrence is usually situated extrarectally, and is detected either as induration on digital examination or by endoluminal ultrasonography, CT or MRI. These investigations can also detect recurrence before it causes symptoms. Local recurrence rates vary between 2 and 25 per cent and are higher after abdominoperineal excision than after sphincter-saving resection. The most common cause is inadequate removal of the whole tumour at the initial operation. This is due to the presence of microscopic tumour deposits in

Figure 72.29 Cancer-specific survival rates following surgery for rectal cancer according to Dukes’ stages. Redrawn with permission from Keighley MRB, Williams NS. Surgery of the anus, rectum and colon. London: WB Saunders, 1999.
Further reading

If the mesorectum is removed in its entirety, the local recurrence rate can be reduced to less than 5 per cent. Less common causes of local recurrence include implantation of viable cells on the suture line and the development of a new primary tumour. Eighty per cent of all local recurrences develop within two years following surgery, and they are very difficult to treat. The best prospect of salvage is by surgical resection. However, it is possible to achieve apparently complete removal in only a minority of cases, and will usually involve hysterectomy, bladder resection and even partial sacrectomy. Radiotherapy also has an important role, but many patients will have already been exposed to a maximal dose during the treatment of the primary tumour.

Carcinoid tumour

Carcinoid tumour originates in the submucosa, with the mucous membrane over it being intact. Consequently, it seldom produces evidence of its presence in the early stages, when it presents as a small plaque-like elevation. The incidence of clinical malignancy, i.e. the occurrence of metastases, is 10 per cent. This is much less than that for carcinoid tumour of the small intestine, but it is greater than that for carcinoid tumour of the appendix. Multiple primary carcinoid tumours of the rectum are not infrequent. The neoplasm is of slow progression, and usually metastasises late. Large carcinoids (over 2 cm) are almost always malignant.

Treatment

Local excision is sufficient treatment for small carcinoids. Resection of the rectum is advisable if the growth is more than 2.5 cm in diameter, if recurrence follows local excision or if the growth is fixed to the perirectal tissues. Even when metastases are present, resection may prolong life.

FURTHER READING

ANATOMY AND PHYSIOLOGY

Surgical anatomy

The anal canal commences at the level where the rectum passes through the pelvic diaphragm and ends at the anal verge. The muscular junction between the rectum and anal canal can be felt with the finger as a thickened ridge – the anorectal ‘bundle’ or ‘ring’.

Anal canal anatomy

The anorectal ring

The anorectal ring marks the junction between the rectum and the anal canal (Figure 73.1). It is formed by the joining of the puborectalis muscle (Figure 73.2), the deep external sphincter, conjoined longitudinal muscle and the highest part of the internal sphincter. The anorectal ring can be clearly felt digitally, especially on its posterior and lateral aspects.

The puborectalis muscle

Puborectalis, part of the funnel-shaped muscular pelvic diaphragm, maintains the angle between the anal canal and rectum and hence is an important component in the continence mechanism (Figure 73.2). The muscle derives its nerve supply from the sacral somatic nerves, and is functionally indistinct from the external anal sphincter. The position and length of the anal canal, as well as the angle of the anorectal junction, depend to a major extent on the integrity and strength of the puborectalis muscle sling. It gives off fibres that contribute to the longitudinal muscle layer.

The external sphincter

The external sphincter forms the bulk of the anal sphincter complex and, although traditionally it has been subdivided into deep, superficial and subcutaneous portions, it is a single muscle (Goligher), which is variably divided by lateral extensions from the longitudinal muscle layer. Some of its fibres are attached posteriorly to the coccyx, whereas anteriorly they fuse with the perineal muscles. Being a somatic voluntary muscle, the external sphincter is red in colour and is innervated by the pudendal nerve.

To understand:
- The anatomy of the anus and anal canal and their relationship to surgical disease and its treatment
- The pathology, clinical presentation, investigation, differential diagnosis and treatment of diseases that affect the anus and anal canal
- That anal disease is common and its treatment tends to be conservative, although surgery may be required
- That too aggressive or inappropriate surgery may render the patient permanently disabled

LEARNING OBJECTIVES

The anus and anal canal

John Cedric Goligher, 1912–1998, Professor of Surgery, University of Leeds, Leeds, UK. Goligher is reputed to have said to his staff: ‘It is a simple system here: if you do not agree with the style or requirements of the man above you, leave’.

Figure 73.1 Relevant anatomy of the anus. Redrawn with permission from Mann CV. Surgical treatment of haemorrhoids. London: Springer, 2002.
The intersphincteric plane

Between the external sphincter muscle laterally and the longitudinal muscle medially exists a potential space, the intersphincteric plane. This plane is important as it contains intersphincteric anal glands (see below under The anal glands) and is also a route for the spread of pus, which occurs along the extensions from the longitudinal muscle layer. The plane can be opened up surgically to provide access for operations on the sphincter muscles.

The longitudinal muscle

The longitudinal muscle is a direct continuation of the smooth muscle of the outer muscle coat of the rectum, augmented in its upper part by striated muscle fibres originating from the medial components of the pelvic floor. Most of the muscle continues caudally before splitting into multiple terminal septa that surround the muscle bundles of the subcutaneous portion of the external sphincter to insert into the skin of the lowermost part of the anal canal and adjacent perianal skin. Milligan and Morgan named the most medial of these septa, passing around the inferior border of the internal sphincter, the ‘anal intermuscular septum’. As it descends, however, it gives off fibres that pass medially across the internal sphincter to reach the submucosal space and laterally across the external sphincter and ischiorectal space to reach the fascia of the pelvic side walls. As well as providing a supportive mesh for the anal canal and other muscular components, its ramifications provide potential pathways for the spread of infection. During defaecation, its contraction widens the anal lumen, flattens the anal cushions, shortens the anal canal and everts the anal margin; subsequent relaxation allows the anal cushions to distend and thus contribute to an airtight seal.

The internal sphincter

The internal sphincter is the thickened (2–5 mm) distal continuation of the circular muscle coat of the rectum, which has developed special properties and which is in a tonic state of contraction. This involuntary muscle commences where the rectum passes through the pelvic diaphragm and ends above the anal orifice, its lower border palpable at the intersphincteric groove, below which lie the most medial fibres of the subcutaneous external sphincter, and separated from it by the anal intermuscular septum. When exposed during life, it is pearly-white in colour and its circumferentially placed fibres can be seen clearly. Although innervated by the autonomic nervous system, it receives intrinsic non-adrenergic and non-cholinergic (NANC) fibres, stimulation of which causes release of the neurotransmitter nitric oxide, which induces internal sphincter relaxation.

The epithelium and subepithelial structures

The pink columnar epithelium lining the rectum extends through the anorectal ring into the surgical anal canal. Passing downwards, the mucous membrane becomes cuboidal and redder in colour (Figure 73.3), whereas above the anal valves it is plum coloured. Just below the level of the anal valves there is an abrupt, albeit wavy, transition to stratified squamous epithelium, which is the colour of parchment. This wavy junction constitutes the dentate line. The dentate line is a most important landmark both morphologically and surgically, representing the site of fusion of the proctodeum and post- allantoic gut, and being the site of the crypts of Morgagni (synonym: anal crypts, sinuses). The latter are small pockets between the inferior extremities of the columns of Morgagni through which anal ducts that communicate with deeper placed anal glands open into the anal lumen. The squamous epithelium lining the lower anal canal is thin and shiny and is known as the anoderm; it differs from the true skin in that it has no epidermal appendages, i.e. hair and sweat glands. At the dentate line, the anoderm is attached more firmly to deeper structures. The mucosa and submucosa above the dentate line is uneven and thrown into folds, the so-called anal...
cushions. There are variations in the numbers and positions of these cushions, but there are usually three, corresponding to those seen in later life. These are described classically as occupying the left lateral, right posterior and right anterior positions, and they continue proximally as the primary rectal foldings. Secondary foldings (the rectal columns of Morgagni) lie both over and between the primary folds. This area is the caudal limit of the so-called epithelial transitional zone, below which the stratified squamous epithelium is richly innervated by sensory nerve endings serving several modalities including touch, pain and temperature. The bulk of the anal cushions themselves, situated in the upper part of the anal canal, receive only visceral afferent innervation and, although there is perception of stretching, sensitivity to noxious stimuli is much more blunted than distally.

Between the epithelial layer and the internal sphincter lies the submucosa, consisting of vascular, muscular and connective tissue supportive elements. From the longitudinal muscle, medial extensions cross the internal anal sphincter and form part of the supporting meshwork of the submucosa, blending with the true submucosal smooth muscle layer and thereby supporting the mucosa itself. Parks described the increased density of fibres that insert into the mucosa of the anal crypts at the level of the dentate line, termed the 'mucosal suspensory ligament'. One feature of this structure is that it separates the superior (portal) and inferior (systemic) haemorrhoidal plexuses, another that the mucosa is more firmly tethered to underlying tissues at this level than above. It is important to appreciate that the meshwork of supporting tissues (muscle fibres and connective tissue) within the subepithelial space is intimately linked to deeper structures within the anal sphincter complex, including the internal sphincter, longitudinal muscle layer and external anal sphincter, and indeed structures beyond the sphincter complex. With age, the smooth muscle component of this mesh is reduced and muscle fibres are gradually replaced with fibroelastic connective tissue, which in turn becomes fragmented.

**Blood supply**

In addition to the meshwork support of the lining of the anal canal, the subepithelial space contains venous dilatations supported by the same fibroelastic connective tissue and smooth muscle scaffolding. Debate has centred on the nature of the vascular component of haemorrhoids, but the seminal anatomical studies of Thomson have clarified this issue. Venous dilatations are seen in the submucosa both above and below the level of the dentate line; they are much more numerous above, although tend to be larger below. The historical description of the blood supply to the upper anal canal as constant, with bifurcation of the main trunk of the superior rectal artery into right and left branches and with subsequent division of the former into anterior and posterior divisions thereby determining the sites of haemorrhoids around the anal circumference, was questioned by Thomson. He demonstrated that the divisions of the superior rectal artery were not constant and that, furthermore, the anal submucosa in a proportion of his specimens received a blood supply from the middle and inferior rectal arteries. He was also able to show the presence of free communications between tributaries of the superior, middle and inferior rectal veins, as well as tiny direct arteriovenous communications with the submucosal venous dilatations. These communications have been shown both histologically and radiologically, and the oxygen tension of the blood contained within the venous dilatations (as well as the colour) is more arterial than venous.

**Venous drainage**

The anal veins are distributed in a similar fashion to the arterial supply. The upper half of the anal canal is drained by the superior rectal veins, tributaries of the inferior mesenteric vein and thus the portal venous system, and the middle rectal veins, which drain into the internal iliac veins. The inferior rectal veins drain the lower half of the anal canal and the subcutaneous perianal plexus of veins: they eventually join the internal iliac vein on each side.

**Lymphatic drainage**

Lymph from the upper half of the anal canal flows upwards to drain into the postrectal lymph nodes and from there goes to the para-aortic nodes via the inferior mesenteric chain. Lymph from the lower half of the anal canal drains on each side first into the superficial and then into the deep inguinal group of lymph glands. However, if the normal flow is blocked, e.g. by tumour, the lymph can be diverted into the alternative route (Summary box 73.1).

---

**Summary box 73.1**

**Anal canal anatomy**

- The internal sphincter is composed of circular, non-striated involuntary muscle supplied by autonomic nerves.
- The external sphincter is composed of striated voluntary muscle supplied by the pudendal nerve.
- Extensions from the longitudinal muscle layer support the sphincter complex.
- The space between the sphincters is known as the intersphincteric plane.
- The superior part of the external sphincter fuses with the puborectalis muscle, which is essential for maintaining the anorectal angle, necessary for continence.
- The lower part of the anal canal is lined by sensitive squamous epithelium.
- Blood supply to the anal canal is via superior, middle and inferior rectal vessels.
- Lymphatic drainage of the lower half of the anal canal goes to inguinal lymph nodes.

**The anal glands**

Anal glands (which are not vestigial remnants of sexual scent glands) may be found in the submucosa and intersphincteric space (Figure 73.4), and normally number between 0 and 10 in an individual. They drain via ducts into the anal sinuses at the level of the dentate line. Not all sinuses have a duct draining to them and, occasionally, more than one gland can discharge into the same sinus. Their function is unknown, although they secrete mucin (distinct from that secreted by the rectal epithe-
Examination of the anus

Careful clinical examination will be diagnostic in the vast majority of patients complaining of anal symptoms, but it requires a relaxed patient who is informed of what the examination will entail, a private environment, a chaperone (for the security of both parties) and good light. Most commonly, the patient is examined in the left lateral (Sims) position with the buttocks overlying the edge of the examination couch and with the axis of the torso crossing, rather than parallel with, the edge of the couch. Alternatively, in younger patients, the prone jackknife or knee–elbow positions may be used (Figure 73.5). The examining couch should be of sufficient height to allow easy inspection and access for any necessary manoeuvres. A protective glove should be worn.

Inspection

The buttocks are gently parted to allow inspection of the anus and perineum: the presence of any skin lesions and whether they are confined to the perineum or evident elsewhere on general examination, e.g. psoriasis, lichen planus, or on genital examination, e.g. warts, candidiasis, lichen sclerosus et atrophicus, the vesicles of herpes simplex virus (HSV); evidence of anal leakage; whether the anus is closed or patulous; and the position of the anus and perineum at rest and on bearing down (the latter may reveal prolapse of haemorrhoids or even the rectum). Pain on parting the buttocks, perhaps together with the presence of a sentinel tag, may indicate the presence of an underlying fissure, but may also prompt the need for examination under anaesthesia to exclude more suspicious pathology, for example squamous cell carcinoma of the anal canal.

Digital examination with the index finger

With an adequately lubricated index finger, the soft tissues around the anus are palpated for induration, tenderness and subcutaneous lesions. The index finger is then introduced gently into the anal canal along its posterior aspect. At the apex of the canal, the sling of puborectalis is felt posteriorly; supralevalator induration feels bony hard and is more easily appreciated if unilateral. The posterior surface of the prostate gland with its median sulcus can be palpated anteriorly in male patients; in female patients, the uterine cervix can be palpated. The presence of any distal intrarectal, intra-anal or extraluminal mass is recorded. Sphincter length, resting tone and voluntary squeeze...
are assessed. On withdrawal, the examining finger is inspected for the presence of mucus, blood or pus, and to identify stool colour.

**Proctoscopy**

Proctoscopy (Figure 73.6), performed with the patient in the same position, allows a detailed inspection of the distal rectum and anal canal. Minor procedures can also be carried out through this instrument, e.g. treatment of haemorrhoids by injection or banding (see below Management under Haemorrhoids) and biopsy. Asking the patient to bear down on slow withdrawal of the proctoscope may reveal a descending intussusception.

**Sigmoidoscopy**

Although sigmoidoscopy (see Chapter 72) is strictly an examination of the rectum, it should always be carried out even when an anal lesion has been confirmed. Rectal pathology, e.g. colitis or carcinoma, is frequently associated with an anal lesion, e.g. fissure or haemorrhoids. Not infrequently, rectal pathology is found that is independent of the anal lesion and which requires treatment (Summary box 73.2).

---

**PHYSIOLOGICAL ASPECTS OF THE ANAL SPHINCTERS AND PELVIC FLOOR, AND SPECIAL INVESTIGATIONS**

Anal continence and defaecation are highly complex processes that necessitate the structural and functional integrity of the cerebral, autonomic and enteric nervous systems, the gastrointestinal tract (especially the rectum) and the pelvic floor and anal sphincter complex, any of which may be compromised and lead to disturbances of function of varying severity. The sphincter mechanism provides the ultimate barrier to leakage and its integrity can be assessed fairly simply and objectively in the physiology laboratory (Swash and Henry). Perineal position and degree of descent on straining (markers of pelvic floor and pudendal nerve function) can be quantified, and functional anal canal length, resting tone (reflective predominantly of internal sphincter activity) and squeeze increment (reflective of external sphincter function) can be measured by a variety of simple manometric techniques (Figure 73.7). The structural integrity of the sphincters can be visualised with endoluminal ultrasound (Figure 73.8), and neuromuscular function can be measured by assessment of conduction velocity along the pudendal nerve on each side, or, more painfully, by needle electromyogram (EMG) studies (Figures 73.9 and 73.10). In the elderly especially, but also in younger patients, disorders relating to rectal sensorimotor dysfunction can lead to ‘overflow’ of rectal contents through what may be an otherwise normal sphincter. The dynamics of defaecation can also be assessed radiologically by evacuation proctography, in which radio-opaque pseudo-stool is inserted into the rectum and the patient asked to rest, squeeze and then bear down to evacuate the rectal contents under real-time imag-
Physiological aspects of the anal sphincters and pelvic floor, and special investigations

Figure 73.11 Integrated dynamic proctography. (a) At rest; (b) during evacuation. Visualisation of the rectum is achieved using barium-impregnated 'synthetic stool'. The effects of straining and evacuation on the electromyographic activity of the sphincter muscles and intrarectal pressure can be simultaneously recorded (Williams).

Proctography can be combined with synchronous EMG and pressure studies (Williams) (Figure 73.11) to yield more information about possible reasons (mechanical (rectocoele, intussusception) or functional (anismus, lack of effort)) for disordered defaecation in an individual. More recently, use of the
The much more expensive modality of dynamic magnetic resonance proctography has become more widespread, although studies in which the subject is asked to evacuate in the supine position may be less physiological than those in which the subject adopts a sitting position within an open magnet. Results of all physiological and imaging tests have to be compared with a robust normal range and within the context of the patient’s symptoms, and are used to guide rational rather than empirical treatment strategies.

**CONGENITAL ABNORMALITIES**

Early in embryonic life there is a common chamber – the cloaca – into which the hind gut and the allantois open. This endoderm-lined chamber is separated from the surface ectoderm of the embryo by the cloacal membrane. The cloaca becomes divided into two parts, dorsal (rectum) and ventral (urogenital sinus), by the downgrowth of a septum. The dorsal part of the cloacal membrane, known as the anal membrane, is thus composed of an outer layer of ectoderm and an inner layer of endoderm. Resorption of this anal membrane by the 8th week of embryonic life creates the anal canal.

**Imperforate anus**

Imperforate anus (see Chapter 8) (strictly, it should be anal ‘agenesis’ or ‘atresia’) has historically been divided into two main groups – high and low – depending on the level of termination of the rectum in relation to the pelvic floor. Treatment and prognosis are influenced by any associated abnormalities of the sacrum and genitourinary systems. In both sexes, low defects embrace rectoperineal fistula (Figure 73.12), covered anus and anal membrane. The most frequent defect in boys with imperforate anus is one in which the distal rectum is sited within the puborectalis sling, but terminates as a fistula into the bulbar urethra (Figure 73.13) (see also Chapter 8, Figure 6.32) or prostatic urethra above the main anal sphincter complex. Boys with a fistula into the bladder neck (a high defect) have the poorest prognosis because of the underdevelopment of the sacrum and pelvic and anal musculature. The most common defect in girls is a rectovestibular fistula, in which the fistula opens into the posterior vestibule (not the vagina) (Figure 73.12). The finding of a single perineal orifice indicates a persistent cloaca in which the rectum, vagina and urinary tract form a confluence (Figure 73.13); the longer the common channel, the greater the likelihood of more complex defects, including vaginal and uterine septation, duplication or atresia. An anterior anus, although not imperforate, is not fully located within the sphincter mechanism and is regarded as part of the spectrum of anorectal malformations (Figure 73.12).

**Clinical management**

Careful perineal examination will usually provide the most important clues about the neonate’s type of malformation. The presence of meconium on the perineum indicates a low defect and meconium in the urine is evidence of a urinary tract fistula. During the first 24 hours, the baby should receive intravenous fluids and antibiotics, and should be evaluated for associated congenital anomalies. By 24 hours, the distal limit of air within the rectum, seen on a lateral prone radiograph, indicates the distance between the rectal stump and perineum (Figure 73.14).

**Treatment**

Low anomalies with a perineal fistula can be treated by an anoplasty. More complex malformations require early colostomy, with definitive repair performed several months later. This may
involve posterior sagittal anorectoplasty (PSARP, Pena) with or without transabdominal mobilisation of the left colon and division of any communication with the urinary tract. In girls with a cloaca and long common channel, urinary and vaginal reconstruction is also required. Postoperatively, a programme of anal dilatation is instituted, and any residual colostomy is closed at a later date. Ultimate bowel function (voluntary bowel movements, continence, constipation) is related to the type of anorectal abnormality and the presence of associated defects, especially sacral (Summary box 73.3).

Summary box 73.3

Imperforate anus
- A rare congenital disorder
- Classified as being high or low depending on the site of the rectal termination in relation to the pelvic floor
- Low defects: relatively easy to correct, but prone to constipation
- High defects: more difficult to correct and prone to faecal incontinence

Post-anal dermoid

The space in front of the lower part of the sacrum and coccyx may be occupied by a soft, cystic swelling – a post-anal dermoid cyst. Hidden in the hollow of the sacrum, it is unlikely to be discovered unless a sinus communicating with the exterior is present or it develops as a result of inflammation. Such a cyst usually remains asymptomatic until adult life, when it is prone to becoming infected. Exceptionally, because of its size, it gives rise to difficulty in defaecation. The cyst is easily palpable on rectal examination.

Differential diagnosis

Especially in a child, an anterior sacral meningocoele must be excluded. This enlarges when the child cries and is frequently associated with paralysis of the lower limbs and incontinence. When a discharging sinus is present, a post-anal dermoid will probably be mistaken for a pilonidal sinus or even an anal fistula. Pressure over the sacrococcygeal region with a finger in the.

Alberto Pena, contemporary, Professor of Pediatric Surgery, Schneider Children’s Hospital, New York, NY, USA.
rectum may cause a flow of sebaceous material, and injection of contrast media followed by radiography reveals a bottle-necked cyst in front of the coccyx.

Treatment
Treatment involves complete excision of the cyst and, if present, the sinus. In the case of large cysts, it is necessary to remove the coccyx to gain access. The coccyx should also be removed en bloc in any child with a presacral dermoid because of the risk of sacrococcygeal teratoma.

Post-anal dimple
A post-anal dimple (synonym: fovea coccygea) is a dimple in the skin beneath the tip of the coccyx, sometimes amounting to a short blind pit. It is noticed from time to time in the course of a clinical examination and is of no consequence.

Pilonidal sinus
The term 'pilonidal sinus' describes a condition found in the natal cleft overlying the coccyx, consisting of one or more, usually non-infected, midline openings, which communicate with a fibrous track lined by granulation tissue and containing hair lying loosely within the lumen. A common affliction among the military, it has been referred to as 'jeep disease'.

Aetiology and pathology
Although acquired theories of development are better accepted than the more historical congenital theories, exact mechanisms of development are speculative. Evidence that supports the acquired theory of origin of pilonidal sinuses can be summarised as follows:

- Intergluteal pilonidal sinus is an occupational disease of hairdressers, the hair within the interdigital cleft or clefts being from the customers. Pilonidal sinuses of the axilla and umbilicus have also been reported.
- The age incidence of the appearance of pilonidal sinus (82 per cent occur between the ages of 20 and 29 years) is at variance with the age of onset of congenital lesions.
- Hair follicles have almost never been demonstrated in the walls of the sinus.
- The hairs projecting from the sinus are dead hairs, with their pointed ends directed towards the blind end of the sinus.
- The disease mostly affects men, in particular hairy men.
- Recurrence is common, even though adequate excision of the track is carried out.

It is thought that the combination of buttoc k friction and shearing forces in that area allows shed hair or broken hairs which have collected there to drill through the midline skin, or that infection in relation to a hair follicle allows hair to enter the skin by the suction created by movement of the buttocks, so creating a subcutaneous, chronically infected, midline track. From this primary sinus, secondary tracks may spread laterally, which may emerge at the skin as granulation tissue-lined, discharging openings. Usually, but not invariably (when diagnosis may be confused with anal fistula or hidradenitis suppurativa), the sinus runs cephalad. Carcinoma arising in chronic pilonidal disease has been described, but is exceedingly rare.

Clinical features
The condition is seen much more frequently in men than in women, usually after puberty and before the fourth decade of life, and is characteristically seen in dark-haired individuals rather than those with softer blond hair (Oldham). Patients complain of intermittent pain, swelling and discharge at the base of the spine, but little in the way of constitutional symptoms. There is often a history of repeated abscesses that have burst spontaneously or which have been incised, usually away from the midline. The primary sinus may have one or many openings, all of which are strictly in the midline between the level of the sacrococcygeal joint and the tip of the coccyx.

Conservative treatment
As the natural history of the condition is usually one of regression, in those whose symptoms are relatively minor, simple cleaning out of the tracks and removal of all hair, with regular shaving of the area and strict hygiene, may be recommended.

Treatment of an acute exacerbation (abscess)
If rest, baths, local antiseptic dressings and the administration of a broad-spectrum antibiotic fail to bring about resolution, the abscess should be drained through a small longitudinal incision made over the abscess and off the midline, with thorough curetage of granulation tissue and hair. This procedure may or may not be associated with complete resolution.

Surgical treatment of chronic pilonidal disease
The multitude of surgical procedures advocated to eradicate pilonidal disease, combined with the lack of prospective trials, attests to the lack of overall superiority of one method over the others. Time spent on work and perceived recurrence rates, but more usually surgeon preference, influence the choice of method, which includes the laying open of all tracks with or without marsupialisation, the excision of all tracks with or without primary closure, and the excision of all tracks and then closure by some other means designed to avoid a midline wound (Z-plasty, Karydakis procedure (Figure 73.15)). Bascom's procedure involves an incision lateral to the midline to gain access to the sinus cavity, which is rid of hair and granulation tissue (Figure 73.16), and excision and closure of the midline pits (Figure 73.17). The lateral wound is left open (Figure 73.18). Irrespective of procedure, postoperative wound care is important and centres around elimination of hair (ingrown, local or other) from the wound.

Recurrent pilonidal sinus
Three possibilities account for this disappointment:

- part of the sinus complex has been overlooked at the primary operation;
- new hairs enter the skin or the scar;
- there is persistence of a midline wound caused by shearing forces and scarring; in this situation, revisional surgery may include re-excision followed by wound closure and

obliteration of the natal cleft either by myocutaneous rotational buttock flap or cleft closure (Bascom).

**ANAL INCONTINENCE**

**Aetiology**

As continence is dependent upon the structural and functional integrity of both the neurological pathways and the gastrointestinal tract, the risk factors for anal incontinence are many (Summary box 73.4). Patients complaining of the involuntary loss of rectal contents require a comprehensive assessment of the nature and severity of symptoms; past history, especially of gastrointestinal disease, neurological conditions, obstetric events and anal surgery; and careful clinical examination (in the elderly, incontinence is often one of overflow secondary to rectal impaction, and proctitis may lead to such an irritable rectum that even the strongest sphincter is occasionally overwhelmed). A combination of history and examination will usually be diagnostic, but special investigations are then usually required to clarify the exact cause, including exclusion of an underlying malignancy, and to direct management.

Sphincteric causes of incontinence may be classified as structural, in which there is disruption (or atrophy) of part of the sphincter muscles, neuropathic (previously termed idiopathic), in which the nerve supply to the sphincters is damaged, usually by chronic straining or complicated vaginal delivery (prolonged second stage), or a combination of the two. The most common causes of sphincteric disruption are obstetric damage, anal surgery (following haemorrhoidectomy, dilatation or sphincterotomy for anal fissure, and fistulotomy for anal fistula) and trauma (including anal intercourse, forced or otherwise).
In general, conservative measures to reduce symptoms are employed initially. These may be in the form of stool bulking or constipating agents, nurse-led bowel retraining including specific biofeedback programmes, or anal plugs, which expand within and thus seal the anal canal. Failure of such measures and severity of symptoms may result in selection for surgery.

Operations to reunite divided sphincter muscles

In situations in which there is a discrete disruption of the sphincters, the ends of the divided muscle are found and reunited by a double overlap repair (Figure 73.19).

Operations to reef the external sphincter and puborectalis muscle

If the sphincter muscles are stretched and patulous (as they often are in old age and in cases of rectal prolapse) they may be tightened by a post-anal repair, which, through the use of darns of absorbable material to narrow down and plicate the external sphincter and the puborectalis sling (Figure 73.20), aims to recreate the anorectal angle and to restore length to the anal canal and strength to the anal sphincter. The approach is usually through the intersphincteric plane. The operation is now much less popular because long-term outcomes have been reported as poor.

Operations to augment the anal sphincters

If the degree of sphincter disruption or weakness is such that restoration of function cannot be achieved by direct means, the sphincter can be augmented by using muscle transposed from nearby (gluteus maximus or gracilis) or by using an artificial

In general, conservative measures to reduce symptoms are employed initially. These may be in the form of stool bulking or constipating agents, nurse-led bowel retraining including specific biofeedback programmes, or anal plugs, which expand within and thus seal the anal canal. Failure of such measures and severity of symptoms may result in selection for surgery.
Anal incontinence

Sphincter. Transposition of the gracilis muscle around the anal canal is followed by electrical stimulation, with conversion from a fast-twitch to a less fatiguable slow-twitch muscle by an implanted pacemaker (Williams) (Figure 73.21). Because of its magnitude, this technique is performed only in highly selected and motivated patients, most of whom have had more conventional treatment that has failed to cure their incontinence; it is effective in approximately 60 per cent of patients in the long term. A simpler means of augmenting the sphincter, developed initially for urinary incontinence, is the placement of an inflatable silastic cuff around the anal canal. When evacuation is required, the cuff is deflated by squeezing a small balloon positioned in the scrotum or labia, the balloon being attached to a subcutaneous reservoir (Figure 73.22). However, because this device is a foreign body that exerts pressure on the bowel wall, erosion and infection have been found to be common problems. To reduce the risk of septic complications the operation should be covered by antibiotics active against both aerobic and anaerobic organisms. Paradoxically, all of these methods used to treat incontinence may be associated with difficulties in rectal evacuation.

More recently, again as a result of its use in urinary incontinence, sacral nerve stimulation has been used to treat faecal incontinence, with encouraging short- and medium-term results.
Rather than any direct action on sphincter strength, this technique appears to work by sensorimotor neurophysiological modulation of the hindgut through electrical stimulation of the sacral nerve roots via a needle positioned through one of the posterior sacral foramina (Figure 73.23). A potential advantage of this technique is its relatively non-invasive nature, as well as the fact that its effects can be tested by temporary stimulation using an external stimulator before the expensive permanent pacemaker is implanted. A much cheaper and less invasive novel technique to treat faecal incontinence, again mediated through neuromodulation is percutaneous posterior tibial nerve stimulation (PTNS) whereby the tibial nerve at the ankle is electrically stimulated once per week for several minutes. The course of treatment is usually for 12 weeks and is administered on an outpatient basis. Results from prospective comparative studies are eagerly awaited.

For some patients, and in those in whom quality of life remains poor despite attempts at restoring continence, a permanent stoma can provide relief from a condition which is both disabling and socially isolating.

exaggerated shearing forces acting at that site at defaecation, combined with a less elastic anoderm endowed with an increased density of longitudinal muscle extensions in that region of the anal circumference. Anterior anal fissure is much more common in women and may arise following vaginal delivery. Perpetuation and chronicity may result from repeated trauma, anal hypertonicity and vascular insufficiency, either secondary to increased sphincter tone or because the posterior commissure is less well perfused than the remainder of the anal circumference.

**Clinical features**

Simple epithelial splits, because of their location involving the exquisitely sensitive anoderm, acute anal fissures are characterised by severe anal pain associated with defaecation. This usually resolves spontaneously after a variable time only to recur at the next evacuation, as well as the passage of fresh blood, normally noticed on the tissue after wiping. Chronic fissures are characterised by a hypertrophied anal papilla internally and a sentinel tag externally (both consequent upon attempts at healing and breakdown), between which lies the slightly indurated anal ulcer overlying the fibres of the internal sphincter. When chronic, patients may also complain of itching secondary to irritation from the sentinel tag, discharge from the ulcer or discharge from an associated intersphincteric fistula, which has arisen through infection penetrating via the fissure base. Although most sufferers are young adults, the condition can affect any age, from infants to the elderly. Men and women are affected equally. Anterior fissures account for about 10 per cent of those encountered in women, but only 1 per cent in men. A fissure sited elsewhere around the anal circumference or with atypical features should raise the suspicion of a specific aetiology, and failure of adequate examination in the clinic should prompt early examination under anaesthesia, with biopsy and culture to exclude Crohn’s disease, tuberculosis, sexually transmitted or human immunodeficiency virus (HIV)-related ulcers (syphilis, Chlamydia, chancroid, lymphogranuloma venereum, HSV, cytomegalovirus, Kaposi’s sarcoma, B-cell lymphoma) and squamous cell carcinoma (Summary box 73.5).
bivalved speculum at the intersphincteric groove. In the closed
knife position. The distal internal sphincter is palpated with a
thesia, and with the patient in the lithotomy or prone jack-
open or a closed method, under local, regional or general anaes
positions (Notaras). The procedure can be carried out using an
the fissure itself – usually either in the right or the left lateral
ateral anal sphincterotomy

Fissure healing can also be achieved by a posterior division
of the exposed fibres of the internal sphincter in the fissure base,
which is divided, and the wound is closed with absorbable

Operative measures
Historically, under regional or general anaesthesia, forceful
manual (four- or eight-digit) sphincter dilatation was used to
reduce sphincter tone; however, this was achieved in an uncon-
trolled fashion with potential disruption at multiple sites of
the internal (and even external) sphincter. The risk of inconti-
ence following this procedure has now made it unpopular,
although more conservative controlled stretching is still prac-
tised in young men with very high sphincter tone.

Fissure healing can also be achieved by a posterior division
of the exposed fibres of the internal sphincter in the fissure base,
but this is associated with prolonged healing, as well as passive
anal leakage thought mainly to be due to the resulting keyhole
gutter deformity; however, it may be indicated if there is an
associated intersphincteric fistula.

Lateral anal sphincterotomy
In this operation, the internal sphincter is divided away from
the fissure itself – usually either in the right or the left lateral
positions (Notaras). The procedure can be carried out using an
open or a closed method, under local, regional or general anaes-
thesia, and with the patient in the lithotomy or prone jack-
knife position. The distal internal sphincter is palpated with a
bivalved speculum at the intersphincteric groove. In the closed
method, a small longitudinal incision is made over this, and the
submucosal and intersphincteric planes are carefully developed
to allow precise division of the internal sphincter with a knife
or scissors to the level of the apex of the fissure; the wound is
then closed with absorbable sutures. Alternatively, either plane
can be entered using a scalpel (No. 11 blade), with the blade
advanced parallel to the sphincter and then rotated such that
the sharp edge faces the internal sphincter, which can then be
divided along its distal third. Pressure should be applied to the
wound for a few minutes to prevent haematoma formation. In
the open technique, the anoderm overlying the distal internal
sphincter is divided longitudinally to expose the sphincter,
which is divided, and the wound is closed with absorbable
sutures. Although the fissure needs no specific attention, prob-
lomatic papillae and external tags can be excised concomitantly.

Early complications of sphincterotomy include haemorrhage,
haematoma, bruising, perianal abscess and fistula. Despite low
recurrence rates, the most important complication is inconti-
nence of a variable nature and severity, which may affect up to
30 per cent of patients, particularly women, who have weaker,
shorter sphincter complexes and in whom there may already
have been covert sphincter compromise incurred by childbirth.

Anal advancement flap
The recognition of the risk to continence following internal
sphincterotomy has led some to advocate a different approach,
especially in women and those with normal or low resting anal
pressures, developed from the treatment of anal stenosis. After
excision of the edges of the fissure and, if necessary, its base
overlying the internal sphincter, an inverted house-shaped flap
of perianal skin is carefully mobilised on its blood supply and
advanced without tension to cover the fissure, and then sutured
with interrupted absorbable sutures (Figure 73.25). The patient
is maintained on stool softeners and bulking agents postop-
eratively, and usually also on topical sphincter relaxants; minor
downbreak of one anastomotic edge does not herald ultimate
failure (Summary box 73.6). The technique appears to work
irrespective of sphincter hypertonicity or patient gender.
Summary box 73.6

Treatment of an anal fissure

- Conservative initially, consisting of stool-bulking agents and softeners, and chemical agents in the form of ointments designed to relax the anal sphincter and improve blood flow
- Surgery if above fails, consisting of lateral internal sphincterotomy or anal advancement flap

Hypertrophied anal papilla

Anal papillae occur at the dentate line and are remnants of the ectodermal membrane that separated the hindgut from the proctodaeum. As these papillae are present in 60 per cent of patients examined proctologically, they should be regarded as normal structures. Anal papillae can become elongated, as they frequently do in the presence of an anal fissure. Occasionally, an elongated anal papilla may be the cause of pruritus. An elongated anal papilla associated with pain and/or bleeding at defaecation is sometimes encountered in infancy. Haemorrhage into a hypertrophied anal papilla can cause sudden rectal pain. A prolapsed papilla may become nipped by contraction of the sphincter mechanism after defaecation. Occasionally, a red oedematous papilla is encountered, with local pain and a purulent discharge from the associated crypt. This condition of 'cryptitis' may be cured by laying open the mouth of the infected anal gland and excising the papilla. Troublesome papillae may be simply excised.

Proctalgia fugax

This problem is characterised by attacks of severe pain arising in the rectum, recurring at irregular intervals and apparently unrelated to organic disease. The pain is described as cramp-like, often occurs when the patient is in bed at night, usually lasts only for a few minutes and disappears spontaneously. It may follow straining at stool, sudden explosive bowel action or ejaculation. It seems to occur more commonly in patients suffering from anxiety or undue stress, and it is also said to afflict young doctors. The pain may be unbearable – it is possibly caused by segmental cramp in the pubococcygeus muscle. It is unpleasant and incurable, but is fortunately harmless and gradually subsides. If patients have frequent attacks, they may benefit from amitryptiline. Salbutamol inhalers have been suggested as treatment for acute attacks. A more chronic form of the disease has been termed the 'levator syndrome' and can be associated with severe evacuatory dysfunction. Biofeedback techniques have been used to help such patients; in the past, some surgeons tried severing the puborectalis muscle, but this can cause incontinence and should never be carried out.

HAEMORRHOIDS

The prevalence of haemorrhoids when patients are assessed proctoscopically far outweighs the prevalence of symptoms, and the term should only be used when patients have symptoms referable to them. Occasionally, patients with portal hypertension develop rectal varices, but these should not be confused with haemorrhoids as the consequences may be disastrous. Internal haemorrhoids (Greek: haima, blood; rhoos, flowing; synonym: piles, Latin: pila, a ball) are symptomatic anal cushions and characteristically lie in the 3, 7 and 11 o’clock positions (with the patient in the lithotomy position). In addition, haemorrhoids may be observed between the main pile masses, in which case they are internal haemorrhoids at the secondary position. External haemorrhoids relate to venous channels of the inferior haemorrhoidal plexus deep in the skin surrounding the anal verge and are not true haemorrhoids; they are usually only recognised as a result of a complication, which is most typically a painful solitary acute thrombosis. External haemorrhoids associated with internal haemorrhoids ('interoexternal piles') result from progression of the latter to involve both haemorrhoidal plexuses and are best thought of as being external extensions of internal haemorrhoids. Secondary internal haemorrhoids arise as a result of a specific condition, although the mechanisms involved may be the same as those involved in the formation of primary internal haemorrhoids. The most important cause, albeit relatively uncommon, is carcinoma of the anorectum (Figure 73.26), but there are many other causes, which may be categorised as follows:

- local, e.g. anorectal deformity, hypotonic anal sphincter;
- abdominal, e.g. ascites;
- pelvic, e.g. gravid uterus, uterine neoplasm (fibroid, carcinoma of the uterus or cervix), ovarian neoplasm, bladder carcinoma;
- neurological, e.g. paraplegia, multiple sclerosis.

Figure 73.26 Carcinoma of the rectum associated with haemorrhoids, a not infrequent diagnostic pitfall.
Primary internal haemorrhoids

Theories of development

Portal hypertension and varicose veins

Misconceptions concerning the vascular anatomy of the anal canal (specifically the lack of appreciation of communications between portal and systemic systems and the ‘normality’ of venous dilatations) led to theories of development of primary internal haemorrhoids that lasted for several centuries. Man’s upright posture (we know little about haemorrhoidal problems in animals), lack of valves in the portal venous system and raised abdominal pressure were thought to contribute to the development of anal varicosities. If raised portal venous pressure were indeed the cause, one would expect a high incidence in subjects suffering from portal hypertension; however, although such patients have a higher incidence of ano-rectal varices, these are a separate anatomical and clinical entity from haemorrhoids, which are seen no more frequently than in those without cirrhosis, portal hypertension and oesophageal varices.

Other vascular causes

Historically, some considered haemorrhoids to be haemangiomas or to result from changes in the erectile tissue that forms part of the continence mechanism, such as hyperplasia of the ‘corpus cavernosum recti’.

Infection

Repeated infection of the anal lining, secondary to trauma at defaecation, has been postulated as a cause of weakening and erosion of the walls of the veins of the submucosa. This hypothesis is difficult to accept, as one of the truly incredible properties of the anal canal is its resistance to infection, as well as the ability of its mucosa to heal after surgical intervention despite the torrent of micro-organisms passing over it.

Diet and stool consistency

Much emphasis has been placed on the role of constipation in the development of haemorrhoids and, indeed, much of the management of sufferers involves attempts to ‘normalise’ bowel habits. A fibre-deficient diet results in a prolonged gut transit time, which is associated with the passage of smaller, harder stools that require more straining to expel. The presence of a hard faecal mass in the rectum could obstruct venous return, resulting in engorgement of the anal veins with the act of straining at stool or sitting for prolonged periods on the lavatory with a relaxed perineum, causing a disturbance of vascular flow. However, the epidemiological pattern of constipation is different from that of haemorrhoidal disease and, indeed, an association has been demonstrated between haemorrhoids and diarrhoeal disorders.

Anal hypertonia

The association between raised anal canal resting pressure and haemorrhoids is well known, but whether anal hypertonia causes symptoms attributable to haemorrhoids or whether anal cushion hypertrophy causes anal hypertonia is a subject of debate. The fact that surgical haemorrhoidectomy restores resting pressures to the normal range is not absolute evidence that the pile masses themselves are the cause of the hypertonia. It should be remembered, however, that there are a significant proportion of patients who suffer haemorrhoidal symptoms in whom the anal canal is relatively patulous, and there is mucosal prolapse, which is associated with perineal descent and pudendal neuropathy.

Ageing

In contrast to the anal cushion of early life, with age, the supporting structures show a higher proportion of collagen than muscle fibres and are fragmented and disorganised. Presumably, these changes arise over time with continued use of the anal canal for defaecation; however, similar changes are noted histologically in surgically excised haemorrhoids in younger patients.

Current view

Shearing forces acting on the anus (for a variety of reasons) lead to caudal displacement of the anal cushions and mucosal trauma. With time, fragmentation of the supporting structures (a normal consequence of ageing, but perhaps accelerated in those with haemorrhoids) leads to loss of elasticity of the cushions such that they no longer retract following defaecation.

Clinical features

Bleeding, as the name haemorrhoid implies, is the principal and earliest symptom. The nature of the bleeding is characteristically separate from the motion and is seen either on the paper on wiping or as a fresh splash in the pan. Very rarely, the bleeding may be sufficient to cause anaemia. Pain is not commonly associated with the bleeding and its presence should make the clinician alert to the possibility of another diagnosis; however, pain may result from congestion of pile masses below a hypertonic sphincter. Piles associated with bleeding alone are called first-degree haemorrhoids (Summary box 73.7).

Summary box 73.7

Haemorrhoids: clinical features

- Haemorrhoids or piles are symptomatic anal cushions
- They are more common when intra-abdominal pressure is raised, e.g. in obesity, constipation and pregnancy
- Classically, they occur in the 3, 7 and 11 o’clock positions with the patient in the lithotomy position
- Symptoms of haemorrhoids: bright-red, painless bleeding, mucous discharge, prolapse, pain only on prolapse

Patients may complain of true ‘piles’, lumps that appear at the anal orifice during defaecation and which return spontaneously afterwards (second-degree haemorrhoids), piles that have to be replaced manually (third-degree haemorrhoids) (Figure 73.27) or piles that lie permanently outside (fourth-degree haemorrhoids). By this stage, there is often a significant cutaneous component to the pile masses, which arise through repeated congestion and oedema. In addition to the main symptoms of pain and prolapse, patients may complain of anal irritation, which may occur as a result of mucus secretion from the caudally displaced rectal mucosa, minor leakage through a now imperfect anal seal or difficulties in cleaning after defaecation because of the irregularity of the anal verge (Summary box 73.8).
Summary box 73.8

Four degrees of haemorrhoids
- First degree – bleed only, no prolapse
- Second degree – prolapse, but reduce spontaneously
- Third degree – prolapse and have to be manually reduced
- Fourth degree – permanently prolapsed

Complications
Profuse haemorrhage is uncommon. The bleeding mainly occurs externally but it may continue internally after the bleeding haemorrhoid has retracted or has been returned. In these circumstances, the rectum is found to contain blood (Summary box 73.9).

Summary box 73.9

Complications of haemorrhoids
- Strangulation and thrombosis (Figure 73.28)
- Ulceration
- Gangrene
- Portal pyaemia
- Fibrosis

Treatment of complications
- Strangulation, thrombosis and gangrene. In these cases, it was formerly believed that surgery would promote portal pyaemia. However, if adequate antibiotic cover is given from the start, this is not found to be so, and immediate surgery can be justified in many patients. The other risk if surgery is performed at this stage, that of postoperative stenosis, results in some surgeons reviewing the situation much later and carrying out haemorrhoidectomy only if necessary. Besides adequate pain relief, bed rest with frequent hot baths and warm or cold saline compresses with firm pressure usually cause the pile mass to shrink considerably in 3–4 days (the authors’ preference is shrinkage through external application of small bags of frozen peas). An anal dilatation technique has in the past been used as an alternative treatment to surgery for painful ‘strangulated’ haemorrhoids (Figure 73.28). However, because of the risk of incontinence this is no longer advised.
- Severe haemorrhage. The cause usually lies in a bleeding diathesis or the use of anticoagulants. If such causes are excluded, a local compress containing adrenaline solution, with an injection of morphine and blood transfusion if necessary, will usually suffice. However, after adequate blood replacement, ligation and excision of the piles may be required.

Management
Exclusion of other causes of rectal bleeding, especially colorectal malignancy, is the first priority. In the absence of a specific predisposing cause, important measures include attempts at normalising bowel and defaecatory habits: only evacuating when the natural desire to do so arises, adopting a defaecatory position to minimise straining, and the addition of stool softeners and bulking agents to ease the defaecatory act. Various proprietary creams can be inserted into the rectum from a collapsible tube fitted with a nozzle, at night and before defaecation. Suppositories are also useful.

In those with first- or second-degree piles whose symptoms are not improved by conservative measures, injection sclerotherapy (Mitchell), the submucosal injection of 5 per cent phenol in arachis oil or almond oil, may be advised. Any invasive treatment, however, must be with full agreement of the patient, who should be informed of the potential risks of such interventions. The aim is to create fibrosis, cause obliteration of the vascular channels and hitch up the anorectal mucosa.

Clinton Mitchell of Illinois, IL, USA was the first to use carbolic acid for injecting haemorrhoids. Itinerant irregular practitioners exploited the method.

Figure 73.27 Third-degree haemorrhoids (courtesy of CV Mann, The Royal London Hospital, London, UK).

Figure 73.28 An attack of piles. Prolapsed strangulated piles, as commonly seen, on the left. A less common mass on the right with fibrofatty covering.
With the awake patient in the left lateral position and under direct vision with a proctoscope, about 5 mL of sclerosant is injected into the apex of the pile pedicle (Figure 73.29) using a (now) disposable needle and syringe (Figure 73.30). The procedure is repeated for each pile and the patient reassessed after 8 weeks; if necessary, the injections are repeated. Pain upon injection means that the needle is in the wrong place and should be withdrawn. Injections that are too superficial are heralded by the rapid bulging of the mucosa, which turns white; this leads to superficial ulceration but rarely serious septic sequelae. However, injections placed too deeply can have disastrous consequences, including pelvic sepsis, prostatitis, impotence and rectovaginal fistula.

For more bulky piles, banding has been shown to be efficacious, but it is associated with more discomfort. The Barron’s bander is a commonly available device used to slip tight elastic bands onto the base of the pedicle of each haemorrhoid (Figure 73.31). The bands cause ischaemic necrosis of the piles, which slough off within 10 days; this may be associated with bleeding, about which the patient must be warned. As with sclerotherapy, three piles may be treated at one session, and the process may be repeated after several weeks if necessary. The techniques of cryotherapy (Lloyd Williams) and infrared photocoagulation (Leicester) are not often used nowadays.

**Operation**

**Indications**

The indications for haemorrhoidectomy include:
- third- and fourth-degree haemorrhoids;
- second-degree haemorrhoids that have not been cured by non-operative treatments;
- fibrosed haemorrhoids;
- interoexternal haemorrhoids when the external haemorrhoid is well defined.

If there is any doubt about the diagnosis of haemorrhoids, examination under anaesthesia and, if indicated, biopsy are necessary. The other strong indication for surgery is haemorrhoidal bleeding sufficient to cause anaemia. Beyond these, the indications summarised above are more relative than absolute, because in these situations surgery aims simply to improve symptoms and, of course, is not without risk. For instance, elderly multiparous women with hypotonic sphincters who are just continent before haemorrhoidectomy may find that the procedure results in frank incontinence, a far worse condition than that for which they originally sought help.

**Figure 73.29** Correct site (cross) for injecting a haemorrhoid (after WB Gabriel, London, UK).

**Figure 73.30** Gabriel’s syringe (a) has now been replaced by disposable syringes (b).

**Figure 73.31** Barron’s banding apparatus, with the appearance of a typical ‘banded’ haemorrhoid.
Technique

It is usual for the patient to have been taking stool softeners in the days before surgery and a preoperative enema to empty the rectum is administered. The procedure is usually performed under general or regional anaesthesia with the patient in the lithotomy or prone jack-knife position. The perianal skin is shaved and a formal examination performed. Haemorrhoidectomy can be performed using an open or a closed technique. The open technique is most commonly used in the UK and is known as the Milligan–Morgan operation—named after the surgeons who described it. The closed technique is the popular technique in the United States. Both involve ligation and excision of the haemorrhoid, but in the open technique the anal mucosa and skin are left open to heal by secondary intention, and in the closed technique the wound is sutured.

- **Open technique.** The anoderm and subcutaneous tissues between the pile masses may be injected with dilute adrenaline (epinephrine, 1:300,000 dilution) to reduce bleeding and aid preservation of the skin bridges left following excision. Artery forceps are applied to the skin-covered external components of the piles and traction exerted to reveal the internal components, which are also grasped by artery forceps. When held out by the assistant, these pairs of artery forceps form a triangle (Figure 73.32a). The operator takes the left lateral pair of artery forceps in the palm of the hand and places the extended forefinger in the anal canal to support the internal haemorrhoid. In this way, traction is applied to the skin of the anal margin. With scissors or cutting diathermy, a V-shaped cut is made through the skin and those fibres inserting into it around the skin-holding artery forceps. Traction by both operator and assistant, combined with careful dissection, will expose the lower border of the internal sphincter. The dissection proceeds up the anal canal, with the sides of the mucosal dissection converging towards the pile apex and with the internal sphincter visible and separate from the dissected pile (Figure 73.32b). A transfixion ligature of strong Vicryl is applied to the pedicle at this level (Figure 73.32c), the pile is excised well distal to the ligature and, after ensuring haemostasis, the ligature is cut long. Each haemorrhoid is dealt with in this manner, taking care to leave mucocutaneous bridges. If there are significant secondary haemorrhoids under these bridges, they can

![Figure 73.32 Ligation and excision of haemorrhoids. Open technique: (a) the artery forceps have been applied; (b) dissection of the left lateral pedicle; (c) transfixion of the pedicle. Reproduced with permission from Nicholls RJ, Dozois RR. Surgery of the colon and rectum. Edinburgh: Churchill Livingstone, 1997.](image-url)
be filleted out by scissor dissection. Haemostasis must be absolute at the end of the procedure, when a soft absorbable anal dressing is inserted. The margins of the skin wounds are trimmed so as not to leave overhanging edges (Figure 73.33). Bleeding subcutaneous arteries having been secured, the areas denuded of skin are dressed with three pieces of petroleum jelly gauze. A pad of gauze and wool and a firmly applied T-bandage complete the operation.

- **Closed technique.** The haemorrhoid is excised, together with the overlying mucosa, as illustrated in Figure 73.34a. The haemorrhoid is dissected carefully from the underlying sphincter and haemostasis is achieved. The pedicle is transfixed and ligated with 3/0 Vicryl or Dexon. Any residual small haemorrhoids should be removed by filleting them out after undermining the edges of the cut mucosa. The mucosal defect is then closed completely with a continuous suture using the same stitch that was employed to ligate the haemorrhoid pedicle. The remaining haemorrhoids are excised and ligated in a similar fashion, ensuring that there are adequate mucosal and skin bridges between each area of excision to avoid a subsequent stenosis.

With the aim of symptom relief but preservation of the anal cushions, the technique of stapled haemorrhoidopexy (Longo), which utilises a purpose-designed stapling gun (PPH, Ethicon Inc.), has recently been described. This procedure excises a strip of mucosa and submucosa (together with the vessels travelling within them) circumferentially, well above the dentate line. Activation of the gun also simultaneously repairs the cut mucosa and submucosa by stapling the edges together (Figure 73.35). This procedure is quick to perform, and controlled trials suggest that it is less painful and less traumatic than conventional haemorrhoidectomy and, at least in the short term, it seems to be equally efficacious. However, evidence is emerging that the technique is associated with higher recurrence rates than following conventional haemorrhoidectomy, and associated with more additional surgery. The patient, after counselling, may choose to accept a higher recurrence rate to take advantage of the short-term benefits, or not (Summary box 73.10).

---

**Figure 73.33** The appearance of the anus at the conclusion of the operation. (Note that to avoid stricture formation, it is necessary to ensure that a bridge of skin and mucous membrane remains between each wound.) ‘If it looks like a clover the trouble is over, if it looks like a dahlia, it is surely a failure.’ Reproduced with permission from Nicholls RJ, Dozois RR. Surgery of the colon and rectum. Edinburgh: Churchill Livingstone, 1997.

**Figure 73.34** Closed technique of haemorrhoidectomy. (a) The haemorrhoidal tissue is excised. (b) Bleeding is controlled by diathermy. (c) The defect is closed with a continuous suture after first undermining the anoderm on each side. Redrawn with permission from Keighley, MRB, Williams NS. Surgery of the anus, colon and rectum, 2nd edn. Philadelphia, PA: WB Saunders, 1999.
Summary box 73.10

Treatment of haemorrhoids

- Symptomatic – advice about defaecatory habits, stool softeners and bulking agents
- Injection of sclerosant
- Banding
- Transanal haemorrhoidal dearterialisation/haemorrhoidopexy
- Haemorrhoidectomy

Transanal haemorrhoidal dearterialisation

Transanal haemorrhoidal dearterialisation (THD) is used for the treatment of second- and third-degree haemorrhoids. Some have recently advocated transanal Doppler-guided ligation of those vessels feeding the haemorrhoidal masses, to which others have added suture ‘mucopexy’ to deal with any prolapse. Long-term outcomes are unknown, but recurrence rates for fourth-degree haemorrhoids (certainly when additional procedures are not incorporated) are high.

Postoperative care

In these days of economic stringencies, the patient is discharged from hospital within a day or two of the operation. In many countries, the procedure is often performed on a day-care basis. The patient is instructed to take two warm baths each day and is given a bulk laxative to take twice daily together with appropriate analgesia. There is some evidence that a 5-day course of oral metronidazole may reduce pain. Dry dressings are applied as necessary, a sterile sanitary towel usually being ideal. The patient is seen again 3–4 weeks after discharge and a rectal examination is performed. If there is evidence of stenosis, the patient is encouraged to use a dilator.

Postoperative complications

Postoperative complications may be early or late. Early complications include pain, which may require opiate analgesia; retention of urine, especially in men, which rarely may need relief by catheterisation; and reactionary haemorrhage, which is much more common than secondary haemorrhage. The haemorrhage may be mainly or entirely concealed, but will become evident on examining the rectum. If persistent following adequate analgesia, the patient must be taken to the operating theatre and the bleeding point secured by careful diathermy or under-running with a ligature on a needle, care being taken to avoid damage to the internal sphincter. Should a definite bleeding point not be found, the anal canal and rectum are packed.

Late postoperative complications include:

- Secondary haemorrhage. This is uncommon, occurring about the 7th or 8th day after operation. It is usually controlled by morphine but, if the haemorrhage is severe, an anaesthetic should be given and the bleeding controlled.
- Anal stricture, which must be prevented at all costs. A rectal examination at the postoperative review will indicate whether strictureing is to be expected. It may then be necessary to give a general anaesthetic and dilate the anus. After that, daily use of the dilator should give a satisfactory result.
- Anal fissures and submucous abscesses.
Incontinence, especially if there has been inadvertent damage to the underlying internal sphincter. Although uncommon, this is obviously a very serious problem that is difficult to treat (Summary box 73.11).

Summary box 73.11

Complications of haemorrhoidectomy

- **Early**
  - Pain
  - Acute retention of urine
  - Reactionary haemorrhage
- **Late**
  - Secondary haemorrhage
  - Anal stricture
  - Anal fissure
  - Incontinence

External haemorrhoids

A thrombosed external haemorrhoid relates anatomically to the veins of the superficial or external haemorrhoidal plexus and is commonly termed a ‘perianal haematoma’. It presents as a sudden onset, olive-shaped, painful blue subcutaneous swelling at the anal margin and is usually consequent upon straining at stool, coughing or lifting a heavy weight (Figure 73.36). The thrombosis is usually situated in a lateral region of the anal margin. If the patient presents within the first 48 hours, the clot may be evacuated under local anaesthesia. Untreated it may resolve, suppurate, fibrose and give rise to a cutaneous tag, burst and the clot extrude, or continue bleeding. In the majority of cases, resolution or fibrosis occurs. Indeed, this condition has been called ‘a 5-day, painful, self-curing lesion’ (Milligan).

**PRURITUS ANI**

This is intractable itching around the anus, a common and embarrassing condition. Usually, the skin is reddened and hyperkeratotic and it may become cracked and moist.

**Causes**

The causes are numerous. A useful mnemonic is ‘pus, polypus, parasites, piles, psyche’:

- **Lack of cleanliness**, excessive sweating and wearing rough or woollen underclothing.
- **An anal or perianal discharge** that renders the anus moist. The causative lesions include an anal fissure, fistula-in-ano, prolapsed internal or external haemorrhoids, genital warts and excessive ingestion of liquid paraffin. A mucous discharge is an intense pruritic agent and a polyp can be the cause.
- **A vaginal discharge**, especially caused by *Trichomonas vaginalis* infection.
- **Parasitic causes**. Threadworms should be excluded, especially in young subjects. Children suffering from threadworms should wear gloves at night, lest they scratch the perianal region and are reinfested with ova by nail biting – “parasites lost, parasites regained”. Scabies and pediculosis pubis may infest the anal region.
- **Epidermophytosis** is a common cause, especially if the skin between the toes is also infected; microscopic and cultural examinations are essential. Half-strength Whitfield’s ointment quickly gives relief and is the sheet anchor of treatment.
- **Allergy** is sometimes the cause, in which case there is likely to be a history of other allergic manifestations, such as urticaria, asthma or hay fever. Antibiotic therapy may be the precipitating factor.
- **Skin diseases** localised to the perianal skin: psoriasis, lichen planus and contact dermatitis.
- **Bacterial infection**, such as intertrigo resulting from a mixed bacterial infection. Erythrasma caused by Corynebacterium minutissimum is responsible for some cases and its presence is detected by ultraviolet light, which induces a pink fluorescence.
- **A psychoneurosis**. It is alleged that in a few instances neurotic individuals become so immersed in their complaint that a pain–pleasure complex develops, the pleasure being the scratching. Possibly this is true, but such a syndrome should not be assumed without firm grounds for coming to this conclusion.
- **Diabetes** can sometimes present with pruritus ani, and the urine should be tested in all patients.

**Treatment**

The cause is treated. Symptomatic treatment includes the following:

- **Hygiene measures**. Cotton wool should be substituted for toilet paper. Soap is avoided and replaced by water alone,
and the area pat-dried rather than rubbed. These measures alone, combined with wearing cotton underwear and the application of calamine lotion or zinc and castor oil, are all that is necessary to cure some cases. If there is much anal hair trapping the moisture and discharge, shaving can be very helpful.

- **Hydrocortisone.** In patients with dermatitis, and only in patients with dermatitis, the topical application of 0.5 or 1 per cent prednisolone cream is often beneficial; sometimes after discontinuation of the therapy, the pruritus is liable to return, in which case 5 per cent lidocaine hydrochloride (Xylocaine) ointment can be substituted for a time.

- **Strapping the buttocks** keeps moist opposing surfaces apart, but is not well tolerated. If the moistness originates from anal discharge, a cotton wool anal plug will seal the anal orifice.

**Operative treatment**

This may be necessary for a concomitant lesion of the anorectum that is thought to initiate or contribute to the pruritus. Otherwise, surgery is not indicated (Summary box 73.12).

**Summary box 73.12**

**Pruritus ani**

- Common
- Numerous causes including skin diseases, parasites (threadworm), anal discharge, allergies, diabetes
- Treat the cause if possible
- Symptomatic treatment is the mainstay

**ANORECTAL ABSCESSES**

Acute sepsis in the region of the anus is common. A fundamental distinction that has to be made is whether the sepsis is in that area by chance (simple boil, skin appendage infection) or whether it has arisen as a consequence of the presence of the anorectum, specifically the anal glands. Overall, anorectal sepsis is more common in men than women, although infections with skin-type organisms (and thus unrelated to fistula) are evenly distributed. The cryptoglandular theory of intersphincteric anal gland infection (Parks) holds that, upon infection of a gland, pus, which travels along the path of least resistance, may spread caudally to present as a perianal abscess, laterally across the external sphincter to form an ischiorectal abscess or, rarely, superiorly above the anorectal junction to form a supralevalator intermuscular or pararectal abscess (depending on its relation to the longitudinal muscle), as well as circumferentially in any of the three planes: intersphincteric/intermuscular, ischiorectal or pararectal supralevalator (Figure 73.37). Sepsis unrelated to anal gland infection may occur at the same or at other sites (Figure 73.38), including submucosal abscess (following haemorrhoidal sclerotherapy, which usually resolve spontaneously), mucocutaneous or marginal abscess (infected haematoma), ischiorectal abscess (foreign body, trauma, deep skin-related infection) and pelvirectal supralevalator sepsis originating in pelvic disease. Underlying rectal disease, such as neoplasm and particularly Crohn’s disease, may be the cause. Similarly, patients with generalised disorders, such as diabetes and acquired immunodeficiency syndrome (AIDS), may present with an anorectal abscess; in these patients, abscesses may run an aggressive course.

**Presentation**

A perianal abscess, confined by the terminal extensions of the longitudinal muscle, is usually associated with a short (2–3 day)
History of increasingly severe, well-localised pain and a palpable tender lump at the anal margin. Examination reveals an indurated hot tender perianal swelling. Patients with infection in the larger fatty-filled ischiorectal space, in which tissue tension is much lower, usually present later, with less well-localised symptoms but more constitutional upset and fever. On examination, the affected buttock is diffusely swollen with widespread induration and deep tenderness. If sepsis is higher, deep rectal pain, fever and sometimes disturbed micturition may be the only features, with nothing evident on external examination but tender suprarectal induration palpable on digital examination above the anorectal junction.

**Differential diagnosis**
The only conditions with which an anorectal abscess is likely to be confused are abscesses connected with a pilonidal sinus, Bartholin’s gland or Cowper’s gland.

**Management**
Management of acute anorectal sepsis is primarily surgical, including careful examination under anaesthesia, sigmoidoscopy and proctoscopy, and adequate drainage of the pus. For perianal and ischiorectal sepsis (with an incidence of 60 and 30 per cent, respectively), drainage is through the perineal skin, usually through a cruciate incision over the most fluctuant point, with excision of the skin edges to deroof the abscess (Figure 73.39). Pus is sent for microbiological culture (Grace) and tissue from the wall is sent for histological appraisal to exclude specific causes. With a finger in the anorectum to avoid creation of a false opening, the cavity is carefully curetted. A gentle search may be made for an underlying fistula if the surgeon is experienced, and, if obvious, a loose draining seton may be passed; injudicious probing in the acute stage is, however, potentially dangerous and may lead to a much more difficult situation. Unless by highly experienced hands, immediate fistulotomy should not be performed. After irrigation of the cavity, the wound is lightly tucked; antibiotics are prescribed if there is surrounding cellulitis and especially in those less resistant to infection, such as diabetics. If the pus subsequently cultures skin-type organisms, there will be no underlying fistula and the patient can be reassured. If gut flora are cultured, it is likely, but not inevitable, that there is an underlying fistula.

The management of suprarectal sepsis is dependent upon its exact anatomy (within or outside the rectal wall) and its origin. Sepsis originating in pelvic disease necessitates appropriate management of the underlying cause (appendiceal, gynaecological, diverticular, Crohn’s disease, malignancy), although intrarectal drainage may be apt to avoid creation of an extraspincteric fistula. Cephalad extension of an interspincteric fistula can be safely drained into the rectum, whereas suprarectal extension of a trans-spincteric fistula should be drained via the skin of the buttock. Rarely, a colostomy may be necessary to control severe sepsis, especially in the immunocompromised individual (Summary box 73.13).

**Summary box 73.13**

**Anorectal abscess**
- Usually produces a painful, throbbing swelling in the anal region. The patient often has swinging pyrexia
- Subdivided according to anatomical site into perianal, ischiorectal, submucous and pelvirectal
- Underlying conditions include fistula-in-ano (most common), Crohn’s disease, diabetes, immunosuppression
- Treatment is drainage of pus in first instance, together with appropriate antibiotics
- Always look for a potential underlying problem

A fistula-in-ano, or anal fistula, is a chronic abnormal communication, usually lined to some degree by granulation tissue, which runs outwards from the anorectal lumen (the internal opening) to an external opening on the skin of the perineum or buttock (or rarely, in women, to the vagina). Anal fistulae may be found in association with specific conditions, such as Crohn’s disease, tuberculosis, lymphogranuloma venereum, actinomycosis, rectal duplication, foreign body and malignancy (which may also very rarely arise within a longstanding fistula), and suspicion of these should be aroused if clinical findings are unusual. However, the majority are termed non-specific, idiopathic or cryptoglandular, and interspincteric anal gland infection is deemed central to them.

**Presentation**
For reasons that are unknown, non-specific anal fistulae are more common in men than women. The overall incidence is about nine cases per 100000 population per year in Western Europe, and those in their third, fourth and fifth decades of life are most commonly affected. Patients usually complain of intermittent purulent discharge (which may be bloody) and pain (which increases until temporary relief occurs when the pus discharges). There is often, but not invariably, a previous episode of acute anorectal sepsis that settled (incompletely) spontaneously or with antibiotics, or which was surgically drained. The passage of flatus or faeces through the external opening is suggestive of a rectal rather than an anal internal opening.

**Figure 73.39** Incision of an ischiorectal abscess. The cavity is explored and, if septa exist, they should be broken down gently with a finger and the necrotic tissue lining the walls of the abscess removed by the finger wrapped in gauze. It is wise to biopsy the wall and send the pus for culture. Nothing further is done at this stage.

**FISTULA-IN-ANO**
Classification

The most widespread and useful classification of anal fistulae is that proposed by Parks, based on the centrality of intersphincteric anal gland sepsis (the internal opening is usually at the dentate line), which results in a primary track whose relation to the external sphincter defines the type of fistula and which influences management (Figure 73.40). Classifications based simply on level are less practical because they mean different things to different people, although the description of a fistula as high, indicating a high risk of incontinence if laid open, or low, with a lower but still some risk to function, is often used. Similarly, ‘simple’ and ‘complex’ are commonly used adjectives – complexity may be endowed by the level at which the primary track crosses the sphincters, the presence of secondary extensions or the difficulties faced in treatment. The vast majority of fistulae are intersphincteric or trans-sphincteric.

Intersphincteric fistulae (45 per cent) do not cross the external sphincter (bar, for the purist, the most medial subcutaneous fibres running below the distal border of the internal sphincter); most commonly they run directly from the internal to the external openings across the distal internal sphincter, but may extend proximally in the intersphincteric plane to end blindly with or without an abscess, or enter the rectum at a second internal opening.

Trans-sphincteric fistulae (40 per cent) have a primary track that crosses both internal and external sphincters (the latter at a variable level) and which then passes through the ischiorectal fossa to reach the skin of the buttock. The primary track may have secondary tracks arising from it, which often reach the roof of the ischiorectal fossa, which may rarely pass through the levators to reach the pelvis and which may spread circumferentially (horseshoe). Circumferential spread of sepsis may occur in the intersphincteric and pararectal planes, as well as in the ischiorectal plane.

Suprasphincteric fistulae (5 per cent) have a primary track whose relation to the external sphincter defines the type of fistula. Palpable induration between external opening and anal verge is a very useful way of demonstrating the primary track; the presence of secondary extensions or the difficulties faced in treatment. The vast majority of fistulae are intersphincteric or trans-sphincteric.

Suprasphincteric fistulae are very rare, are thought by some to be iatrogenic and are difficult to distinguish from high-level trans-sphincteric tracks (for which, fortunately, management strategies are similar). Extrasphincteric fistulae run without specific relation to the sphincters and usually result from pelvic disease or trauma.

Clinical assessment

A full medical (including obstetric, gastrointestinal, anal surgical and continence) history and proctosigmoidoscopy are necessary to gain information about sphincter strength and to exclude associated conditions. The key points to determine are the site of the internal opening; the site of the external opening(s); the course of the primary track; the presence of secondary extensions; and the presence of other conditions complicating the fistula. Palpable induration between external opening and anal margin suggests a relatively superficial track, whereas supralevator induration suggests a primary track above the elevators or high in the roof of the ischiorectal fossa, or a high secondary extension. Intersphincteric fistulae usually have an external opening close to the anal verge. Goodsall’s rule (Figure 73.41), used to indicate the likely position of the internal opening according to the position of the external opening(s), is helpful but not infallible. The site of the internal opening may be felt as a point of induration or seen as an enlarged papilla. Probing in an awake patient is painful, unhelpful and can be dangerous. Full examination under anaesthesia should be repeated before surgical intervention. Dilute hydrogen peroxide, instilled via the external opening, is a very useful way of demonstrating the site of the internal opening; gentle use of probes (Figure 73.42) and a finger in the anorectum usually delineates primary and secondary tracks and their relations to the sphincters. Any concerns about fistula topography at clinical examination or examination under anaesthesia (more common after previous unsuccessful surgery) should prompt further investigations before surgical intervention.

Special investigations

A successful outcome after fistula surgery requires an accurate assessment of the fistula itself, the sphincter through which it passes and patient expectations (especially in terms of risk to continence). Clinical examination will give some indication

![Figure 73.40](https://example.com/figure73.40.png)

**Figure 73.40** Types of anal fistula (Parks’ classification): 1, intersphincteric; 2, trans-sphincteric; 3, suprasphincteric; and 4, extrasphincteric primary tracks.

![Figure 73.41](https://example.com/figure73.41.png)

**Figure 73.41** Goodsall’s rule.

![Figure 73.42](https://example.com/figure73.42.png)

**Figure 73.42** Retrograde probing of an anal canal sometimes reveals the internal orifice of the fistula.
of functional anal sphincter length, resting tone and voluntary squeeze; these may be more objectively assessed by manometry, whereas endoanal ultrasound gives useful information about sphincter integrity – the knowledge so gained may well influence surgical strategy. Endoanal ultrasound, especially with hydrogen peroxide, can also be used to delineate fistulae, although definition of sepsis outside or above the sphincters is limited by the probe’s focal range and scarring makes interpretation difficult. Nonetheless, ultrasound, which is more accurate than clinical examination, is useful to determine whether a fistula is relatively straightforward or not. Magnetic resonance imaging (MRI) is acknowledged to be the ‘gold standard’ for fistula imaging, but it is limited by availability and cost and is usually reserved for difficult recurrent cases. The great advantage of MRI is its ability to demonstrate secondary extensions, which may be missed at surgery and which are the cause of persistence (Figure 73.43). Fistulography and computed tomography (CT) both have limitations but are useful techniques if an extraspincteric fistula is suspected.

**Surgical management**

Patients with minimal symptoms, especially if they have compromised sphincters, may be managed expectantly. Eradication of sepsis requires surgery, the aim of which must be balanced with the preservation of continence. Most fistulae are relatively straightforward to deal with; however, a minority are extremely problematic and are not the realm of the ‘occasional proctologist’. The multitude of strategies advocated attests to these difficult situations; comparisons between techniques are difficult to make because of the heterogeneity of patient groups, the variability in classification, the inapplicability of certain techniques in some situations, inadequate reporting of functional outcomes, inadequate follow up and surgeon preference over-riding entry into prospective randomised trials.

![Figure 73.43](image)

Figure 73.43 Coronal magnetic resonance imaging (MRI) scan (STIR sequence) demonstrating a primary track running up the right ischiorectal space (short white arrow), which then crosses the sphincters to open into the anal canal just below the puborectalis. However, there is a blind secondary extension (long white arrow) passing to the contralateral side in the roof of the left ischiorectal fossa (and involving the levators), which was missed at surgery and which was the cause of fistula persistence.

**Fistulotomy**

That the fistulous track must be laid open from its termination to its source was a rule promulgated by John of Arderne more than 600 years ago. Fistulotomy, or laying open, is the surest way of getting rid of a fistula, but, by definition, it involves division of all those structures lying between the external and internal openings. It is therefore applied mainly to interspincteric fistulae and trans-spincteric fistulae involving less than 30 per cent of the voluntary musculature (but not anteriorly placed fistulae in women); however, even then, it is not immune to postoperative defects in continence. After full examination under anaesthesia in the lithotomy or prone jack-knife position, during which the internal opening should have been identified, a grooved fistula probe is passed from the external to the internal opening (Figure 73.44), the amount of sphincter below and above the probe is noted and, if indicated, the track is laid open over the probe. Granulation tissue is curetted and sent for histological appraisal and the wound edges are trimmed. Secondary tracks, often identified as granulation tissue that persists despite curettage, should be laid open or drained. Marsupialisation reduces wound size and speed up healing. Primary tracks crossing the external sphincter more deeply have been managed with good outcomes by fistulotomy and immediate reconstitution of the divided muscle – failure to eradicate all sepsis and subsequent breakdown of the repair, however, are very problematic. Alternatively, a staged fistulotomy may be carried out in which secondary tracks are laid open and only part of the sphincter enclosed by the primary track is divided, with the remainder encircled by a loose seton. After sufficient time for healing of the wound and fibrosis, the seton-enclosed track is divided at a second stage.

**Fistulectomy**

This technique involves coring out of the fistula, usually by diathermy cautery; it allows better definition of fistula anatomy than fistulotomy, especially the level at which the track crosses the sphincters and the presence of secondary extensions. If the spincteric component of the fistula is deemed low enough to allow safe fistulotomy, then this may proceed (at the expense of longer healing times than conventional fistulotomy). If laying open is not advisable, then the sphincteric component can be managed by another method.

**Setons**

Setons (Latin: seta, bristle) have been used in a variety of ways in fistula surgery and it is important for surgeons to be clear about what they are trying to achieve in a particular situation. Loose setons are tied such that there is no tension upon the encircled tissue; there is no intent to cut the tissue. A variety of materials have been used, but the seton should be non-absorbable, non-degenerative and comfortable. Tight or cutting setons are placed with the intention of cutting through the enclosed muscle.

---

**John of Arderne**, 1307–1390, was the first English surgeon of note. He practised at Newark-upon-Trent, Nottinghamshire and, from 1370, in London, UK. He described his operation for the treatment of fistula in about 1376.
Uses of loose setons

- For long-term palliation to avoid septic and painful exacerbations by establishing effective drainage; most often in Crohn’s disease and in those with problematic fistulae not wishing to countenance the possibility of incontinence.
- Used before ‘advanced’ techniques (fistulectomy, advancement flap, cutting seton); acute sepsis and secondary extensions are eradicated and a loose seton is passed across the sphincteric component of the primary track to simplify the fistula and allow fibrosis.
- As part of a staged fistulotomy.
- As part of a therapeutic strategy to preserve the external sphincter in trans-sphincteric fistulae. Secondary tracks in the ischiorectal fossa are laid open. Access to the site where the primary track crosses the external sphincter may sometimes necessitate division of the anococcygeal ligaments to reach the deep post-anal space. The internal sphincter is laid open to the level of the internal opening (or higher if there is a cephalad intersphincteric extension) to eradicate the presumed source and the sepsis in the intersphincteric space. A seton is then passed along the residual track around the denuded external sphincter and tied loosely, and the wounds are dressed. Initial postoperative management includes daily wound irrigation and light wound redressing. The seton is left in place for three months and, if there is evidence of good healing, simply removed. Such a strategy certainly protects against the consequences of external sphincter division, with an incidence of healing in the short term of 50–60 per cent.

Uses of cutting setons

Cutting setons aim to achieve the high fistula eradication rates associated with fistulotomy, but without the degree of functional impairment endowed by division of the sphincters at a single stage. The enclosed muscle is gradually severed (‘cheese widing through ice’) such that the divided muscles do not spring apart, and the site of the fistula track is replaced by a thin line of fibrosis as it is brought down. Some recommend prior
internal sphincter division, others incorporation of the internal sphincter within the cutting seton. A variety of seton material has been used, either elastic and ‘self-cutting’ or non-elastic and tightened at intervals, with the sphincter being divided at varying speeds. In eastern parts of the world, the same aim has been achieved by chemical cautery using an Ayurvedic method, known in India as Kshara sutra, in which a specially prepared seton thread burns through the enclosed tissue. This outpatient method has been shown to be equivalent to one-stage fistulotomy in patients with intersphincteric and distal trans-sphincteric fistulae.

Advancement flaps

When the sphincter complex is not too indurated and adequate intra-anal access can be obtained, the advancement flap technique can be employed, which aims to preserve both anatomy and function. The principles are prior elimination of acute sepsis and secondary tracks, with ideally a direct track from internal to external openings; coring out of the entire track; and closure of the communication with the anal lumen with an adequately vascularised flap consisting of mucosa and internal sphincter, sutured without tension to the anoderm, well distant from the site of the (excised) internal opening. Modifications include flap orientation (proximally or distally based) and thickness (mucosal, partial or full-thickness internal sphincter), and treatment of the external wound.

Biological agents

The functional consequences of fistulotomy and the poorer eradication rates of sphincter-preserving techniques have led to a search for agents that essentially plug and seal the track and allow ingrowth of healthy tissue to replace it (Summary box 73.14). Intuitively, success must depend on the biomaterial itself and the environment into which it is placed. The poor long-term results of fibrin glue probably result from its relatively rapid resorption, and thus inadequate time for host tissue incorporation. The variable short-term results associated with porcine small intestinal submucosa may reflect early extrusion, premature degradation within an infected field, or the protocol advocated for its use which does not include meticulous eradication of secondary extensions, or the lining of the primary track itself, whether epithelial or granulation tissue. Cross-linked porcine dermal collagen has also, more recently, been studied, but only short-term outcomes (albeit optimistic) are known. Research into biological agents must continue.

Summary box 73.14

Anorectal fistulae

- Are common and may be simple or complex
- Are classified according to their relationship to the anal sphincters
- May be associated with underlying disease, such as tuberculosis or Crohn’s disease
- Laying open is the surest method of eradication, but sphincter division may result in incontinence

HIDRADENITIS SUPPURATIVA

This is a chronic suppurative condition of apocrine gland-bearing skin, which is found in the axillae, submammary regions, nape of the neck, groin, mons pubis, inner thighs and sides of the scrotum, as well as the perineum and buttocks, and is a source of considerable physical and psychological morbidity. There is no confirmatory test or specific characteristic for diagnosis, which makes definition difficult. Acne, pilonidal sinus and chronic scalp folliculitis may coexist with hidradenitis suppurativa in the condition ‘foliculocclusion tetrad’.

Pathology

Occlusion of gland ducts leads to bacterial proliferation, gland rupture and spread of infection and epithelial components into the surrounding soft tissue and to adjacent glands. Secondary infection (with Staphylococcus aureus, Streptococcus milleri and anaerobes) causes further local extension, skin damage and deformity, with multiple communicating subcutaneous fistulae. There is some evidence that the disease may be related to a relative androgen excess.

Presentation

The condition is not seen before puberty and rarely presents after the fourth decade of life. Overall, it is three times more common in women than men, although anogenital disease is more common in men, and obesity is a common association. When affecting the perineum, lesions begin as multiple raised boils, with recurrent lesions within the same vicinity leading to sinus tract formation, bridged scarring and multiple points of discharge. Rarely, it may involve the anal canal anoderm, but it does not extend above the dentate line or involve the sphincter muscles themselves.

Differential diagnosis

In the early stages, distinction from furunculosis can be difficult. Crohn’s disease, cryptoglandular fistula, pilonidal sinus, tuberculosis, actinomycosis, lymphogranuloma venereum and granuloma inguinale must be considered when later stages present.

Treatment

In the early stages, general measures, including weight reduction and antiseptic soaps, may be helpful. Antibiotics may induce remission, but often the disease relapses and progresses, at which point surgery is indicated. Inadequate treatment may lead to prolonged morbidity but any surgery should be less debilitating than the condition. Surgical intervention ranges from simple incision and drainage of acute sepsis to radical excision of all apocrine gland-bearing skin. Careful laying open of all tracts, possibly as a staged procedure according to anatomical location, is an option that appeals to many patients. Radical excision requires closure by skin graft or rotation flap and, occasionally, a defecting coelostomy to allow healing.

CONDYLOMATA ACCUMINATA (ANAL WARTS)

There is increasing evidence that sexually transmitted infection with human papillomavirus (HPV) forms the aetiological basis of anal and perianal warts, anal intraepithelial neoplasia (AIN) and squamous cell carcinoma of the anus. In those areas of the

The Ayurvedic method is derived from the Ayurveda, the most ancient system of Hindu medicine whose origin is ascribed to Brahma and dates from circa 1400 to 1200BC.
world where sexual promiscuity (especially anal intercourse) is more common, and in immunocompromised individuals (HIV-infected individuals and transplant recipients), there have been dramatic increases in the incidence of these conditions over the last 30 years, most importantly of AIN and anal cancers. Similar virally induced changes have been noted in the genital tracts of women (vulval intraepithelial neoplasia (VIN), cervical intraepithelial neoplasia (CIN) and cancers). There are over 80 subtypes of HPV but certain subtypes (16, 18, 31, 33) are associated with a greater risk of progression to dysplasia and malignancy.

Condylomata accuminata is the most common sexually transmitted disease encountered by colorectal surgeons and is most frequently observed in homosexual men. Associated warts on the penis and along the female genital tract are common.

**Presentation**

Many are asymptomatic but pruritus, discharge, bleeding and pain are usual presenting complaints. In the early stages, examination reveals separate pinkish-white warts close to the anal margin and also often on the anoderm within the distal anal canal. Later, the warts enlarge, coalesce and carpet the skin. Rarely, relentless growth results in giant condylomata (Buschke–Löwenstein tumour), which may obliterate the anal orifice. The diagnosis is aided by aceto-whitening upon application of acetic acid but confirmed by biopsy, which will also indicate the presence or absence of dysplasia.

**Treatment**

Because of the field effect endowed by viral skin infection, long-term resolution can be problematic. Careful serial application of 25 per cent podophyllin to discrete warts on the perianal skin is often used; however, it cannot be used intra-anally. Surgical excision under local, regional or general anaesthesia involves raising and separating the lesions with local infiltration of dilute adrenaline, which allows more accurate scissor or electrocautery excision to maximise the preservation of normal skin.

**ANAL INTRAEPITHELIAL NEOPLASIA**

Anal intraepithelial neoplasia (Figure 73.45) is a multifocal virally induced dysplasia of the perianal or intra-anal epidermis which is associated with the human papilloma virus (most frequently subtypes 6, 11, 16 and 18). The prevalence is <1 per cent of the population with a rising incidence especially in those areas where anoreceptive intercourse and HIV are prevalent. At-risk groups include patients with HIV, as well as immunocompromised patients, women with a history of other genital intraepithelial neoplasia (VIN and CIN) and patients with extensive anogenital condylomata. Patients may be asymptomatic and the diagnosis is often a histological surprise, although increasing numbers in high-risk groups are picked up on anal cytology. It is classified according to the degree of dysplasia on biopsy into AIN I, AIN II and AIN III, according to the lack of keratocyte maturation and extension of the proliferative zone from the lower third (AIN I) to the full thickness of the epithelium (AIN III), in the same manner as cervical or vulval dysplasia. The natural history is uncertain, but progression from AIN II to AIN III to invasive carcinoma has been observed, notably in the immunocompromised. The term Bowen’s disease should probably be avoided.

![Figure 73.45 Extensive anal intraepithelial neoplasia (AIN), which extends intra-anally.](image)

**Presentation**

Around 10 per cent of AIN lesions are diagnosed by the pathologist after excision of abnormal skin lesions. Low-grade lesions may be raised and similar to anal condylomata; however, AIN III lesions are more often flat and may be white, grey, purple or brown in colour. Ulceration would suggest progression to invasive anal carcinoma. Patients’ symptoms include pruritis, pain, bleeding and discharge. AIN is present in 28–35 per cent of excised anal warts. Approximately 10 per cent of AIN III lesions will progress to anal carcinoma at five years. Regression of AIN III rarely occurs, but AIN I and AIN II may regress. The association between AIN III and carcinoma is strengthened by the findings of AIN III in 80 per cent of anal cancer biopsies.

**Diagnosis and management**

A high index of suspicion and targeted biopsy yields the diagnosis, whereas multiple (mapping) biopsies give an indication of the extent and overall severity of the disease. AIN II and III should be regularly monitored clinically and, if necessary, by repeat biopsy to exclude invasive disease. Specialised centres may offer colposcopy of the anus (anoscopy) utilising 5 per cent acetic acid with Lugol’s iodine to assess in vivo the dysplastic areas of the anus. The affected areas show up white and can be biopsied. Focal disease may be excised and local excision is effective for lesions <30 per cent of the circumference of the anus. More widespread disease can be dealt with surgically by wide local excision and closure of the resultant defect by flap or skin graft, with or without covering colostomy (especially if there is intra-anal disease). However, for a condition with uncertain malignant potential, this approach should be used with caution as it carries with it significant morbidity. It is important to remember that female patients are at risk of other anogenital intraepithelial neoplasia; it is recommended that those with AIN III have a yearly cervical smear test.

Topical imiquimod, 5 per cent, or oral retinoids have some effect on the progression of dysplasia and can cause regression by at least two histological grades. Other newer options may include anti-human papilloma virus treatment and vaccination may reduce the incidence long term.

---

Abraham Buschke, 1868–1943, a German dermatologist.

JW Löwenstein described this condition in 1939.

John Templeton Bowen, 1857–1941, Professor of Dermatology, Harvard University Medical School, Boston, MA, USA, described this intradermal precancerous skin lesion in 1912.
### NON-MALIGNANT STRICTURES – ANAL STENOSIS

#### Spasmodic
An anal fissure causes spasm of the internal sphincter. Rarely, a spasmodic stricture accompanies secondary megacolon, possibly as a result of the chronic use of laxatives.

#### Organic
Anal stenosis is a rare but serious complication of anorectal surgery, 90 per cent are seen after haemorrhoidectomy. Other causes include trauma, inflammatory bowel disease, radiation treatment, sexually transmitted disease, tuberculosis and some skin conditions, e.g. scleroderma.

#### Postoperative stricture
This sometimes follows a haemorrhoidectomy performed incorrectly. Removal of excess anoderm and mucosa without adequate skin bridges can lead to scarring and structuring. Stenosis can be seen after stapled haemorrhoidopexy (0.8–5 per cent) and low coloanal anastomoses, especially if a stapling gun is used, but these are really low rectal stenoses.

#### Irradiation stricture
This is an aftermath of irradiation and is particularly seen after chemoradiation for anal carcinoma when a large area of skin and anoderm are irradiated. It can be seen after irradiation for any pelvic tumours.

#### Senile anal stenosis
A condition of chronic internal sphincter contraction is sometimes seen in the elderly. Increasing constipation is present, with pronounced straining at stool. Faecal impaction is liable to occur. The muscle is rigid and feels like a tight rubber ring. There is no evidence of a fissure-in-ano. The treatment is dilatation at frequent intervals.

#### Lymphogranuloma inguinale
Lymphogranuloma inguinale (see Chapter 72) is by far the most frequent cause of a tubular inflammatory stricture of the rectum and 80 per cent of the sufferers are women. Frei's reaction is usually positive. This variety of rectal stricture is particularly common in black populations and may be accompanied by elephantiasis of the labia majora. In the early stages, antibiotic treatment may lead to cure. In advanced cases, excision of the rectum is required.

#### Inflammatory bowel disease
Stricture of the anorectum may complicate Crohn's disease and, in this instance, the stricture is annular and often more than one is present. These stenoses are characterised by transmural scarring and inflammation. Occasionally, an anal stricture may occur in ulcerative colitis. Until a biopsy is obtained, a carcinoma should be suspected if a stricture is found.

#### Endometriosis
Endometriosis of the rectovaginal septum may present as a stricture. There is usually a history of frequent menstrual periods with severe pain during the first 2 days of the menstrual flow.

#### Neoplastic
When free bleeding occurs after dilatation of a supposed inflammatory stricture, carcinoma should be suspected (Grey Turner) and a portion of the stricture should be removed for biopsy. Sometimes in these cases, repeated biopsies show inflammatory tissue only. If, however, the symptoms show a marked progression, malignancy should be strongly suspected.

#### Clinical features
Increasing difficulty in defaecation is the leading symptom. The patient finds that increasingly large doses of aperients are required and, if the stools are formed, they are ‘pipe-stem’ in shape. In cases of inflammatory stricture, tenesmus, bleeding and the passage of mucus are superadded. Sometimes the patient comes under observation only when subacute or acute intestinal obstruction has supervened.

#### Rectal examination
The finger encounters a sharply defined shelf-like interruption of the lumen. If the calibre is large enough to admit the finger, it should be noted whether the stricture is annular or tubular. Sometimes this point can be determined only after dilatation. A biopsy of the stricture must be taken. Often the examination will be painful and needs to be performed under general anaesthesia when biopsies and gentle, graduated dilatation may be undertaken.

#### Treatment
Before starting treatment, it is important to ascertain the cause of the stricture. If associated with Crohn's disease, an anoplasty is contraindicated. Non-operative treatment is recommended for mild stenosis. The use of stool softeners and fibre supplements helps aid the passage of stools.

#### Prophylactic
The passage of an anal dilator during convalescence after haemorrhoidectomy greatly reduces the incidence of postoperative stricture. Efficient treatment of lymphogranuloma inguinale in its early stages should lessen the frequency of stricture from that cause.

#### Dilatation
Anal dilatation can be performed under general anaesthesia and then, by the patient, using an anal dilator. For anal and many rectal strictures, dilatation at regular intervals is all that is required.

#### Anoplasty
For severe anal stenosis, an anoplasty is used to replace loss of anal tissue. The stricture is incised and a rotation or advancement flap of skin and subcutaneous tissue replaces the defect.
and enlarges the anal orifice (Figure 73.46). This technique is particularly useful for postoperative strictures.

**Colostomy**

Colostomy must be undertaken when a stricture is causing intestinal obstruction and in advanced cases of stricture complicated by fistulae-in-ano. In selected cases, this can be followed by restorative resection of the stricture-bearing area. If this step is anticipated, a loop ileostomy is constructed.

**Rectal excision and coloanal anastomosis**

When the strictures are at or just above the anorectal junction and are associated with a normal anal canal, but irreversible changes necessitate removal of the area, excision can be followed by a coloanal anastomosis with good functional results (Summary box 73.15).

### Summary box 73.15

**Benign anal stricture**
- May be spasmodic or organic
- May be iatrogenic, e.g., after haemorrhoidectomy or repair of imperforate anus
- Biopsy must be taken to rule out malignancy
- Can usually be managed by regular dilatation
- Severe anal stenosis may require an anoplasty

### MALIGNANT TUMOURS

**Malignant lesions of the anus and anal canal**

Anal malignancy is rare and accounts for less than 2 per cent of all large bowel cancers. The crude incidence rate is 0.65 per 100,000. Those arising below the dentate line are usually squamous, whereas those above are variously termed basaloïd, cloacogenic or transitional. Collectively, they are known as epidermoid carcinomas, and management and prognosis is similar for this group, which accounts for >70 per cent of anal malignancies. Adenocarcinomas are the next most common. Other tumours include melanoma, lymphoma and sarcoma.

**Squamous cell carcinoma**

Although rare, the incidence of anal squamous cell carcinoma (SCC) is rising, with a direct association with HPV infection, AIN and immunosuppression. Anal SCC is associated with HPV (especially subtypes 16, 18, 31 or 33) in 70–90 per cent of cases (Figure 73.47). Patients at increased risk are those with HIV infection, recipients of organ transplants (renal transplant patients have a 100-fold increased risk) and those with a past history of cancers at ‘sexually accessible’ sites (usually genital). Pain and bleeding are the most common symptoms and the disease is thus often initially misdiagnosed as a benign condition, highlighting the need for a level of suspicion and adequate examination. A mass, pruritus or discharge is less common. Advanced tumours may cause faecal incontinence by invasion of the sphincters and, in women, anterior extension may result in anovaginal fistulation. On examination, anal margin tumours look like malignant ulcers. There may be associated HPV lesions. Anal canal tumours are palpable as irregular indurated tender ulceration. Sphincter involvement may be evident.

**Management**

Historically, early anal margin tumours were treated by local excision and anal canal tumours by abdominoperineal excision of the rectum. Nowadays, primary treatment is by chemoradiotherapy (combined modality therapy (CMT)) (Nigro), the chemotherapy usually including a combination of 5-fluorouracil (5-FU) with mitomycin C or cisplatin. Metastases are rare at presentation (5 per cent) and treatment is aimed at local control. Initial staging involves a clinical examination and biopsy of the primary tumour, as well as examination of inguinal nodes. Local staging is by MRI scanning and CT is used to assess lungs and abdomen for metastatic spread. Positron emission tomography (PET) CT may help in equivocal inguinal node assessment. The surgeon has an important role in management: initial diagnosis is surgical; small marginal tumours are still best treated by local excision; radical surgery is indicated in those with persistent or recurrent disease following CMT; and a defunctioning stoma may be indicated for those in whom treatment and disease regression is associated with radionecrosis, incontinence or fistula. Despite good results with chemoradiotherapy 20–25 per cent of patients will have local disease relapse. After thorough assessment, these patients may require radical abdominoperineal resection, including excision of the posterior wall of the vagina in 70 per cent of women and reconstruction of the perineum using myocutaneous flaps.

**Other anal malignancies**

Adenocarcinomata within the anal canal are usually extensions of distal rectal cancers. Rarely, adenocarcinoma may arise from anal glandular epithelium or develop within a longstanding...
Sir James Paget, 1814–1899, surgeon, St Bartholomew’s Hospital, London, UK, described this disease in 1874.

(usually complex) anal fistula; treatment is as for low rectal cancers (i.e. abdominoperineal excision of the rectum (APER) with or without previous radiotherapy or chemoradiotherapy), but prognosis is less good. Melanocytes can be found in the transitional zone of the anal canal. Malignant melanoma of the anus is very rare and usually presents as a bluish-black soft mass that may mimic a thrombosed external pile, although it may be amelanotic (Figure 73.48). The prognosis, irrespective of treatment, is extremely poor. Perianal Paget’s disease is exceedingly rare (Summary box 73.16).

Summary box 73.16

Anal cancer
- Uncommon tumour, which is usually a squamous cell carcinoma
- Associated with human papilloma virus (HPV)
- More prevalent in patients with HIV infection
- May affect the anal verge or anal canal
- Lymphatic spread is to the inguinal lymph nodes
- Treatment is by chemoradiotherapy in the first instance
- Major ablative surgery is required if the above fails

CHAPTER 74

URINARY SYMPTOMS

Haematuria

Blood in the urine (haematuria) may be the only indication of cancer and other pathology in the urinary tract (Figure 74.1). Microscopic haematuria may be detected by dipstick testing in a routine health check. A substantial haemorrhage imparts a red or brownish tinge to the urine (macroscopic haematuria) and the patient may pass clots. False-positive stick tests and the discoloured urine caused by beetroot and some drugs (e.g. Dindevan (phenindione), Pyridium (phenazopyridine) and Furadantin (nitrofurantoin)) are distinguishable by the absence of red blood cells on urinary microscopy.

Haematuria may be intermittent or persistent. If the patient experiences pain with haematuria, the characteristics of the pain may help to identify the source of the bleeding. If there is a malignant cause for the haematuria, there is usually no pain.

In practice, all patients with haematuria should be investigated even if they are taking anticoagulant drugs. In many, all tests will be negative: the chance of finding a urological cause in patients under 40 years of age with microscopic haematuria is small. However, bleeding into the urinary tract may be caused by an occult nephropathy so it is important to check for significant proteinuria and hypertension in these patients (Summary box 74.1).

Pain

Renal pain

A deep-seated, sickening ache in the loin characterises acute upper urinary tract inflammation or obstruction, probably as the result of stretching of the capsule of the kidney. Even small and peripheral kidney stones may cause pain, even in the absence of infection. Large slow-growing masses such as tumours or cysts

Summary box 74.1

Haematuria

- Is always abnormal whether microscopic or macroscopic
- May be caused by a lesion anywhere in the urinary tract
- Is investigated by:
  - examination of midstream specimen for infection
  - cytological examination of a urine specimen
  - intravenous urogram and/or urinary tract ultrasound scan
  - flexible or rigid cystoscopy
- Is commonly caused by urinary infection, especially in young women
PART 12  |  GENITOURINARY

URINARY SYMPTOMS AND INVESTIGATIONS

Summary box 74.2

**Pain from the upper urinary tract**
- Pain of acute obstruction of the renal pelvis is typically deep in the loin and ‘bursting’ in character
- Ureteric colic (usually due to stone) is characterised by sharp exacerbations against a constant background
- Pain is referred to the groin, scrotum or labium as calculus obstruction moves distally in the ureter

Summary box 74.3

**Pain from the lower urinary tract**
- Is commonly felt as suprapubic discomfort, worsening as the bladder fills
- Cystitis causes burning or scalding urethral pain (dysuria)
- May be referred to the tip of the penis in men, even when lesion is in the bladder

Summary box 74.4

**Altered bladder function**
- Failure bladder storage function leads to urgency and frequency of micturition, often by day and by night
- Failure of bladder emptying function is most commonly caused by obstruction to the bladder outflow (e.g. by prostatic enlargement) but can also be caused by weakness of the detrusor muscle
- Chronic retention of urine may present as nocturnal bed-wetting

Pain from the upper urinary tract

- This is experienced as a penetrating ache in the perineum and rectum, sometimes with associated inguinal discomfort. The patient is characteristically depressed by the relentless pain. Pelvic pain is often blamed on ‘chronic prostatitis’, ‘prostadynia’ or ‘chronic prostate pain syndrome’, but it occurs in both men and women. It is notoriously difficult to treat, a characteristic shared with various chronic scrotal pain syndromes.

Urethral pain

- Urethral pain is a scalding or burning felt in the vulva or penis, especially during voiding (Summary box 74.3).

Altered bladder function

- The normal bladder has two phases of function. During the filling phase, the bladder acts as a reservoir to collect urine until it is emptied in the voiding phase. Inappropriate contraction of the bladder detrusor muscle during filling (instability) is perceived as a sensation of urgency. There may be frequent micturition with or without urge incontinence. Sleep may be disturbed by nocturia. Instability may be idiopathic in both sexes or part of the bladder response to outflow obstruction, notably in prostatic disease. When detrusor instability has a demonstrable neurological cause, it is known as hyperreflexia.

Symptoms of impaired emptying are most commonly the result of bladder outflow obstruction, but detrusor failure presents a similar picture. The patient has difficulty initiating voiding (hesitancy) and the stream is variable or slow. Abdominal straining improves the weak flow. When micturition is complete, the bladder may still feel full. With time, the bladder becomes chronically overfilled. Urine spills out, typically at night when sleep halts trips to the lavatory (chronic retention with overflow) (Summary box 74.4).

**INVESTIGATION OF THE URINARY TRACT**

With the exception of renal and scrotal masses or tenderness, a palpable bladder or an abnormal prostate on digital rectal examination, urological conditions are most likely to be diagnosed from the history or by investigations.

Urine

Dipsticks (Multistix, Labstix) are a convenient way to screen urine for blood, protein or nitrites. When the urine is macroscopically clear and negative on dipstick testing, microscopy and culture of a midstream clean-catch specimen are usually negative. The presence of protein and nitrites (produced by organisms in the urine) indicates the likelihood of infection. The significance of microscopic haematuria is discussed above. Some dipsticks also give an indication of the pH and specific gravity of the urine.

Microscopy confirms the presence of white and red blood cells in the urine, and bacteria may also be visible. Protein casts suggest disease of the renal parenchyma, as does red cell dysmorphia seen on phase contrast microscopy. Schistosoma ova have a typical appearance (Figure 74.2), and vegetable or meat fibres may be present if there is a fistula connecting the bowel with the urinary tract.

Cytological examination of the urinary sediment is sensitive and specific for poorly differentiated transitional cell tumours anywhere in the urinary tract. However, false negatives are common when the cancer is well differentiated. A chemical test...
cortical necrosis, there is a loss of glomeruli, whereas in pyelonephritis, tubular function is most severely affected. In obstructive nephropathy, back pressure on the renal parenchyma causes all three types of damage.

Levels of blood urea and serum creatinine can be affected by various factors but, when taken together they serve as a useful clinical guide to overall renal function. A creatinine clearance test will give an approximate value for glomerular filtration rate but is prone to error. A more accurate assessment of glomerular function can be obtained from an estimate of the clearance of chromium-51-labelled ethylenediaminetetraacetic acid. Surgeons will usually call on their nephrological colleagues for more detailed investigations of tubular function and renal blood flow.

The specific gravity of the urine is fixed at a low level when the kidney loses the power to concentrate because of renal tubular dysfunction. Estimation of the urinary loss of sodium, β-microglobulin or the tubular enzyme N-acetylglycosamin (NAG) will further define the nature of any functional impairment (Summary box 74.6).

**Summary box 74.6**

**Tests of renal function**

- Elevated blood urea and serum creatinine levels usually indicate a significant impairment of renal function
- More sophisticated renal assessment is required to quantify the functional deficit

**Imaging**

A plain abdominal x-ray showing the kidneys, ureters and bladder (the KUB) is a simple and useful test. Abnormalities of the spine and other bony structures including scoliosis, spina bifida, degenerative disease of the spine, metastases, fractures and arthritis may be relevant to the urological diagnosis. The soft-tissue renal shadows, outlined by their more radiolucent fatty coverings, overlie the upper attachments of the psoas muscles. A full bladder often presents a hazy outline arising from the pelvis.

Most urinary calculi absorb x-rays and lie in the region of the renal shadows and along the course of each ureter. These normally follow the tips of the transverse processes of the vertebrae, cross the sacroiliac joints and head for the ischial spine before hooking medially towards the bladder base. Stones with a low calcium content and those overlying bony structures may be difficult to see on the plain film. Pelvic phleboliths are very common and can look like lower ureteric calculi. Uric acid stones are the most common radiolucent calculi (Summary box 74.7).

**Summary box 74.7**

**Straight abdominal radiograph**

- Most urinary calculi are radiodense
- Uric acid calculi are typically radiolucent

---

**Figure 74.2** Schistosoma ovum (courtesy of Dr Nawal Derius).
Intravenous urography (urography)

Excretion renography has been a mainstay of urological investigation since the introduction of intravenous contrast media in the 1930s. These are organic chemicals to which iodine atoms are attached to absorb x-rays. When such a chemical is injected intravenously, it is filtered from the blood by the glomeruli and does not undergo tubular absorption. As a result, it rapidly passes through the renal parenchyma into the urine, which it renders radio-opaque.

Although intravenous urography (IVU) gives excellent images of the urinary tract (Figure 74.3), its use should be restricted because in a few patients the iodine in the contrast medium may cause an anaphylactic reaction. Patients with a history of allergy, atopy and eczema are particularly vulnerable, but severe reactions may occur without warning. Less invasive and dangerous imaging techniques are clearly to be preferred if they are able to give comparable diagnostic information (Summary box 74.8).

Summary box 74.8

Intravenous urography

- IVU can cause a dangerous hypersensitivity reaction in a small number of patients

Preparation

A laxative will clear faeces that might otherwise obscure details of urinary tract anatomy. Modest fluid restriction is permissible, but dehydration is dangerous because it may precipitate acute renal failure.

Technique

The patient is observed carefully while the first few drops of contrast medium (Urografin or Niopam 370) are injected. The earliest films show the renal parenchyma opacified by contrast medium – the nephrogram phase. A delayed nephrogram on one side indicates unilateral functional impairment. Distortion of the renal outline or failure of part of the kidney to function suggests a space-occupying lesion.

After a few minutes, the contrast is excreted into the collecting system, opacifying the calyces and the renal pelvis. Later films show the ureters and, at the end of the study, the patient is asked to pass urine and a final film is taken to show details of the bladder area. It is important to bear in mind that the static images of IVU provide only snapshots of dynamic events in the urinary tract. The appearance of a normal ureter changes as peristaltic waves of contraction pass along it.

IVU is particularly valuable to demonstrate tumours and calculi within the urinary tract, which are sometimes difficult to see on ultrasonography. It may also be useful to show details of abnormal anatomy that are difficult to interpret on an ultrasonogram.

As ultrasonography and other forms of scanning have become more sophisticated, the indications for the urogram are fewer and it may eventually fall into disuse. Obstruction to the upper urinary tract interferes with transport of contrast medium into the urine, which will show up as a non-functioning kidney on the standard urogram films. In these circumstances, a further x-ray taken many hours after injection of the contrast medium may show hazy opacification of a dilated system. Distortion of the calyces or the renal outline can equally be caused by a tumour or by harmless simple cysts. In each of these cases, more information can be obtained from ultrasonography or computed tomography (CT).

Retrograde ureteropyelography (synonym: retrograde ureterogram)

A ureteric catheter is passed into the ureteric orifice through a cystoscope (Figure 74.4). Contrast medium injected through the catheter will demonstrate the anatomy of the upper urinary tract. This is particularly useful if there is doubt about an intraluminal lesion (Figure 74.5) or if renal function is deficient (before surgery for pelviureteric junction obstruction, for instance). When a transitional tumour is found, it can be sampled by aspiration of urine from the upper tract or by brush biopsy. Retrograde ureteropyelography is possible under topical urethral anaesthesia using a flexible cystoscope. Introducing infection into a poorly draining part of the system carries a serious risk of septicaemia. If there is to be any delay in correcting the blockage surgically, facilities must be available to decompress the kidney by retrograde stenting or percutaneous nephrostomy.
Antegrade pyelography
Percutaneous puncture of a dilated renal collecting system is reasonably simple. The most common indication is the placement of a nephrostomy tube to drain an obstructed infected kidney or to provide access for percutaneous nephrolithotomy. Antegrade pyelography – in which contrast medium is introduced through the nephrostomy – can be helpful when retrograde studies are prevented by obstruction at the extreme lower end of the ureter.

Digital subtraction arteriography
Refinements in radiological imaging have now almost eliminated the need for translumbar aortography. Satisfactory imaging of the renal vessels can be achieved by digital subtraction angiography after intravenous injection of contrast medium. More precise information can be obtained by intra-arterial injection through a fine catheter inserted into the femoral artery using the Seldinger technique. Arteriography is now rarely used to demonstrate tumour vascularity in a hypernephroma (Figure 74.6), but a flush venogram is useful when CT suggests tumour invasion of the renal vein and vena cava.

Cystography
Cystography is now most commonly a component of videourodynamic assessment (see Chapter 76). Its role in assessing ureteric reflux in children has been largely superseded by radioisotope scanning and dynamic ultrasonography.

Urethrography
Ascending urethrography is valuable to demonstrate the extent of a urethral stricture (Figure 74.7) and the presence of false passages and diverticula associated with it. A urethrogram can be used to assess the extent of urethral trauma, but there is a serious danger that contrast medium may pass into the circulation. Lipiodol carries the danger of fat embolus and should never be used, and death has followed the use of barium emulsion. Umbradil viscous V is a radio-opaque water-soluble gel that contains the local anaesthetic lignocaine. It can be injected gently and safely using Knutsson’s apparatus even if the urothelium is breached.

Venography
Extension of a renal carcinoma from the renal vein into the vena cava can usually be demonstrated by ultrasound or CT, but venography was used for this purpose.

Ultrasonography
Ultrasonography is perhaps the imaging technique most widely used in urology. Kidney size, the thickness of its cortex and the presence and degree of hydronephrosis can be measured with great accuracy. Intrarenal masses can be diagnosed as smooth walled and fluid filled (simple cysts) or solid and complex (possible tumours). Stones produce a bright ultrasonic reflection and cast an acoustic shadow (Figure 74.8). The volume of urine in the bladder before and after micturition can be calculated, and even tiny filling defects within it detected. Scrotal contents can be displayed in great detail. The prostate is accessible by the transrectal route. Only the lower ureter resists effective investigation by transabdominal ultrasonography because of its small calibre and its proximity to the large bones of the pelvis and spine (Summary box 74.9).
Summary box 74.9

Ultrasonography
- Ultrasound scanning provides broadly similar anatomical information to an intravenous urogram but without the risks.

Transrectal ultrasonography
This has become a routine component of the investigation of suspected carcinoma of the prostate. Most commonly, suspicion has arisen because the level of prostate-specific antigen is raised or there is an abnormality of the texture or outline of the prostate on digital rectal examination. The features of carcinoma or benign enlargement of the prostate, although not absolutely specific, are sufficiently well recognised to allow an experienced ultrasonographer to identify promising sites for transrectal fineneedle biopsy.

Computed tomography
CT is particularly useful to assess structures in the retroperitoneum (Figure 74.9). In renal carcinoma it will show:
- the size and site of the tumour and the degree of invasion of adjacent tissue;
- the presence of enlarged lymph nodes at the renal hilum;
- invasion of the renal vein and vena cava.

CT is of crucial importance in the initial staging and follow up of men with testicular cancer, in whom the presence of retroperitoneal lymph node masses features in advanced disease. It has also been used to stage bladder and prostate cancer, but its value is less clearcut in these diseases. Non-contrast CT is also used routinely in the diagnosis of urinary calculi (Figures 74.10 and 74.11).

Magnetic resonance imaging and positron emission tomography
These technologies give information about the function of organs as well as detailed structural images. As they become more widely available, they are replacing many of the routine imaging techniques.

Radioisotope scanning
Radioisotope scanning is used to obtain information about function in individual renal units. Diethyltriaminepentaacetic acid (DTPA) behaves in the kidney like inulin: it is filtered by the glomeruli and not absorbed by the tubules. Using a gamma camera, DTPA labelled with technetium-99m can be followed during its transit through individual kidneys to give a dynamic representation of renal function. A 99mTc-DTPA scan is particularly useful to prove that collecting system dilatation is caused by obstruction. In obstruction, radioactivity will remain in the kidney even if urine flow is stimulated by administr
Anuria is defined as the complete absence of urine production. Oliguria is present when less than 300 mL of urine is excreted in a day (Summary box 74.11).

**Summary box 74.11**

**Diagnosing anuria**
- Check that the bladder is empty before diagnosing anuria
- Ultrasound the bladder

The maintenance of renal function and urine production depends upon perfusion of the kidneys with oxygenated blood. Reduced renal blood flow or hypoxia impairs renal function. When both are present, the danger of acute renal failure is even greater.

Renal failure is traditionally divided into:
- prerenal;
- renal;
- postrenal (obstructive).

**Prerenal**

Prerenal causes of acute renal failure include:
- hypovolaemia;
- blood loss;
- sepsis;
- cardiogenic shock;
- anaesthesia;
- hypoxia.

**Hypovolaemia**

This may result from inadequate fluid intake or from excessive loss of body water. Dehydration, prolonged vomiting, diarrhoea and other abnormal gastrointestinal fluid losses, burns and excessive sweating are all common causes of hypovolaemia.

**Blood loss**

This is usually caused by trauma or surgery, but acute blood loss from the gastrointestinal tract or haemorrhage associated with childbirth may be sufficient to cause hypovolaemic renal impairment.

**Sepsis**

Gram-negative septicaemia from a urinary tract source is a particularly potent cause of bacteraemic shock. Sepsis from the biliary tract and overwhelming infection from other sites, especially in the immunocompromised individual, are also associated with acute renal failure.

**Cardiogenic shock**

Acute dysrhythmia secondary to myocardial infarction, cardiac tamponade and pulmonary embolus may all result in reduced cardiac output of often poorly oxygenated blood.

**Anaesthesia**

Hypotension is a hazard of epidural and spinal anaesthesia.

**Hypoxia**

Prolonged hypoxia from any cause may occasionally be responsible.

---

**ANURIA**

Max Nitze, 1848–1906, urological surgeon, Vienna, Austria.
Harold Horace Hopkins, 1918–1994, Professor of Applied Optics, The University of Reading, Reading, UK.
Renal causes of acute renal failure include:
- drugs;
- poisons;
- contrast media;
- eclampsia;
- myoglobinuria;
- incompatible blood transfusion;
- disseminated intravascular coagulation.

**Drugs**

Aminoglycosides, cephalosporins and diuretics can be nephrotoxic, particularly if used in combination. They are quite commonly used in patients whose renal function is already compromised by sepsis or circulatory abnormalities. Prolonged use of non-steroidal anti-inflammatory drugs (NSAIDs) can cause a chronic interstitial nephritis and papillary necrosis; they also reduce renal plasma flow and therefore have nephrotoxic properties. Angiotensin-converting enzyme inhibitors used for the control of hypertension can cause a rapid reduction in the
glomerular filtration rate; this is particularly liable to occur in patients who have a reduced renal blood flow.

Poisons
Some of these are nephrotoxic.

Contrast media
Even modern contrast media may cause renal failure when injected into a dehydrated patient with compromised renal function.

Eclampsia
The early recognition of pre-eclampsia is vital to avoid the nephrotoxic consequences of toxaemia and uncontrolled hypertension.

Myoglobinuria
The presence of myoglobin in the urine is associated with the ‘crush’ syndrome after major trauma. Less severe injuries can also cause the syndrome, especially if a compartment syndrome is unrecognised or pressure areas break down.

Incompatible blood transfusion
This may lead to renal failure with myoglobinuria.

Disseminated intravascular coagulation
Disseminated intravascular coagulation usually follows major sepsis or massive blood transfusion and may occur post-partum.

Obstructive
Obstructive causes of acute renal failure include:

- calculi;
- pelvic malignancy;
- surgery;
- retroperitoneal fibrosis;
- bilharzia;
- crystalluria.

Calculi
Renal calculus disease is probably the most common cause of acute obstruction leading to anuria. The patient is likely to have unilateral renal colic against a background of non-function of the contralateral kidney, often due to previous surgery or pre-existing obstruction by calculi.

Pelvic malignancy
Carcinomas arising from the bladder, prostate, cervix, ovary or rectum can all lead to obstruction of one or both ureters. A history of haematuria and vaginal or rectal bleeding signpost the diagnosis. A large pelvic mass is commonly palpable on bimanual examination.

Surgery
The ureters are vulnerable to damage during pelvic and retroperitoneal surgery, but injury should be avoided if proper care is taken. It is unusual, but not impossible, to damage both ureters.

Retroperitoneal fibrosis
For details of retroperitoneal fibrosis, see Chapter 75.

Bilharzia
Schistosomiasis may lead to ureteric fibrosis and stenosis, and may be responsible for the development of squamous cell carcinoma of the bladder.

Crystalluria
Uric acid crystalluria can develop in patients receiving chemotherapy for leukaemia or lymphoma unless they are given prophylactic treatment with allopurinol.

Clinical aspects
Answers to the following questions should indicate the probable cause of reduced urine output.

- Is urine being produced? Bladder catheterisation is essential if a voided sample cannot be obtained. If urine is available, check the specific gravity, look for the presence of casts (implying a renal cause), test for myoglobinuria and send a sample for culture and microscopy.
- Is there an obvious prerenal cause? This can usually be answered by clinical examination, assessment of the patient’s vital signs, examination of the fluid balance chart and measurement of the arterial oxygen concentration.
- Is there ureteric obstruction? Hydronephrosis may not be marked in acute obstruction, but ultrasonography will usually show some degree of ureteric dilatation. A plain abdominal x-ray should be checked for calculi.
- What drugs have been given recently? If a drug is thought to be responsible for renal impairment, it should obviously be withdrawn unless its use is vital.
- Is this a progression to chronic renal failure? The presence of shrunken kidneys on ultrasound, normochromic anaemia and hypertension suggest progression to a chronic state even if a previous history of renal failure is not available.

Management and treatment
Renal failure caused by acute tubular necrosis may progress through three recognisable phases:

1. oliguria;
2. the diuretic phase;
3. recovery.

The initial management is aimed at prompt restoration of the circulating volume deficit and correction of tissue hypoxia. Most patients will require a level of care that is available only in a specialised unit. As a minimum, monitoring with a pulse
oximeter and central venous pressure measurements will supplement basic observations. For patients with hypovolaemia or sepsis, inotropic support with dopamine may improve cardiac efficiency and increase renal blood flow. If urine production is not promptly restored, frusemide (furosemide) can be given, but this is not always successful and the drug itself may be nephrotoxic. Mannitol may be used as a plasma expander and osmotic diuretic, but care must be taken not to overload the circulation. The aim is to achieve the best possible blood pressure, with a central venous pressure of 7–9 cmH₂O. It may be that 100 per cent oxygen is needed to maintain the oxygen tension (PO₂).

If these measures fail, acute tubular necrosis has supervened. Excess fluid loads must be avoided and fluid input restricted to match the reduced output plus insensible losses (500–800 mL per 24 hours depending on ambient conditions). Abnormal losses due to vomiting, nasogastric aspiration, diarrhoea or fistulae should be monitored and replaced.

A hyperkalaemic acidosis is the characteristic metabolic abnormality of the oliguric phase of renal failure. Correction of the metabolic acidosis with intravenous bicarbonate is tempting but not always advisable. Rising serum potassium is life-threatening and requires effective intervention. A calcium resuscitron enema is the simplest remedy. The ion-exchange resin can also be administered orally but is unpalatable. Cautious use of intravenous dextrose and insulin should be considered if ion exchange fails. The help of a renal physician is highly desirable because urgent dialysis may become necessary to save life (Summary box 74.12).

**Summary box 74.12**

**Shared management with nephrologist**

- Enlist the help of a nephrologist at an early stage in the management of renal failure

The diuretic phase traditionally occurs between the eighth and tenth day but may be delayed as long as 6 weeks. Glomerular filtration recommences but tubular function takes longer to recover. A heavy loss of sodium and potassium can be expected, and fluid and electrolyte requirements must be carefully judged. In most patients the diuretic phase is followed by the recovery phase, but some never recover and will need renal replacement therapy if they are to survive.

Factors that influence the outcome of acute renal failure include the need for artificial ventilation, the need for inotropic support and the presence of jaundice. There is a significant mortality rate.

**Nutritional support**

Many patients are unable to eat. If enteral feeding is impossible, parenteral nutrition must be administered, with extreme care to avoid circulatory overload.

**Infection**

These patients are at increased risk of generalised infection. Swabs taken from the nose and throat, sputum specimens and urine, if available, should be sent for culture. If antibiotics are required, they should be non-nephrotoxic.

**General nursing care**

Meticulous recording of fluid balance is obviously central to the successful management of these patients. Patients who are seriously ill or comatose need regular turning and care of pressure areas if they are to avoid pressure sores. Physiotherapy to the chest and extremities will aid recovery.

**Renal support**

Renal replacement is needed for those patients in whom the oliguric or anuric phase is associated with significant uremic symptoms (vomiting, muscular twitching, itching and altered states of consciousness) or uncontrollable hyperkalaemia (Summary box 74.13).

**Summary box 74.13**

**Life-threatening hyperkalaemia**

- In acute renal failure, significant hyperkalaemia is life-threatening and should be corrected at an early stage

**Peritoneal dialysis**

Provided that the patient has not had recent abdominal surgery, peritoneal dialysis can be performed by insertion of a fenestrated catheter under local anaesthetic. This is placed just inferior to the umbilicus in the midline. Sterile dialysis fluid is then run into the peritoneal cavity, where it equilibrates with the extracellular fluid using the peritoneum as a dialysis membrane. After a variable time, the fluid is drained into a closed drainage system. The process is repeated in cycles. Occasionally, when anauria is prolonged, a cuffed catheter needs to be inserted, as used in chronic ambulatory peritoneal dialysis. The disadvantages of acute peritoneal dialysis are the potential for introducing infection into the peritoneum and the rather slow rate of correcting metabolic imbalance, particularly hyperkalaemia.

**Haemodialysis**

A few sessions of haemodialysis may be life-saving. A double lumen catheter is placed over a guidewire into one of the great veins (jugular, subclavian or femoral). Between sessions of dialysis the lines are kept patent by filling them with heparin solution. Haemodialysis can result in a rapid correction of metabolic abnormalities, but also tends to result in considerable fluctuations of the overall fluid balance. The other disadvantage is that heparinisation is necessary, and this may be undesirable after a recent surgical procedure.

**Haemofiltration**

This, like haemodialysis, requires the use of an extracorporeal machine but causes much less haemodynamic upset. This may be of critical importance for the acutely ill patient.

**Obstructive renal failure**

When the patient is too ill for surgery to remove the cause of obstruction to the upper urinary tract, the treatment of obstructive renal impairment is drainage, either externally using a nephrostomy or internally using an indwelling stent (Summary box 74.14).
Summary box 74.14

Catheterisation and stents

- Urethral or suprapubic catheterisation will relieve obstruction distal to the bladder
- Indwelling stents to relieve ureteric obstruction can be inserted cystoscopically or percutaneously

Percutaneous nephrostomy

Under ultrasonographic guidance and local anaesthetic, a fine bore hollow needle is introduced via the flank through the parenchyma and into the expanded collecting system of the obstructed kidney. Once it penetrates the system, contrast medium can be injected through the needle to define its exact position. A wire passed through the lumen of the needle is used to guide the insertion of a series of dilators, which enlarge the track until it will accept a suitably sized nephrostomy tube (Figure 74.13). This will drain urine and pus, provided that the latter is not too viscous. The tube is anchored firmly in place to allow continued drainage as renal function recovers.

Insertion of a J-stent

The ureter can be drained into the bladder by the insertion of a pigtail- or J-stent (see Figure 74.13). The procedure begins with a retrograde ureterogram under fluoroscopic control to provide an image of the ureter. This will often give an indication of the cause of the obstruction. A guidewire is introduced through the ureteric orifice and guided up the ureter into the renal pelvis. The stent is rail-roaded over the guidewire until its distal end also lies within the renal pelvis above the obstruction. When the guidewire is removed, the ends of the stent curl to form a J-shape or a pigtail to secure the device against migration. Stents can be placed under topical urethral anaesthesia using the flexible cystoscope and may be safely left in position for several months. As a foreign body in the urinary tract, stents are prone to infection and encrustation if neglected. It is vital to keep careful records to account for all stents inserted.

If the J-stent cannot be inserted cystoscopically, it may be placed from above through a nephrostomy.

Open surgery

This is a rarity when the minimally invasive methods described above are available. Retrograde insertion of a nephrostomy through an incision in the renal pelvis is the preferred method because it can be surprisingly difficult to locate even dilated calyces by blind puncture of the renal parenchyma.

Figure 74.13 X-ray showing a left-sided, pigtail nephrostomy tube draining a kidney obstruction by a ureteric calculus, seen at the level of L3–4. A J-stent is in the right ureter, which has been cleared of stones.

CHAPTER 75

The kidneys and ureters

**LEARNING OBJECTIVES**

To recognise and understand:
- Important congenital abnormalities of the upper urinary tract
- Important cystic diseases of the kidney
- The management of open and closed trauma to the kidney and ureter
- The aetiology, presentation and surgical management of obstruction to the upper urinary tract
- The pathophysiology of renal stone formation
- The management of urinary tract calculi
- The management of sepsis in the upper urinary tract
- Important renal neoplasms and their presentation
- The surgery of upper urinary tract tumours

**SURGICAL ANATOMY**

The parenchyma of each kidney usually drains into seven calyces, three upper, two middle and two lower calyces (Figure 75.1). Each of the three segments represents an anatomically distinct unit with its own blood supply. One or more renal arteries are present as physiological end arteries that provide the sole blood supply to the tissue they serve. The renal veins are commonly multiple, variable and richly anastomotic. When approached anteriorly, the main artery is typically hidden behind the renal vein.

**CONGENITAL ABNORMALITIES OF THE KIDNEY**

**Absence of one kidney**

About one in 1400 people have a single kidney (Table 75.1). Sometimes a ureter and renal pelvis are present with no kidney. The contralateral kidney is typically hypertrophied. The possible absence of the contralateral kidney must be considered when planning nephrectomy.

**Renal ectopia**

Ectopic kidneys are found in one in 1000 people, usually on the left near the pelvic brim. The other kidney is generally normal. A diseased ectopic kidney may present diagnostic problems and may be mistakenly excised as an unexplained pelvic mass.

**Horseshoe kidney**

A horseshoe kidney is a pair of ectopic kidneys fused usually at their lower poles and lying in front of the fourth lumbar vertebra and great vessels. It is found in one in 1000 necropsies and is more common in men. Upper pole fusion is rare.

**Clinical features**

Horseshoe kidneys are vulnerable to disease, possibly because the ureters are angulated (Figure 75.2) causing urinary stasis, infection and nephrolithiasis. A pelviureteric junction obstruction (see below) has the same consequences. Horseshoe kidney is usually a radiological diagnosis. Usually the urogram shows the lower pole calyces bilaterally point towards the midline. Rarely, all or most of the calyces are reversed (Figure 75.3). Horseshoe kidney is not a contraindication to pregnancy but may predispose to urinary complications.

Kaspar Friedrich Wolff, 1733–1794, Professor of Anatomy and Physiology, St Petersburg, Russia, described the mesonephric duct and body in 1759.
Division of the relatively avascular isthmus between the kidneys is usually only indicated in the course of surgery for abdominal aortic aneurysm. The blood supply of the horseshoe comes unpredictably from nearby major vessels (Summary box 75.1).

**Summary box 75.1**

**Horseshoe kidneys**
- Horseshoe kidneys are liable to pelviureteric obstruction, infection and stone
- An unrecognised pelvic kidney may cause diagnostic confusion during surgery

**Unilateral fusion**
Unilateral fusion (synonyms: crossed dystopia, cross fused renal ectopia) is rare but the urogram is striking. Both kidneys are in one loin and usually fused. The ureter of the lower kidney crosses the midline to enter the bladder on the contralateral side. Both renal pelves can lie one above each other medial to the renal parenchyma (unilateral long kidney) or the pelvis of the crossed kidney faces laterally (unilateral S-shaped kidney; Figure 75.4).

**Congenital cystic kidneys**
Congenital cystic kidneys (synonym: polycystic kidneys) are hereditary, potentially lethal and transmitted by either parent as an autosomal dominant trait. Thus, the risk of inheriting the condition is high. The disease does not usually manifest clinically before the age of 30 years.

**Pathology**
The kidneys are huge: the cysts distort the renal capsule. Cysts of various sizes contain clear fluid, thick brown material or coagulated blood. There may be a congenital cystic disease of the liver. The aetiology is uncertain.

**Clinical features in the adult**
The condition is slightly more common in women than men. There are six clinical features:
1. an irregular upper quadrant abdominal mass;
2. loin pain;
3. haematuria;
4. infection;
5. hypertension;
6. uraemia.

**Renal enlargement**
Less florid examples are revealed unexpectedly at laparotomy or on abdominal imaging. Unilateral renal swelling, in which one kidney contains larger cysts than the other, may be confused with a cystic renal tumour.

**Pain**
Pain is commonly a dull loin ache. Haemorrhage into a cyst causes more severe pain, as does a calculus passing from the diseased kidney.

**Haematuria**
Cyst rupture into the renal pelvis may cause recurrent haematuria. Profuse haematuria is uncommon.

**Infection**
Pyelonephritis is common in patients with congenital cystic kidney, presumably because of urinary stasis.

![Figure 75.2 Horseshoe kidney. Note the ureters passing in front of the fused lower poles.](image1)

![Figure 75.3 Urogram of a horseshoe kidney. Only rarely are all the calyces directed towards the spinal column.](image2)
Hypertension
After the age of 20 years, most patients are hypertensive.

Uraemia
Congenital cystic kidneys produce large volumes of poor quality urine with a trace of albumin but no casts or cells. Non-specific symptoms of chronic renal failure develop as functioning renal tissue is replaced by cysts. Severe anaemia is common. Signs of renal failure often begin in middle life and the patient soon needs renal replacement therapy.

Imaging
There are multiple cysts in both kidneys and sometimes cysts in the liver and other organs. Blood and debris in the cysts may mimic the heterogeneity of a cystic adenocarcinoma. Simple cysts are usually solitary and have smooth thin walls and homogeneous contents (Figure 75.5). Cytologic examination of cyst fluid obtained by fine-needle aspiration will rule out cancer.

The urogram is typical: the renal shadows are enlarged in all directions; the renal pelvis is compressed and elongated; and the calyces are stretched over the cysts (Figure 75.6).

Treatment
As kidney failure develops, a low-protein diet postpones the inevitability of renal replacement therapy. Infection, anaemia, hypertension and disturbances of calcium metabolism also need treatment by a nephrologist.

Surgery to uncap the cysts (Rovsing’s operation) is rarely indicated (Summary box 75.2).

Summary box 75.2
- Polycystic kidney disease
  - Inherited as an autosomal dominant trait
  - An important cause of end-stage renal failure
  - Pain, haematuria, infection and hypertension are common
  - Often fatal in early middle age

Summary box 75.3
- Simple renal cysts
  - Common
  - Often multiple
  - Diagnosed on ultrasound
  - Rarely require treatment
  - Treat only if causing obstruction

Differential diagnosis
In sheep-rearing districts, hydatid cysts of the kidney are common. On the right side, they can be mistaken for a hydatid cyst of the liver. Occasionally, the patient complains of passing ‘grape skins’ (ruptured daughter cysts) in the urine. Removal of the cyst must follow the principles used in excision of hydatid cyst of the liver. For a large cyst, nephrectomy may be safer.
Aberrant renal vessels

Multiple renal arteries are most common on the left. The renal arteries are functional end-arteries, so division of an aberrant renal artery leads to infarction of a section of parenchyma. Aberrant renal veins are common and can be divided with impunity. Aberrant arteries probably do not cause hydronephrosis, although a hydronephrotic renal pelvis may bulge between renal vessels, making them noticeable (Figure 75.7).

**CONGENITAL ABNORMALITIES OF THE RENAL PELVIS AND URETER**

Duplication of a renal pelvis

Duplication of a renal pelvis, usually unilateral and left-sided (Figure 75.8), is found in about 4 per cent of patients. The small upper renal pelvis drains the upper calyces; the larger lower renal pelvis drains the middle and lower groups of calyces.

Duplication of a ureter

Duplicated ureter is found in about 3 per cent of urograms often joining in the lower third of their course (Figure 75.9) with a common ureteric orifice. When the ureters open independently into the bladder, the ureter from the upper pelvis opens distally and medially (Figure 75.10).

Clinical features

Infection, calculus formation and pelviureteric junction obstruction are more common than in normal kidneys but most are discovered by chance. One moiety may be dysplastic and non-functioning. Two ureters opening separately may both be abnormal in function, position or both. In children, this may result in a refluxing lower pole ureter and an upper pole ureter terminating in a ureterocele with a risk of infection and/or obstruction.

An ectopic second ureteric opening is a rare cause of puzzling symptoms. In females, an ectopic ureter opens either into the urethra below the sphincter (Figure 75.11) or into the vagina. The history suggests the diagnosis which is confirmed by urography. A girl or woman who voids normally but who has dribbled urine for as long as she can remember probably has an ectopic ureteric orifice. The orifice is difficult to see because it is guarded by a valve.

In the male, the aberrant opening is above the external urethral sphincter so the patient is continent. The ureteric orifice at the apex of the trigone, the posterior urethra, in a seminal vesicle or in an ejaculatory duct is likely to be functionally abnormal, and infection is common.

Treatment

Asymptomatic duplication of the kidney is harmless. A severely diseased or atrophic moiety is effectively treated by partial nephrectomy. A refluxing ureter may need reimplanting. An ectopic ureter in the female frequently drains hydronephrotic and chronically infected renal tissue, which is best excised. Rarely, the incontinence can be cured and renal function preserved by implanting the ectopic ureter into the bladder or contralateral ureter (Summary box 75.4).
Summary box 75.4

Duplication of the kidneys and ureters
- Is commonly asymptomatic and harmless
- One or both moieties may be dysplastic
- There may be urinary reflux, incontinence or obstruction

Congenital megaureter

Congenital megaureter is a rare oddity that may be bilateral and associated with other congenital anomalies. Functional obstruction at the lower end of the ureter ends in progressive dilatation and infection. The ureteric orifice appears normal and a ureteric catheter passes easily. Reflux is not a feature of the untreated condition but occurs if the ureteric orifice is opened endoscopically. Spontaneous improvement occurs but infection or deteriorating function will require refashioning and reimplantation of the affected ureter.

Post-caval ureter

The right ureter passes behind the vena cava instead of lying to the right. If this causes obstructive symptoms, the ureter can be divided and rejoined in front of the cava. Unusually, the retrocaval portion of the ureter is fibrotic and must be excised.

Ureterocele

Ureterocele is a cystic enlargement of the intramural ureter, probably due to congenital atresia of the ureteric orifice. Present from childhood, the condition is often unrecognised until adult life. The 'adder head' on excretory urography (Figure 75.12) is typical. Ureterocele is confirmed by the cystoscopic appearance of a translucent cyst enlarging and collapsing as urine flows into it (Figure 75.13). Treatment should be avoided unless there are symptoms arising from infection and/or stone formation. Ureterocele is most common in women; occasionally, the cyst may cause obstruction to the bladder outflow by prolapsing into the internal urethral opening.

Endoscopic diathermy incision is effective treatment for a symptomatic ureterocele, although a micturating cystogram is advisable to detect postoperative urinary reflux. In advanced unilateral cases with hydronephrosis or pyonephrosis, consider nephrectomy.

INJURIES TO THE KIDNEY

In civilian life, injuries to the kidney result most often from either blows or falls on the loin or crushing injury to the abdomen, typically in a road traffic accident. Haematuria after trivial injury to the kidney should suggest the possibility of a pre-existing disease, e.g. calculus, hydronephrosis or tuberculosis.

The range of injury extends from a small sub-capsular haematoma to a complete tear through the kidney (Figure 75.14).
The kidney may be partially or wholly torn from its vascular pedicle; one pole may be completely detached.

Closed renal injury is usually extraperitoneal. In young children with little extraperitoneal fat, the peritoneum, which is closely applied to the kidney, can tear with the renal capsule, leaking blood and urine into the peritoneum (Summary box 75.5).

**Summary box 75.5**

**Haemorrhage**
- Lethal haemorrhage is a serious risk in kidney trauma

---

**Clinical features of closed renal trauma**

There is local pain and tenderness, sometimes with superficial soft-tissue bruising.

**Haematuria**

Haematuria may not appear until days after the injury. Profuse bleeding may cause clot colic.

**Severe delayed haematuria**

Sudden haematuria between the third day and third week after trauma in a recovering patient is caused by a clot becoming dislodged.

**Meteorism**

Abdominal distension 24–48 hours after renal injury is probably a result of retroperitoneal haematoma implicating splanchnic nerves (Summary box 75.6).

**Summary box 75.6**

**Clinical features of closed renal trauma**
- There may be no external bruising
- Haematuria indicates kidney damage and should prompt careful monitoring and urgent investigation
- Delayed haemorrhage may occur

**Management and treatment**

Watchful treatment of closed renal trauma is often successful. Consider the possibility of injury to other organs at an early stage.
• Cross-match blood and secure intravenous access if there is any evidence of hypovolaemic shock or continuing haemorrhage.
• Advise bed-rest while there is macroscopic haematuria and restrict activity for a week after the urine clears.
• Administer appropriate analgesia.
• Keep hourly observations.
• Antibiotics should be given to prevent infection of the haematoma.
• Check the urine passed for haematuria and chart the result.
• Urgent intravenous urography (IVU) or contrast-enhanced CT will clarify the extent of renal damage and show that the other kidney is normal.
• Blood should be sent for grouping and serum saved for cross-matching in all cases.

Surgical exploration

Surgical exploration is necessary in less than 10 per cent of closed injuries; it is indicated if there is progressive blood loss or there is an expanding loin mass. The aim is to stop bleeding while conserving as much renal tissue as possible. A renal arteriogram performed preoperatively will help to frame an operative strategy. Embolisation may arrest the haemorrhage if a bleeding vessel can be identified.

Damage to other abdominal organs is checked during a transperitoneal approach. Release of the tamponading effect of the perirenal haematoma can result in massive haemorrhage and the surgeon must be prepared for this. When the kidney is irretrievably ruptured or avulsed from its pedicle, nephrectomy is the only course. Small tears can be sutured over a haemostatic sponge or a piece of detached muscle. Large single rents in the kidney are best dealt with by passing a tube nephrostomy through the defect and suturing the renal tissue around it. Partial nephrectomy may be practicable for localised injury.

When a solitary kidney is sufficiently damaged to need exploration, it must be repaired. Failing this, the wound is packed firmly with gauze to stop the bleeding in the hope that some renal function may be retained when the ruptured kidney heals (Summary box 75.7).

Summary box 75.7

Surgical treatment in closed renal trauma
- Exploration of the kidney may be associated with massive blood loss as the haematoma is opened
- Check that the contralateral kidney is functioning because nephrectomy is a possibility

Complications

Heavy haematuria may lead to clot retention requiring bladder washout.

Pararenal pseudohydronephrosis may occur weeks later from a combination of complete cortical tear and ureteric obstruction caused by scarring.

Hypertension, resistant to drugs, resulting from renal fibrosis, may occur long after injury. Nephrectomy may be necessary.

Post-traumatic aneurysm of the renal artery (Figure 75.15) is rare. There is loin pain and a non-tender swelling may be felt if the aneurysm is large. Congestion of the parenchyma leads to intermittent haematuria. Aortography is diagnostic. Excision or nephrectomy is indicated to prevent fatal rupture of the aneurysm.

INJURIES TO THE URETER

Rupture of the ureter

This is an uncommon result of a hyperextension injury of the spine. The diagnosis is rarely made until there is swelling in the loin or iliac fossa associated with a reduced urine output. An IVU or contrast-enhanced CT shows extravasation of contrast.

Injury to one or both ureters during pelvic surgery

This occurs most often during vaginal or abdominal hysterectomy when the ureter is mistakenly divided, ligated, crushed or excised. Pre-emptive ureteric catheterisation makes it easier to identify the ureters.

Injury recognised at the time of operation

Ureterovesical continuity should be restored by one of the methods described below unless the patient’s condition is poor. Deliberate ligation of the proximal ureter and temporary percutaneous nephrostomy is then the best course until the patient is well enough for a repair (Summary box 75.8).

Summary box 75.8

Ureteric injury during operation
- Surgical trauma during pelvic surgery is the most common cause of ureteric trauma
- Preoperative catheterisation of the ureters makes them easier to protect
- Injuries discovered during surgery should be repaired immediately

Figure 75.15 Aneurysm of the renal artery containing lamellated thrombus.
Injury not recognised at the time of operation

Unilateral injuries

There are three possibilities:

1. **No symptoms.** Ligation of a ureter may lead to silent atrophy of the kidney. The injury may be unsuspected until the patient undergoes urological imaging.

2. **Loin pain and fever,** possibly with pyonephrosis, occur with infection of the obstructed system. Loss of function will be permanent unless obstruction is relieved by promptly inserting a percutaneous nephrostomy.

3. **A urinary fistula** develops through the abdominal or vaginal wound. The IVU or contrast-enhanced CT shows extravasation with or without obstruction of one or both ureters. Nephrostomies may be inserted and repair postponed until oedema and inflammation have subsided, but delayed repair often leaves the patient incontinent. Early repair is safe if the patient is fit for surgery.

Bilateral injury

Ligation of both ureters leads to anuria. Ureteric catheters will not pass and urgent nephrostomy or immediate surgery is essential.

Repair of the injured ureter

An open repair may be avoidable if a stent will pass the obstruction (Table 75.2). If the cut ends of the ureter can be apposed without tension, they should be joined by a spatulated anastomosis over a double pigtail catheter.

If the division is low, the bladder may be hitched and the ureter can be reimplanted. Extra length may be obtained by mobilising the kidney.

In the Boari operation (Figure 75.16), a flap of bladder wall is fashioned into a tube to replace the lower ureter. The disadvantage of implanting the ureter end to side into the contralateral ureter (a transureteroureterostomy) is that it risks converting a unilateral injury into a bilateral one.

<table>

Nephrectomy may be best when the patient’s outlook is poor and the other kidney is normal. When conservation of all renal tissue is vital, replacement of the damaged ureter by a segment of ileum is necessary (Summary box 75.9).

Summary box 75.9

**Repair of ureteric injury**

When surgical damage to a ureter is discovered postoperatively:

- Repair need not be delayed
- Ideally surgical repair should be performed by a urologist

**HYDRONEPHROSIS**

Hydronephrosis is an aseptic dilatation of the kidney caused by obstruction.

**Unilateral hydronephrosis**

See Summary box 75.10.

Summary box 75.10

**Causes of unilateral ureteric obstruction**

**Extramural obstruction**

- Tumour from adjacent structures, e.g. cervix, prostate, rectum, colon or caecum
- Idiopathic retroperitoneal fibrosis
- Retrocaval ureter

**Intramural obstruction**

- Congenital stenosis, physiological narrowing of the pelviureteric junction leading to pelviureteric junction obstruction
- Ureterocele and congenital small ureteric orifice
- Inflammatory stricture following removal of ureteric calculus, repair of a damaged ureter or tuberculous infection
- Neoplasms of the ureter or bladder cancer involving the ureteric orifice

**Intraluminal obstruction**

- Calculus in the pelvis or ureter
- Sloughed papilla in papillary necrosis (especially in diabetics, analgesic abusers and sickle cell disease)

Figure 75.16 Boari operation: a strip of bladder wall is fashioned into a tube to bridge the gap between the cut ureter and the bladder.

Achille Boari, 19th century Italian, urological surgeon from Ferrara; he described the technique of a bladder flap in dogs in 1894, it was first performed in a patient in 1936.
Bilateral hydronephrosis
Bilateral hydronephrosis is usually the result of urethral obstruction, but the lesions described above may occur bilaterally.

When due to lower urinary obstruction, the cause may be:

- congenital:
  - posterior urethral valves;
  - urethral atresia;
- acquired:
  - benign prostatic enlargement or carcinoma of the prostate;
  - postoperative bladder neck scarring;
  - urethral stricture;
  - phimosis.

The ureters can be obstructed in their intramural course by detrusor hypertrophy caused by urethral obstruction.

Pathology
There is calyceal dilatation and pressure atrophy of the kidney. A kidney destroyed by longstanding hydronephrosis is a thin-walled, lobulated, fluid-filled sac.

Clinical features
Unilateral hydronephrosis
Unilateral hydronephrosis (commonly caused by idiopathic pelviureteric junction obstruction or calculus) is more common in women and on the right.

Presenting features include the following:

- Mild pain or dull aching in the loin, often a dragging heaviness worsened by excessive fluid intake. The kidney may be palpable.
- Intermittent hydronephrosis (Dietl’s crisis). Loin swelling is associated with acute renal pain. The pain goes and the swelling disappears when a large volume of urine is passed.
- Antenatal detection in the fetus by ultrasound scan. Many of these cases are benign, but postnatal investigation is required to detect those with significant pelviureteric junction obstruction (Summary box 75.11).

Summary box 75.11

<table>
<thead>
<tr>
<th>Idiopathic pelviureteric obstruction</th>
</tr>
</thead>
<tbody>
<tr>
<td>May be asymptomatic</td>
</tr>
<tr>
<td>Can present as intermittent loin pain often exacerbated by a fluid load</td>
</tr>
</tbody>
</table>

Bilateral hydronephrosis
From lower urinary obstruction
Symptoms of bladder outflow obstruction predominate. The kidneys are usually impalpable because renal failure intervenes before they enlarge.

From bilateral upper urinary tract obstruction
Idiopathic retroperitoneal fibrosis affects both ureters and idiopathic pelviureteric junction obstruction can be bilateral. Symptoms may be referred to one side.

From pregnancy
Dilatation of the ureters and renal pelves occurs early in pregnancy up to the 20th week. It results from the effects on the ureteric smooth muscle of high levels of circulating progesterone and is part of normal pregnancy. The ureters return to their normal size within 12 weeks of delivery. This physiological condition is associated with an increased liability to infection and there is a possibility that abdominal pain during pregnancy may be erroneously ascribed to ureteric obstruction (Summary box 75.12).

Summary box 75.12

<table>
<thead>
<tr>
<th>Ureteric dilatation in pregnancy</th>
</tr>
</thead>
<tbody>
<tr>
<td>Physiological dilatation of the ureter is common in pregnancy</td>
</tr>
</tbody>
</table>

Imaging
Ultrasound scanning (Figure 75.17) is the least invasive means of detecting hydronephrosis and is regularly used to diagnose pelviureteric junction obstruction in utero.

IVU helps only if there is significant function in the obstructed kidney. The extrarenal pelvis is dilated and the minor calyces lose their normal cupping and become ‘clubbed’. If the level of obstruction is in doubt, it can help to take follow-up films 36 hours after the contrast has been injected. Contrast slowly diffuses to fill the obstructed system down to the blockage.

Isotope renography is the best test to confirm obstructive dilatation of the collecting system. A substance (usually diethylenetriaminepenta-acetic acid (DTPA) or MAG-3) is injected intravenously. The DTPA is labelled with technetium-99m, a gamma-ray emitter, so that the passage of 99mTc-labelled DTPA through the kidneys can be tracked using a gamma camera. 99mTc-DTPA is cleared from a normal kidney but stays...
in the renal pelvis on the obstructed side and is retained even if urine flow is increased by administering frusemide (Figure 75.18).

Very occasionally, a Whitaker test is indicated. A percutaneous puncture of the kidney is made and fluid is infused at a constant rate with monitoring of intrapelvic pressure. An abnormal rise in pressure confirms obstruction. Retrograde pyelography (Figure 75.19) is rarely indicated but will confirm the site of obstruction immediately before corrective surgery (Summary box 75.13).

**Summary box 75.13**

**Imaging**
- Obstruction of the ureter is diagnosed by a combination of ultrasound scanning and isotope renography
- An obstructed kidney is worth preserving if it is contributing more than 20 per cent of total renal function

**Treatment**
The indications for operation are bouts of renal pain, increasing hydronephrosis, evidence of parenchymal damage and infection. Nephrectomy should be considered only when the kidney has been largely destroyed. Mild cases should be followed by serial ultrasound scans and operated upon if dilatation is increasing.

**Pyeloplasty**
In the Anderson–Hynes operation (Figure 75.20), the upper third of the ureter and the renal pelvis are mobilised. A renal vein overlying the distended pelvis can be divided, but an artery in this situation should be preserved to avoid infarction of the territory that it supplies. The anastomosis is made in front of such an artery. A nephrostomy tube or a ureteric stent protects the anastomosis. Laparoscopic pyeloplasty is becoming increasingly popular.

**Endoscopic pyelolysis**
Disruption of the pelviureteric junction by a balloon passed up the ureter and distended under radiographic control has been used to treat idiopathic pelviureteric junction obstruction.

---

*Robert Whitaker*, urologist, Addenbrooke's Hospital, Cambridge, UK.
*James Christie Anderson*, 1899–1984, urologist, The Royal Hallamshire Hospital, Sheffield, UK.
*Wilfred Hynes*, 1903–1991, plastic surgeon, The Plastic and Jaw Department, The Royal Sheffield Hospital, Sheffield, UK. Anderson and Hynes devised the operation in 1949. It is nowadays done laparoscopically, particularly in children. Robotic-assisted laparoscopic dismembered pyeloplasty has also been carried out.
The long-term efficacy of this and various forms of endoscopic pyelotomy has still to be proved. The alternative minimal access procedure, laparoscopic pyeloplasty, is increasingly popular.

**RENAI CALCULI**

**Aetiology**
This subject is complex and the following represents a brief summary of current opinion.

**Dietetic**
Deficiency of vitamin A causes desquamation of epithelium forming a nidus on which a stone is deposited. This mechanism is probably active in the formation of bladder calculi.

**Altered urinary solutes and colloids**
Dehydration concentrates urinary solutes until they precipitate. Reduction of urinary colloids, which adsorb solutes, or mucoproteins, which chelate calcium, might tend to crystal and stone formation.

**Decreased urinary citrate**
The presence of citrate in urine, 300–900 mg per 24 hours (1.6–4.7 mmol per 24 hours) as citric acid, keeps relatively insoluble calcium phosphate and citrate in solution.

**Renal infection**
Infection favours the formation of urinary calculi. Clinical and experimental stone formation are common when urine is infected with urea-splitting streptococci, staphylococci and especially *Proteus* spp.

**Inadequate urinary drainage and urinary stasis**
Stones are liable to form when urine is static.

**Prolonged immobilisation**
Immobilisation is liable to result in skeletal decalcification and an increase in urinary calcium favouring the formation of calcium phosphate calculi.

**Hyperparathyroidism**
Hyperparathyroidism leading to hypercalcaemia and hypercalciuria is found in 5 per cent or less of those who present with radio-opaque calculi. In cases of recurrent or multiple stones, this cause should be eliminated by appropriate investigations (see Chapter 51). A parathyroid adenoma should be removed before definitive treatment for the urinary calculi.

**Types of renal calculus**

**Oxalate calculus (calcium oxalate)**
Oxalate stones are irregular with sharp projections (Figure 75.21). A calcium oxalate monohydrate stone is hard and radiodense.

**Phosphate calculus**
A phosphate calculus (calcium phosphate often with ammonium magnesium phosphate (struvite)) is smooth and dirty white. It grows in alkaline urine, especially when urea-splitting Proteus organisms are present. The calculus may enlarge to fill most of the collecting system, forming a stag-horn calculus (Figure 75.22). Even a large stag-horn calculus may be asymptomatic for years until it presents with haematuria, urinary infection or renal failure.

**Uric acid and urate calculi**
These are hard, smooth and often multiple and multifaceted. Pure uric acid stones are radiolucent. CT will distinguish them from other causes of filling defects including tumours of the ureter. Most uric acid stones contain some calcium, so they cast a faint radiological shadow.

**Cystine calculus**
An uncommon congenital error of metabolism leads to cystinuria. Cystine stones are often multiple and may grow to form a cast of the collecting system. Cystine stones are radio-opaque and very hard.

The first nephrolithotomy was performed by Ambrose Paré (1509–1590) on a prisoner condemned to death by hanging. Paré cut out two stones from his kidney following which he was cured. As he recovered from this procedure, he secured remission from his death penalty and was given a grant of money. "I dressed his wounds, but God healed him."
Clinical features
Renal calculi are common. Approximately 50 per cent of patients present between the ages of 30 and 50 years. The male–female ratio is 4:3 (Summary box 75.14).

Summary box 75.14
Renal stones
- Are common
- May be clinically silent even when large
- Are usually visible on a plain abdominal radiograph
- May be radiolucent when composed of uric acid

Silent calculus
Renal failure may be the first indication of bilateral silent calculi, although secondary infection usually produces symptoms first.

Pain
Pain occurs in 75 per cent of people with urinary stones. Fixed renal pain occurs in the renal angle (Figure 75.23), the hypochondrium, or in both. It may be worse on movement.

Ureteric colic is an agonising pain passing from the loin to the groin. Pain resulting from renal stones rarely lasts more than 8 hours in the absence of infection. There is no pyrexia, although the pulse rate rises because of the severe pain. Ureteric colic is often caused by a stone entering the ureter but it may also occur when a stone becomes lodged in the pelviureteric junction. The severity of the colic is not related to the size of the stone (Summary box 75.15).

Summary box 75.15
Ureteric colic
- Severe exacerbations on a background of continuing pain
- Radiates to the groin, penis, scrotum or labium as the stone progresses down the ureter
- Severity of pain is not related to stone size
- Haematuria is very common
- There may be few physical signs

Abdominal examination
During an attack of ureteric colic, rigidity may be present but not prominent. Percussion over the kidney produces a stab of pain and there may be tenderness on gentle deep palpation. Hydronephrosis or pyonephrosis leading to a palpable loin swelling is rare.

Haematuria
Haematuria, usually small in amount, is common and sometimes is the only symptom of stone disease.

Pyuria
Infection is particularly dangerous when the kidney is obstructed. Pressure builds in the system, organisms are forced into the circulation and a septicaemia can quickly develop.

Investigation of suspected urinary stone disease

X-ray
The ‘KUB’ film shows the kidney, ureters and bladder. A branched stone is unmistakable. (Figure 71.24). An opacity maintaining its position relative to the urinary tract during respiration is likely to be a calculus.

Calcified mesenteric nodes and opacities within the gut will be anterior to the vertebral bodies on a lateral x-ray and thus outside the urinary tract (Summary box 75.16).

Summary box 75.16
Opacities on a plain abdominal radiograph that may be confused with renal calculus
- Calcified mesenteric lymph node
- Gallstones or concretion in the appendix
- Tablets or foreign bodies in the alimentary canal (e.g. cyclopenthiazide (Navidrex-K))
- Phleboliths – calcification in the walls of veins, especially in the pelvis
- Ossified tip of the 12th rib
- Calcified tuberculous lesion in the kidney
- Calcified adrenal gland

Contrast-enhanced CT
CT, preferably spiral, has become the mainstay of investigation of acute ureteric colic.

Excretion urography
IVU will establish the presence and position of a calculus and the function of the other kidney.

Ultrasound scanning
Ultrasound scanning is of most value in locating stones for treatment by extracorporeal shock wave lithotripsy (ESWL) (see below).
Surgical treatment of urinary calculi

Conservative management

Calculi smaller than 0.5 cm pass spontaneously unless they are impacted. Surgical intervention should be avoided. Small renal calculi may cause symptoms by obstructing a calyx or acting as a focus for secondary infection. Most can be safely observed until they pass (Summary box 75.17).

**Summary box 75.17**

**Management of small stones**

- Most small urinary calculi will pass
- Infection in an upper urinary tract obstructed by stone is dangerous and needs urgent surgical intervention

Preoperative treatment

Antibiotic treatment starts before surgery and continues afterwards.

Operation for stone

Most stones should be treated by minimal access and minimally invasive techniques. Open operations are still needed when appropriate expertise is not available or newer techniques have failed (Summary box 75.18).

**Summary box 75.18**

**Kidney stone removal**

- Most urinary calculi can be treated by minimal access techniques

Modern methods of stone removal

Kidney stones

Percutaneous nephrolithotomy

Endoscopic instruments are passed into the kidney by a percutaneous technique (Figure 75.25). Small stones may be grasped under vision and extracted whole. Larger stones are fragmented by an ultrasound, laser or electrohydraulic probe and removed in pieces.

Extracorporeal shock wave lithotripsy

Crystalline stones disintegrate under the impact of shock waves produced by the ESWL machine.

The shocks may be aimed by ultrasound or x-ray imaging (Figure 75.26). The devices also differ in the disruptive force that they can develop. Less powerful machines break stones less effectively and several treatments may be necessary. Weaker shocks hurt less and treatment can be given without general anaesthesia.

Ureteric colic is common after ESWL, and the patient needs analgesia, usually in the form of a non-steroidal anti-inflammatory drug. Bulky stone fragments may impact in the ureter, causing obstruction. To avoid this, a stent should be placed in the ureter to drain the kidney while stone fragments pass. Occasionally, impacted fragments have to be removed ureteroscopically (see below).

The principal complication of ESWL is infection. Many calculi contain bacteria, which are released from the broken stone. It is wise to give prophylactic antibiotics before ESWL, and an obstructed system should be decompressed by a ureteric stent or percutaneous nephrostomy before treatment.

The clearance of stone from the kidney will depend upon the consistency of the stone and its site. Most oxalate and phosphate stones fragment well and, if lying in the renal pelvis, will clear within days. The results with harder stones, especially cystine stones, are less satisfactory. When treating calyceal stones, the patients should be warned that the clearance may take months.

Open surgery for renal calculi

Operations for kidney stone are usually performed via a loin or lumbar approach (Figure 75.27). All of the procedures are difficult unless the kidney is fully mobilised and its vascular pedicle controlled. A sling should be placed around the upper ureter to stop stones migrating downwards.

Pyelolithotomy

Pyelolithotomy is indicated for stones in the renal pelvis. When the wall of the renal pelvis has been dissected from its surrounding fat, an incision is made in its long axis directly on to the stone. The stone is removed with gallstone forceps. Stone fragments in peripheral calyces may be detected by direct palpation or by intraoperative x-ray or nephroscopy. If there is sepsis, a nephrostomy is essential to drain the system.

Extended pyelolithotomy

The plane between the renal sinus and the wall of the collecting system is developed on the posterior surface of the kidney. This avoids major vessels and allows incisions into the calyces so that even large stag-horn stones can be removed intact.
Nephrolithotomy

If there is a complex calculus branching into the most peripheral calyces, it may be necessary to make incisions into the renal parenchyma to clear the kidney. Nephrolithotomy may also be necessary when the adhesions from previous surgery complicate access to the renal pelvis. The renal pedicle is temporarily cross-clamped to reduce bleeding from the vascular renal tissue. Incisions are made posterior and parallel to the most prominent part of the convex renal border, where the territories of the anterior and posterior branches of the renal artery meet (Brödel’s line). Cooling the kidney extends the ischaemia. Nephrolithotomy incisions must be closed with haemostatic sutures and the patient observed for signs of reactionary haemorrhage.

Partial nephrectomy is sometimes preferable for a stone in the lowermost calyx with infective damage to the adjacent parenchyma.

A functionless kidney destroyed by stone disease should be removed, particularly when there is xanthogranulomatous pyelonephritis. This stone-related inflammatory mass must be removed with care because it is liable to be attached to adjacent structures such as the colon.

Treatment of bilateral renal stones

Usually the kidney with better function is treated first, unless the other kidney is more painful or there is pyonephrosis which needs urgent decompression.

Prevention of recurrence

Ideally, stone formers should be investigated to exclude metabolic factors, although the diagnostic yield is low in patients with a single small stone. The urine should be screened for infection. The following investigations are appropriate in bilateral and recurrent stone formers:

- serum calcium, measured fasting on three occasions to exclude hyperparathyroidism;
- serum uric acid;
- urinary urate, calcium and phosphate in a 24-hour collection; the urine should also be screened for cystine;
- analysis of any stone passed.

Dietary advice is not usually helpful in avoiding stone recurrence in people who have a balanced diet. Those who consume excessive amounts of milk products (calcium stones), rhubarb, strawberries, plums, spinach and asparagus (calcium oxalate stones) should be advised to be more moderate.

Patients with hyperuricaemia should avoid red meats, offal and fish, which are rich in purines, and should be treated with allopurinol. Eggs, meat and fish are high in sulphur-containing proteins and should be restricted in cystinuria.
Stone sufferers should drink plenty to keep their urine dilute. Drug treatment is largely ineffective except in those few patients who are shown to have idiopathic hypercalciuria. Bendroflumethiazide (5 mg) and a calcium-restricted diet reduce urinary calcium (Summary box 75.19).

**Summary box 75.19**

**Recurrent stone formation**

- Stones are more common in those who have had a previous stone
- Unless there is a specific biochemical abnormality, high fluid intake is the best prophylactic measure

**URETERIC CALCULUS**

A stone in the ureter usually comes from the kidney. Most pass spontaneously.

**Clinical features**

A stone passing down the ureter often causes intermittent attacks of ureteric colic.

**Ureteric colic**

The waves of agonising loin pain are typically referred to the groin, external genitalia and the anterior surface of the thigh. As the stone enters the bladder, the pain can be referred to the tip of the penis.

**Impaction**

There are five sites of narrowing where the stone may be arrested (Figure 75.28). An impacted stone causes a more consistent dull pain, often in the iliac fossa and increased by exercise and lessened by rest. Distension of the renal pelvis due to obstruction may cause loin pain. The stone may become embedded as the adjacent ureteric wall becomes eroded and oedematous as a result of pressure ischaemia. Perforation of the ureter and extravasation of urine is a rare complication.

Severe renal pain subsiding after a day or so suggests complete ureteric obstruction. If obstruction persists after 1–2 weeks, the calculus should be removed to avoid pressure atrophy of the renal parenchyma.

**Haematuria**

Almost all ureteric colic is associated with transient microscopic haematuria. Serious bleeding is uncommon and should suggest clot colic.

Figure 75.26 Extracorporeal shock wave lithotripsy. (a) The patient being placed on the ultrasound lithotripter. (b) Positioning of the patient being checked by ultrasound.

Figure 75.27 Open operations for renal calculus.
Abdominal examination

There is tenderness and some rigidity over some part of the course of the ureter. The presence of haematuria does not rule out appendicitis because an inflamed appendix can give rise to a local ureteritis leaking some red cells into the urine. The patient with acute ureteric colic is usually in greater pain and less ill than one with appendicitis or acute cholecystitis.

Imaging

Most urinary calculi are radio-opaque. Stones are difficult to see if small or obscured by bowel contents or nearby bones. IVU while the patient has pain can confirm the diagnosis, although spiral CT is preferable. In ureteric colic, there will probably be little or no excretion on the affected side. Occasionally, there is an extravasation of contrast from the dilated system. Late x-rays, taken up to 36 hours after the injection of the dilated system, may show dilatation of the ureter down to an obstructing calculus. A radiolucent uric acid stone may be demonstrated as a filling defect in the contrast-filled system.

Analgesic abusers occasionally fake symptoms to obtain drugs, and emergency imaging is useful in excluding renal colic. If the CT or urogram is normal during an attack, the patient does not have renal colic. The absence of blood in the urine makes colic less likely but its presence can be simulated.

Cystoscopy is not indicated routinely but may reveal oedema around the ureteric orifice when the stone is nearby.

Retrograde ureterography is performed as an immediate preliminary to an endoscopic operation to remove a calculus.

**Treatment**

**Pain**

Non-steroidal anti-inflammatory drugs, such as diclofenac and indomethacin, have replaced opiates as the first line of treatment for renal colic. The value of smooth muscle relaxants, such as propantheline (Pro-Banthine), is debatable.

**Removal of the stone**

Expectant treatment is appropriate for small stones likely to pass naturally (Summary box 75.20). If the patient is not disabled by recurrent attacks of colic, progress can be followed by x-rays every 6–8 weeks.

**Endoscopic stone removal**

**Dormia basket**

The use of wire baskets under image intensifier control has been replaced by ureteroscopic techniques but they may be useful when the instruments and expertise are not available (Figure 75.29). There is a danger of ureteric injury even with small stones.

**Ureteric meatotomy**

Endoscopic incision with a diathermy knife will enlarge the opening and free a stone lodged in the intramural ureter. The consequent urinary reflex rarely causes problems.

**Ureteroscopic stone removal**

A ureteroscope is introduced transurethrally across the bladder into the ureter (Figure 75.30) to remove stones impacted in the
ureter. Stones that cannot be caught in baskets or endoscopic forceps under direct vision are fragmented using an electrohydraulic, percussive or laser lithotripter.

**Push bang**
A stone in the middle or upper part of the ureter can often be flushed back into the kidney using a ureteric catheter. A J-stent secures the calculus in the kidney for subsequent treatment with ESWL.

A flexible fiberoptic ureteroscope can be used for laser destruction of calculi in the renal collecting system or ureter and to retrieve small stones from the kidney.

**Lithotripsy in situ**
A stone in a part of the ureter that can be identified by the imaging system of the lithotripter can be fragmented in situ. This form of treatment is not appropriate if there is complete obstruction or if the stone has been impacted for a long time.

**Open surgery**

**Ureterolithotomy**
An x-ray confirms the position of the stone immediately before surgery.

The skin incision must be appropriate for the position of the stone. Calculi in the upper third of the ureter are approached through a loin or upper quadrant transverse incision as used for a stone in the renal pelvis. Access to midureteric stones is through a muscle-cutting iliac fossa incision; lower ureteric stones are best reached through a Pfannenstiel incision. For stones close to the bladder, exposure is improved by ligating and dividing the superior vesical vascular pedicle. The ureter is exposed in the retroperitoneum and slings are applied above and below the calculus to stop it from escaping. The ureter is incised longitudinally, directly on to the stone, which is freed by blunt dissection and removed with stone forceps. Soft catheters are passed upwards and downwards to ensure that the ureter is clear. The ureterotomy is closed with interrupted absorbable sutures and a drain left to drain urine leakage. The operation can be performed laparoscopically, but alternative minimal access techniques described above are usually preferable.

**IDIOPATHIC RETROPERITONEAL FIBROSIS**
In this rare condition, one or both ureters are bound in progressive fibrosis of the retroperitoneal tissues. Most cases are idiopathic but some may be drug related. A similar clinical picture occurs in patients with leaking aortic aneurysm and infiltrating retroperitoneal malignancy.

The patient complains of persistent backache. The onset of anuria and renal failure prompts investigation of the renal tract, which reveals hydronephrosis. The IVU typically shows medial displacement of the ureters and the CT appearances are diagnostic. The sedimentation rate is markedly raised.

**Treatment**
It may be possible to insert temporary ureteric stents while renal function recovers. If not, percutaneous nephrostomies will drain the obstructed kidneys. Some patients need dialysis. Some advocate conservative treatment with steroids. Surgery involves dissection of the ureters from their fibrous jacket (ureterolysis). Wrapping omentum around the freed ureters discourages recurrent obstruction.

**KIDNEY INFECTIONS**

**Aetiology**
Renal infections arise in the following ways (Summary box 75.21):

- **Haematogenous infection** from a primary site in the tonsils or carious teeth or from cutaneous infections, particularly boils or a carbuncle. Renal tuberculosis occurs by bloodborne spread from lymph nodes in the neck, chest or abdomen.

- **Ascending infection** in the urinary tract is the most common route, and it is most likely to occur when there is vesicoureteric reflux. Urinary stasis and the presence of calculi are common contributory factors.

**Bacteriology**

*Escherichia coli* and other Gram-negative organisms are commonly responsible. In *E. coli* and streptococcal infections, the urine is acidic. *Proteus* spp. and staphylococci split urea to form ammonia, which makes the urine alkaline and promotes the formation of calculi.

...
Kidney infection

- Acute pyelonephritis:
  - In childhood
  - In pregnancy
  - With urinary obstruction
- Chronic pyelonephritis:
  - Reflux nephropathy
  - Pyonephrosis
  - Renal abscess
  - Perinephric abscess

Acute pyelonephritis

Acute pyelonephritis is more common in females, especially during childhood, at puberty, after intercourse, during pregnancy and during menopause. It occurs more on the right and is frequently bilateral.

**Clinical features**

There may be prodromal headache, lassitude and nausea, but the onset of pain is usually sudden, often with a rigor and vomiting. There is acute pain in the flank and hypochondrium. The remitting temperature rises to 39°C or more. The symptoms of cystitis commonly set in, with urgency, frequency and scalding dysuria. There is tenderness in the hypochondrium and in the loin. Rarely, in cases of severe bilateral pyelonephritis, especially when there is an associated obstruction, renal dysfunction may be sufficient to cause uraemia. The risk of life-threatening septicaemia is ever present (Summary box 75.22).

**Summary features box 75.21**

**Clinical features of kidney infections**

- More common in women
- Often associated with septicemia leading to pyrexia and rigors
- Associated with pyuria and occasionally haematuria
- Should be initially treated with broad-spectrum parenteral antibiotics
- Extremely dangerous if the kidney is obstructed

Bacteriological examination of the urine

A midstream urine specimen should be collected into a sterile container; the urine is centrifuged and the sediment examined microscopically. In early acute pyelonephritis, there are usually pus cells and many bacteria. The urine may be misleadingly clear to the eye until the infection becomes established. Culture and sensitivity testing of the causative organisms allows a rational choice of antibiotic, but parenteral treatment with a broad-spectrum antibiotic should be started before the results are available.

**Severe cases**

There are rigors and a temperature of 40°C or more, often without a corresponding tachycardia. There is vomiting, sweating and thirst; the patient feels awful. Blood culture is usually positive, especially if the specimen has been taken during a rigor.

**Differential diagnosis**

It may be difficult to be sure that the patient does not have pneumonia, acute appendicitis or acute cholecystitis. The urgent need is to distinguish acute pyelonephritis from appendicitis, and the site of pain and the presence of marked peritonism are usually helpful. A plain abdominal x-ray may show the outline of a swollen kidney and, if the infection is severe, a ultrasonographer may confirm the appearance of pyelonephritis.

**Special cases**

**Pyelonephritis of pregnancy**

Pyelonephritis of pregnancy usually occurs between the fourth and sixth months of gestation in women with a past history of recurrent urinary infection. In about 10 per cent of cases, the disease runs a severe and protracted course and occasionally leads to abortion or premature birth.

**Urinary infection in childhood**

Urinary infection in childhood may damage the growing kidney. In young children, symptoms are often non-specific but the child may pass cloudy or offensive urine. Pain or screaming on micturition may occur. The older child may complain of loin pain and may develop urinary frequency and secondary enuresis.

Up to 50 per cent of children with urinary infection have an underlying anatomical abnormality (e.g. reflux or obstruction). The diagnosis of infection is confirmed by examination of a clean-catch specimen or a specimen obtained by suprapubic needle puncture. On culture, a pure growth of more than 10⁵ organisms/ml with a significant pyuria is evidence of infection. Such children should be investigated for underlying urinary tract abnormalities and to assess renal function and scarring.

Vesico-ureteric reflux of urine is detectable in about 35 per cent of children with recurrent urinary infection. Renal damage results from the combination of reflux and urinary infection early in life, and reflux nephropathy is a common cause of end-stage renal failure in the UK. Long-term prophylactic antibiotic treatment has become the favoured treatment for recurrent urinary infections resulting from reflux. Surgical reimplantation of the ureters is reserved for those in whom conservative measures fail. However, reimplantation in these patients may fail to cure reflux (Summary box 75.23).

**Summary features box 75.22**

**Urinary infection in childhood**

- A single proven urinary infection in a child should prompt referral to a paediatric urologist

Acute pyelonephritis associated with urinary retention

Acute pyelonephritis is a relatively uncommon complication of chronic urinary retention. Often the organisms are introduced
during instrumentation. Patients with a significant postmicturition urinary residue need prophylactic antibiotics to cover transurethral procedures.

**Treatment**
The treatment of acute pyelonephritis should be prompt, appropriate and prolonged. Investigation to exclude underlying abnormalities in the urinary tract should be undertaken when the acute illness subsides.

While awaiting the bacteriological report and the results of sensitivity tests, a broad-spectrum antibiotic, such as amoxicillin or gentamicin, should be administered, parenterally if necessary. When pain is severe, a morphine-like analgesic drug may be necessary if non-steroidal anti-inflammatory agents are ineffective. The patient should drink copiously; if this is not possible because of nausea and vomiting, an intravenous infusion should be set up.

Most urinary infections acquired outside hospital are sensitive to agents such as trimethoprim and amoxicillin. Hospital-acquired infections are much more likely to be resistant and second-line antibiotics may be needed. Gentamicin and carbencillin are suitable for infections with more resistant strains of *Pseudomonas pyocyanea*, *Proteus* spp. and *Klebsiella* spp. Ciprofloxacin is particularly useful against *Pseudomonas* spp. in patients who do not have septicemia. Despite the efficacy of modern antibacterial drugs, recurrent infection is likely if there is an untreated underlying abnormality of the urinary tract such as a stone, vesicoureteric reflux, fistula to the gastrointestinal tract or retention of urine.

**Chronic pyelonephritis**
Chronic pyelonephritis is often associated with vesicoureteric reflux, sometimes called ‘reflux nephropathy’, is an important cause of renal damage and end-stage renal failure.

**Pathology**
There is interstitial inflammation and scarring of the renal parenchyma with a patchy distribution.

**Clinical features**
The condition is almost three times as common in women as it is in men. Two-thirds of female patients are under 40 years of age, whereas 60 per cent of male patients are over 40.

It is possible, but unusual, for chronic pyelonephritis to remain clinically silent until the symptoms of advanced renal insufficiency appear.

Lumbar pain, dull and non-specific in character, is present in 60 per cent of cases. Increased urinary frequency and dysuria are common. Hypertension, present in 40 per cent of cases, may be of the accelerated (‘malignant’) type. Tiredness, malaise, anorexia, nausea and headache constitute the main complaint in 30 per cent of cases. The true cause of these nonspecific symptoms may elude diagnosis for years.

Normochromic anaemia due to unsuspected renal impairment is an occasional presenting feature (Summary box 75.24).

**Investigations**
The glomeruli are relatively preserved so proteinuria is less marked than in glomerulonephritis (< 3 g daily). Casts are not usually present but white cells are plentiful.

**Pyonephrosis**
Pyonephrosis results from infection of a hydronephrosis, follows acute pyelonephritis or, most commonly, arises as a complication of renal calculus disease. The kidney becomes a multilocular sac containing pus or purulent urine.

**Clinical features**
The classical triad of symptoms is anaemia, fever and a swelling in the loin. When the condition arises as an infected hydronephrosis, the swelling may be very large and the pyrexia very high and associated with rigors. Symptoms of cystitis may be prominent.

**Investigations**
Imaging may show a calculus and will demonstrate dilatation of the pus-filled collecting system.

**Treatment**
Pyonephrosis is a surgical emergency because permanent renal damage and lethal septicaemia threaten. Parenteral antibiotics should be given and the kidney drained. If the pus is too thick to be aspirated through a large percutaneous nephrostomy, consider open nephrostomy. When there is a stone, it should be removed. Nephrectomy may be appropriate when the kidney is destroyed and function on the other side is good.

**Renal carbuncle**
An abscess may form in the renal parenchyma as the result of blood-borne spread of organisms, especially coliforms or *Staphylococcus aureus*. Renal carbuncle is most commonly seen in diabetics, intravenous drug abusers, those debilitated by chronic disease and patients with acquired immunodeficiency.

**Pathology**
The renal parenchyma contains an encapsulated necrotic mass.

---

**Summary box 75.24**

**Chronic pyelonephritis**
- A common cause of end-stage renal failure
- Often associated with ureteric reflux
- May be symptomatically silent
- Leads to progressive renal scarring

Escherichia coli, *Streptococcus faecalis*, *Proteus* spp. or *Pseudomonas* spp. are found in the urine.

**Treatment**
Treatment aims at eradicating predisposing factors such as obstruction or stones and treating the infection, often with repeated courses of antibiotic. Scarred parenchyma is vulnerable to blood-borne organisms and reinfection is likely. Consequently, antibiotics confer only temporary benefit and progressive renal damage is common.

Surgery is indicated only when the disease is confined to one kidney. This is unusual but in such cases nephrectomy or partial nephrectomy may stop the symptoms of infection and make hypertension easier to control. Patients with end-stage renal failure require renal replacement therapy.
**Clinical features**

There is an ill-defined tender swelling in the loin, persistent pyrexia and leukocytosis, simulating a perinephric abscess. Initially there is no pus or bacteria in the urine, but these appear later. The mass in the kidney may be confused with a renal adenocarcinoma (Figure 75.31).

**Treatment**

Resolution by antibiotic treatment alone is unusual. Formal open incision of the abscess may be necessary if the pus is too thick to be drained by percutaneous aspiration.

**Perinephric abscess**

The common causes of perinephric abscess are shown in Figure 75.32. Other causes are infection of a perirenal haematoma and perinephric discharge of an untreated pyonephrosis or renal carbuncle. A mycobacterial perinephric abscess may arise by extension from a nearby tuberculous vertebra.

**Clinical features**

There is swinging pyrexia, abdominal tenderness and fullness in the loin (Figure 75.33). Local signs present early if the infection starts in the lower part of the perinephric fat. Infection at the upper pole is masked by the lower ribs and signs in the loin are less. The white cell count is always markedly raised but there are characteristically no pus cells or organisms in the urine.

**Imaging**

Ultrasonography and CT are diagnostic.

**Treatment**

Open drainage may be necessary if the abscess cannot be aspirated through a percutaneous needle. A lumbar incision is made under antibiotic cover large enough to allow the surgeon to open pockets of pus and to explore for an unruptured cortical abscess. Pus is sent for culture and the wound is closed over a tube drain (Summary box 75.25).

**Summary box 75.25**

**Management of perinephric abscess**

- Collections of pus in or around the kidney should be drained

**Renal tuberculosis**

**Aetiology and pathology**

Tuberculosis of the urinary tract arises from haematogenous infection from a distant focus. The lesions are usually unilateral. Tuberculous granulomas in a renal pyramid coalesce to form an ulcer. Mycobacteria and pus cells discharge into the urine. Untreated lesions enlarge and a tuberculous abscess may form in the parenchyma. The necks of the calyces and the renal pelvis stenosed by fibrosis confine the infection so that there is tuberculous pyonephrosis, sometimes localised to one pole of the kidney. Extension of pyonephrosis or tuberculous renal abscess leads to perinephric abscess and the kidney is progressively replaced by caseous material (putty kidney), which may...
be calcified (cement kidney). At any stage, the plain x-ray may show areas of calcification (pseudocalculi). Less commonly, the kidneys may be bilaterally affected as part of the generalised process of miliary tuberculosis (Figure 75.34).

Renal tuberculosis is often associated with tuberculosis of the bladder and typical tuberculous granulomas may be visible in the bladder wall. In men, tuberculous epididymo-orchitis may occur without apparent infection of the bladder.

**Clinical features**

Renal tuberculosis usually occurs between 20 and 40 years of age, and is more common in men than women.

Urinary frequency is often the earliest symptom and may be the only one. The patient complains of a progressive increase in both daytime and night-time frequency.

*Sterile* pyuria

Routine urine culture is negative but there are white cells in the urine.

**Pain**

Painful micturition is a feature of tuberculous cystitis. First, there is a suprapubic pain if voiding is delayed; later, a burning pain accompanies micturition. When there is secondary infection, a superadded agonising pain referred to the tip of the penis or to the vulva is often associated with haematuria and strangury.

Renal pain is often minimal but there may be a dull ache in the loin.

**Haematuria**

In 5 per cent of cases, the first symptom is haematuria occurring from an ulcer on a renal papilla. The tuberculous lesion may be difficult to detect radiologically and mycobacteria may not be cultured from the urine until months later.

A tuberculous kidney is oedematous and friable and is more liable to damage than a normal kidney.

Malaise and weight loss are usual and a low-level evening pyrexia is typical. A high temperature suggests secondary infection or dissemination, i.e. miliary tuberculosis.

**On examination**

It is unusual for a tuberculous kidney to be palpable. The prostate, seminal vesicles, vasa and scrotal contents should be examined for nodules or thickening (Summary box 75.26).

**Investigation**

**Bacteriological**

Three complete specimens of early-morning urine should be sent for microscopy and culture before specific chemotherapy is started. Staining of the urine sediment with the Ziehl–Neelsen stain occasionally shows the presence of acid-fast bacilli, but proof that these are pathological mycobacteria must await culture on Löwenstein–Jensen medium. When the clinical picture is convincing, it is permissible to start anti-tuberculous therapy in anticipation of the culture results some 6 weeks later.

**X-ray**

An abdominal x-ray may show calcified lesions.

**Intravenous urography**

Early in the disease, the clear-cut outline of a renal papilla may be rendered indistinct by the presence of ulceration. Later, there may be calyceal stenosis (Figure 75.35) and/or hydronephrosis caused by stricture of the renal pelvis or the ureter draining the affected kidney (Figure 75.36). A tuberculous abscess appears
as a space-occupying renal lesion. The bladder may appear shrunken, with its wall irregular or thickened.

**Cystoscopy**
Cystoscopy is not routine in the investigation of urinary tuberculosis but is often performed because there has been haematuria or unexplained bladder symptoms. The tuberculous urothelium is studded with granulomas that cluster particularly around the ureteric orifices, sometimes with ulceration. As the bladder wall fibroses, the bladder capacity decreases. Contraction of the fibrosed ureter tugs at the ureteric orifice, which is displaced upwards, its mouth wide open (the so-called 'golf-hole' orifice).

**Chest x-ray**
A chest x-ray will exclude an active lung lesion.

**Treatment**
Anti-tuberculous chemotherapy is best managed by a specialist. The surgeon must ensure that the state of the urinary tract is reviewed during the first few weeks of therapy because scarring and stricture continue after treatment has started.

Prognosis in renal tuberculosis is good if the patient completes the course of chemotherapy.

**Operative treatment**
Operative treatment should be conservative, aiming to remove large foci of infection, which are difficult to treat with drugs, and correct the obstruction caused by fibrosis. The optimum time for surgery is between 6 and 12 weeks after the start of antituberculous chemotherapy.

A repertoire of procedures is needed to deal with various potential effects of urinary tuberculosis. An obstructed lower pole calyx may be drained into the upper ureter. A strictured renal pelvis needs a pyeloplasty. Ureteric stenosis and shortening may require a Boari operation or a bowel interposition, depending on the level and extent of the fibrosis. If the kidney has no function it is best to perform a nephroureterectomy (Figure 75.37). A badly contracted bladder may be replaced with a neobladder fashioned from a loop of bowel in a substitution cystoplasty.

**NEOPLASMS OF THE KIDNEY**
Neoplasms of the kidney are summarised in Summary box 75.27.

<table>
<thead>

**Benign neoplasms**

**Adenoma**
Pea-like cortical adenomas are occasionally discovered. They are asymptomatic and are benign.

**Angioma**
Angioma may cause profuse haematuria, often in young adults. The bleeding source may be difficult to diagnose without renal angiography.

**Angiomyolipoma**
Angiomyolipoma is an unusual tumour of the kidney often but not always associated with tuberous sclerosis. Its high fat

---

**Figure 75.36** Retrograde ureterogram showing advanced tuberculosis of the right kidney. Right retrograde study shows multiple ureteric strictures and gross distortion of the internal architecture of the affected kidney.
content has a typical appearance on CT. Malignant elements are present in about one-quarter and may metastasise.

**Malignant neoplasms**

**Renal neoplasm in children**

**Wilms’ tumour (synonym: nephroblastoma)**

This mixed tumour contains elements from embryonic nephrogenic tissue (Figure 75.38). Nephroblastoma is usually discovered during the first five years of life, usually in one pole of one kidney. Bilateral tumours pose a difficult problem.

**Pathology**

A rapidly growing tumour is likely to be friable in consistency.

**Clinical features**

An abdominal tumour grows rapidly in a poorly child. The mass may be very large. Some patients are hypertensive.

Haematuria is an unfavourable symptom denoting extension of the tumour into the renal pelvis.

Imaging confirms a solid space-occupying lesion in the kidney, with or without venous invasion, contralateral disease and distant spread.

Metastasis to the lungs occurs early. Liver, bone and brain metastases are rare. Lymphatic spread is uncommon.

**Treatment**

These children are best treated in specialist paediatric oncology units. Most unilateral tumours are treated by chemotherapy followed by nephrectomy. Partial nephrectomy may be possible in patients with bilateral disease.

**Prognosis**

Eighty per cent survive long term with modern chemotherapy and surgery. The prognosis is worse in those with metastases and in older children (Summary box 75.28).

**Renal neoplasm in adults**

**Hypernephroma (synonym: Grawitz’s tumour)**

This adenocarcinoma, the most common neoplasm of the kidney (75 per cent incidence), arises from renal tubular cells.

**Pathology**

The cut surface is usually yellowish or dull white, semi-transparent, with areas of haemorrhage (Figure 75.39). The tumour is often divided into lobules, some of which are cystic. Larger tumours are irregular in shape with central haemorrhage and necrosis.

**Microscopic structure**

The most common pattern is of solid areas of polyhedral or cuboidal clear cells with deeply stained, small, rounded nuclei and abundant cytoplasm containing lipids, cholesterol and glycogen. The cells are occasionally arranged as papillary cysts or tubules. Less commonly, the cells are granular (dark), and both clear and dark cells may be represented in the same tumour. The scanty stroma is richly vascular.

**Spread**

The tumour is prone to grow into the renal vein. Cells enter the circulation and reach the lungs, where they grow to form can-

---

Paul Albert Grawitz, 1850–1932, Professor of Pathology, Greifswald, Germany, described adeno-carcinoma of the kidney in 1884.
nonball secondary deposits (Figure 75.40). Metastasis to bone also occurs and a secondary deposit in a long bone may be the only sign of distant spread for a year or more. Highly vascular metastases may pulsate. Tumour extending beyond the renal capsule is liable to metastasise via the lymph nodes in the hilum of the kidney to the para-aortic nodes and beyond.

Clinical features
Adenocarcinoma of the kidney is more common in men. Haematuria is usually the presenting symptom, sometimes with clot colic. There may be a dragging discomfort in the loin or the patient may detect a mass. In men, a rapidly developing varicocele is a rare but impressive sign, most often on the left side because the left gonadal vein is obstructed where it joins the left renal vein.

Atypical presentations
In 25 per cent of cases there are no local symptoms. The patient presents with symptomatic secondary deposits in bone (Figure 75.41) or the lung (persistent cough or haemoptysis).

Occasionally, persistent pyrexia (37.8–38.9°C) with no evidence of infection is the only symptom. Pyrexia after nephrectomy suggests metastases.

A few patients present with constitutional symptoms and anaemia.

Polycythaemia occurs in 4 per cent of cases as a result of the production of erythropoietin by tumour cells. The erythrocyte sedimentation rate is always raised above the 1–2 mm found in idiopathic polycythaemia vera. The blood count returns to normal after nephrectomy unless there are metastases. Other hormones, such as renin and calcitonin, may be produced by the tumour. Hypercalcemia is common.

Nephrotic syndrome has been reported as a rare presentation of hypernephroma.

Investigation
IVU is being supplanted by CT in the investigation of haematuria. There is typically abnormal calcification and distortion of the renal outline. The calyces may be stretched and distorted. It is important to know whether the contralateral kidney is working (Figure 75.42). CT with enhancement will demonstrate the extent of the lesion and will show whether the hilar lymph nodes or renal vein are involved (Figure 75.43).

Enthusiasm for renal angiography and preoperative embolisation has waned. Occasionally, a flush inferior cava shows the extent of caval involvement by tumour growing in from the renal vein.

A chest x-ray is essential to detect lung secondaries. An isotope bone scan will reveal deposits in bone.
Part 12 | Genitourinary

1306 The Kidneys and Ureters

Treatment
Nephrectomy can be performed through a loin or a transverse or oblique upper abdominal incision. The transabdominal approach has the advantage that the renal pedicle and the inferior vena cava can be widely exposed.

The vascular pedicle should be ligated before the kidney is mobilised because handling the tumour may cause malignant cells to be released into the circulation. The first step in the procedure is to ligate the renal artery in continuity. Once the artery is occluded, the tumour loses most of its profuse blood supply and massive bleeding during mobilisation becomes less likely. Gentle palpation of the renal vein ensures that there is no tumour in its lumen. An empty vein can be divided between ligatures. The renal artery is then divided and the kidney mobilised within its coverings. Aberrant vessels feeding the tumour must be ligated or coagulated to avoid troublesome bleeding. The ureter is then traced downwards as far as is safe, tied and divided.

If the renal vein or the inferior vena cava is invaded, the surgeon must obtain early control of the cava above and below the tumour extension. If there is extension into the thorax, the cardiac team may be needed to put the patient on cardiac bypass so that tumour can, if necessary, be removed from the right side of the heart.

Renal adenocarcinoma responds poorly to radiotherapy or conventional chemotherapy. There have been early promising results from clinical trials of the cytokine interleukin-2 in this condition.

Prognosis
Removal of even a large neoplasm may be curative. In operable cases, 70 per cent of patients are well after three years and 60 per cent after five years. Macroscopic involvement of the renal vein or its tributaries, invasion beyond the capsule and lymphatic involvement all worsen the prognosis (Summary box 75.29).

Figure 75.42 Intravenous urogram in a case of hypernephroma of the left kidney. The only symptom was one attack of painless haematuria. Note the displacement of the upper pole calyces by the mass.

Figure 75.43 Computed tomography scan showing large bilateral renal adenocarcinomas.
Summary box 75.29

Adenocarcinoma of the kidney
- Often presents with haematuria
- May be associated with pyrexia of unknown origin, polycythaemia, hypercalcaemia, anaemia and other paraneoplastic symptoms
- Metastasises via the bloodstream to bone, liver and lung (cannonball secondaries)
- Renal vein extension may embolise to the pulmonary circulation during nephrectomy

Papillary transitional cell tumours of the renal pelvis
These resemble those of the bladder but are much less common (Figure 75.44). They may invade the renal parenchyma, be multifocal and metastasise. Multiple ureteric tumours are thought to arise from a field change that predisposes the whole urothelium to metaplasia rather than seeding down the ureter. Whether the carcinogen is chemical or viral is uncertain.

Clinical features
Haematuria is the most common clinical symptom.

The presence of malignant cells in the urine may indicate whether the tumour is well or poorly differentiated. There is some evidence that those with poorly differentiated tumours do better if they have preoperative radiotherapy. It is therefore useful to obtain cells from the tumour by sampling using a brush or catheter passed up the ureter under radiological control.

Intravenous urography usually demonstrates the tumour (Figure 75.45). Retrograde pyelography may be helpful if the urogram is indistinct.

Treatment
Conventional surgical treatment is by nephroureterectomy. The ureter must be disconnected with a cuff of bladder wall. If this is done by open surgery a second incision is needed to remove the kidney. Alternatively, the ureteric orifice can be widely resected with a resectoscope and the ureter delivered by blunt dissection from the upper abdominal wound used to remove the kidney. Some urologists argue that well-differentiated upper urinary tract transitional tumours should be treated conservatively by resection with appropriate steps taken to avoid the growth of tumour seeded in the percutaneous track.

Squamous cell carcinoma of the renal pelvis
This is rare and often associated with chronic inflammation and leucoplaikia resulting from stone. The tumours are radiosensitive but metastasise early and the prognosis is poor.

Transitional cell tumours of the ureter
These are rare and behave like tumours of the renal pelvis. Treatment is by nephroureterectomy.

About half of patients with tumours of the upper urinary tract will have tumours in the bladder at some stage. Follow up by cystoscopy with regular urography is therefore necessary to detect recurrent tumours.

Balkan nephropathy
Transitional cell tumours of the upper urinary tract have a very high incidence in certain areas of the Balkans. The same population has a high incidence of a form of primary nephropathy. The causative agent has not been identified with certainty but there seems to be an association with the consumption of grain products stored in a damp environment. Tumours that develop against a background of Balkan nephropathy should be treated by nephron-sparing surgery in view of the impaired overall renal function.

Figure 75.44 Papillary transitional cell tumour of the renal pelvis.

Figure 75.45 Intravenous urogram showing a filling defect in the left renal pelvis due to transitional cell carcinoma.

The Balkans are the countries of the southeast of Europe. They lie south of the Danube and Sava rivers, and form a peninsula bounded on the east by the Aegean and Black Seas, on the west by the Adriatic and Ionian Seas, and on the south by the Mediterranean.
Nephrectomy for benign disease
Nephrectomy is now rarely performed for benign disease except when the kidney is atrophic or dysplastic or the cause of accelerated hypertension. Non-functioning kidneys resulting from longstanding obstruction or stone disease are a potential site for infection and even malignancy. In a simple nephrectomy, the kidney is dissected free through the convenient plane between the capsule and its fatty coverings. If this plane is obscured by the scarring of previous surgery, a subcapsular nephrectomy may be safer.

Laparoscopic renal surgery
The benefits of laparoscopy are being progressively applied to the whole range of renal surgery. Laparoscopic nephrectomy is certainly possible for small kidneys destroyed by benign disease. The technique requires special skills and the full costs and benefits are under evaluation. More complex techniques are necessary when there is bulky excised tissue to be extracted. Laparoscopic surgery for pyeloplasty, ureterolysis and nephrectomy for renal malignancy have all been described.

Hypertension and a unilateral renal lesion
Ischaemia of the renal parenchyma leads to the release of pressor agents that cause arterial hypertension. When a renal lesion is discovered during the investigation of hypertension, nephrectomy may make the hypertension more amenable to drug treatment.

PART 12  |  GENITOURINARY

CHAPTER 76  |  The urinary bladder

LEARNING OBJECTIVES

To understand:
- The anatomy, vascular supply and innervation of the bladder in relation to function and disease
- The principles of management of bladder trauma, incontinence and fistulae
- The common causes of acute and chronic urinary retention and management
- The different types of bladder cancer and the principles of management

SURGICAL ANATOMY OF THE BLADDER

- It is lined by transitional epithelium covering the connective tissue lamina propria, which contains a rich plexus of vessels and lymphatics.
- When the detrusor muscle hypertrophies, the inner layer, covered by urothelium, stands out, resulting in the appearance of trabeculation.
- Over the trigone is a thin layer of smooth muscle to which the epithelium is closely adherent and which extends as a sheath around the lower ureters and into the proximal urethra.
- Around the male bladder neck is the smooth muscle internal sphincter innervated by adrenergic fibres, which prevents retrograde ejaculation.
- The distal urethral sphincter is a horseshoe-shaped mass of striated muscle that lies anterior and distal to the prostate, or in the proximal two-thirds of the female urethra. It is distinct from the pelvic floor and is supplied by S2–S4 fibres via the pudendal nerve and by somatic fibres passing through the inferior hypogastric plexus.

Fascial and ligamentous supports of the bladder

At the posterolateral bladder neck, condensations of fascia pass forward medially and laterally to the ureter to join with the prostatic fascia; this fascia needs to be divided during cystectomy. The puboprostatic ligaments are well-defined condensations of the anterior endopelvic fascia; they stretch from the front of the prostate to the periosteum of the pubis and lie lateral to the dorsal vein complex. The urachus and obliterated hypogastric arteries, together with the folds of peritoneum overlying them, are called the median and lateral umbilical ligaments. Condensations of fascia also occur around the superior and inferior vascular pedicles.

Arteries

The superior and inferior vesical arteries are derived from the anterior trunk of the internal iliac artery. Branches from the obturator and inferior gluteal arteries (and from the uterine and vaginal arteries in females) also help to supply the bladder.

Veins

The veins form a plexus on the lateral and inferior surfaces of the bladder. In the male, the prostatic plexus is continuous with the vesical plexus, which drains into the internal iliac vein. In the female, similar large veins are continuous with the vaginal plexus.

Lymphatics

These accompany the veins and drain to nodes along the internal iliac vessels and then to the obturator and external iliac chains. Some lymphatics pass to nodes that are situated posteriorly to the internal iliac artery (hypogastric nodes).

INNERVATION

The parasympathetic input

This is derived from the anterior primary divisions of the second, third and fourth sacral segments (mainly S2 and S3). Fibres pass through the pelvic splanchnic nerves to the inferior hypogastric plexus, from where they are distributed to the bladder (Figure 76.1). The pelvic plexus can be damaged during deep pelvic operations.

The sympathetic input

This arises in the 11th thoracic to the second lumbar segments; fibres pass via the presacral hypogastric nerve (rather than via the sympathetic chains) to the inferior hypogastric plexus.

Somatic innervation

A somatic innervation passes to the distal sphincter mechanism via the pudendal nerves and also via fibres that pass through the inferior hypogastric plexus.
CONGENITAL DEFECTS OF THE BLADDER

Bladder extrophy

Clinical features
Bladder extrophy occurs in 1:50,000 births (male–female ratio 4:1) (Figure 76.2). In the male, the penis is broad and short, and bilateral inguinal herniae may be present. There is separation of the pubic bones (Figure 76.3). In epispadias alone, the pubes are united and external genitalia are almost normal, although in the female the clitoris is bifid (Figure 76.4).

Treatment
The bladder is closed in the first year of life, usually following osteotomy of both iliac bones just lateral to the sacroiliac joints. Later, reconstruction of the bladder neck and sphincters is required. In some patients the reconstructed bladder remains small and requires augmentation. One-stage reconstruction is being practised in some major centres.

Less satisfactorily, urinary diversion can be carried out by means of ureterosigmoid anastomosis, an ileal or colonic conduit, or continent urinary diversion. Long-term complications include: (1) stricture at the site of anastomosis with bilateral hydronephrosis and infection; (2) hyperchloraemic acidosis; and (3) an increased (20-fold) risk of tumour formation (adenoma and adenocarcinoma) at the site of a ureterocolic anastomosis.

Figure 76.4 Female epispadias showing deficient sphincter and bifid clitoris.
**BLADDER TRAUMA**

**Bladder rupture**
This can be intraperitoneal (20 per cent) or extraperitoneal (80 per cent) (Figures 76.5 and 76.6). Intraperitoneal rupture is usually secondary to a blow or fall on a distended bladder, more rarely to surgical damage. Extraperitoneal rupture is caused by blunt trauma or surgical damage. Gross haematuria can be absent. It may be difficult to distinguish extraperitoneal rupture from rupture of the membranous urethra (see Chapter 78). Intraperitoneal rupture is associated with sudden severe pain in the hypogastrium, often accompanied by syncope. The shock subsides and the abdomen distends and there is no desire to micturate. Peritonitis does not follow immediately if the urine is sterile; varying degrees of rigidity are present on examination.

**Investigation**
Computed tomography (CT) is ideal. Plain erect x-rays may show a ground-glass appearance (fluid). Intravenous urography (IVU) may confirm a leak. Retrograde cystography will confirm the diagnosis (Figure 76.7). It is important to image the patient after drainage of contrast as the full bladder may mask extravasation (Summary box 76.1).

**Summary box 76.1**

**Bladder trauma**

- Intraperitoneal or extraperitoneal
- Suspected if there is trauma and damage to the pelvis
- May be diagnosed by retrograde cystography

- Figure 76.5 Intraperitoneal extravasation of urine.
- Figure 76.6 Extraperitoneal extravasation of urine.

**Treatment of intraperitoneal rupture**
A lower midline laparotomy should be performed; the edges of the rent are trimmed and sutured with a single-layer 2/0 absorbable suture. A suprapubic and a urethral catheter are placed. Very rarely, the rupture will be through an unsuspected tumour; a biopsy can be taken before suturing the defect. Laparoscopic approaches are also now being used.

**Injury to the bladder during operation**
The bladder may be injured in: (1) inguinal or femoral herniotomy; (2) hysterectomy; and (3) excision of the rectum. If the injury is recognised, the bladder must be repaired and catheter drainage maintained for 7 days. If it is not recognised, the treatment is similar to that of rupture of the bladder.

When accidental extraperitoneal perforation of the bladder occurs during endoscopic resection, drainage of the bladder with a urethral catheter and the administration of antibiotics usually suffice. If a mass of extravasated fluid is present it is best to place a small drain through a stab incision. A laparotomy will usually be required if an intraperitoneal perforation is caused by transurethral resection (Summary box 76.2).

**Summary box 76.2**

**Management of bladder trauma**

- Extravesical injury – catheter drainage for 10 days
- Intraperitoneal injury – laparotomy, repair and bladder drainage

- Figure 76.7 Cystogram of a patient who has fallen over and developed severe abdominal pain. Leakage of contrast into the peritoneal cavity is seen.
RETENTION OF URINE

Acute retention

There are many possible causes of acute retention of urine (see also Chapter 77) (Summary box 76.3).

Summary box 76.3

The most frequent causes of acute retention

Male
- Bladder outlet obstruction (the commonest cause)
- Urethral stricture
- Acute urethritis or prostatitis
- Phimosis

Female
- Retroverted gravid uterus
- Bladder neck obstruction (rare)

Both
- Blood clot
- Urethral calculus
- Rupture of the urethra
- Neurogenic (injury or disease of the spinal cord)
- Smooth muscle cell dysfunction associated with ageing
- Faecal impaction
- Anal pain (haemorrhoidectomy)
- Intensive postoperative analgesic treatment
- Some drugs
- Spinal anaesthesia

Clinical features

- No urine is passed for several hours.
- Pain is present.
- The bladder is visible, palpable, tender (Figure 76.8) and dull to percussion.
- Potential neurological causes should be excluded by checking reflexes in the lower limbs and perianal sensation.

Treatment

Treatment is to pass a fine urethral catheter (14F – French gauge is defined as the circumference in millimetres) and arrange urological management. Occasionally, in postoperative retention a warm bath can help (Figures 76.9, 76.10, 76.11 and 76.12).
Retention of urine

Urethral catheterisation

Following a thorough hand wash, sterile gloves are donned. The genitalia are cleaned using soapy antiseptic. Lignocaine gel is inserted into the urethra, warning the patient that this may create stinging. The jelly should be massaged posteriorly in an attempt to anaesthetise the sphincter region, and it is of advantage to place a penile clamp for several minutes. A small Foley catheter should be passed while the penis is held taut. In a female patient, the labia should be parted using the middle and index fingers of the left hand, which should not be moved once cleaning has been performed. Providing a stricture is not the cause, the catheter should pass freely. Once urine begins to drain, it is wise to pass a few more centimetres of catheter into the bladder before the balloon is inflated to avoid inflation in the prostate. Force must not be used (Summary box 76.4).

Summary box 76.4

Catheterisation for acute retention of urine

Following catheterisation:
- Record the volume of urine drained
- Examine the abdomen to exclude other pathology (rupture of an aortic aneurysm, ureteric colic or diverticulitis can cause confusion)

If the catheter will not pass, it is usually due to poor technique, lack of anaesthesia, traumatisation of the urethra or a urethral stricture. Occasionally, a large prostatic middle lobe may prevent the catheter entering the bladder; sometimes a coudé catheter will pass. If a catheter cannot be passed the following plan should be pursued.

Suprapubic puncture

Suprapubic puncture with commercially available catheters such as Cystofix or Lawrence Add-a-Cath catheters is straightforward provided that the bladder is palpable. The skin, fascia and retropubic space are anaesthetised with 0.5 per cent lignocaine. Correct placement is confirmed by aspiration. A large-bore needle is then placed into the bladder, down which a fine catheter is passed (Cystofix) and then secured in position. The other option is to place a plastic suprapubic trocar and cannula, which has a removable plastic strip on the side. A standard 12F Foley catheter can be passed down the cannula, the balloon is inflated, the cannula is extracted and the strip is pulled away from the catheter (Add-a-Cath). If urine cannot be aspirated through the fine-bore needle, passing a suprapubic trocar should not be attempted.

If these devices are not available, a catheter can be placed in the bladder under direct vision through a small incision under local anaesthetic.

Urethral instrumentation

In a patient with a known stricture, an experienced urologist may elect to dilate the stricture or to take the patient to theatre to carry out an optical urethrotomy (see Chapter 78).

Chronic retention

In chronic retention there is no pain. These patients are at risk of upper tract dilatation because of high intravesical tension – they require urgent urological referral. Men with impaired renal function may develop post-obstructive diuresis following catheterisation. Such men need careful monitoring, with replacement of inappropriate urinary losses by intravenous saline; they are also at risk of haematuria as the distended urinary tract empties. Often it is several days before full renal recovery occurs.

Retention with overflow

The patient is incontinent with small amounts of urine passing involuntarily from the distended bladder. It usually follows a neglected retention.

Indwelling catheters and closed systems of catheter drainage

The risk of ascending infection is decreased by connecting the catheter to sterile tubing connected to a collecting bag. Irrigations should be avoided unless clot retention occurs. When a catheter has been in situ for a few days, some degree of urethritis and bacteriuria is likely; changing a catheter then entails risks of severe infection if prophylactic antibiotics are not used (Figure 76.13).

Acute retention due to drugs

A number of drugs can induce retention, including antihistamines, anti-hypertensives, anti-cholinergics and tricyclic antidepressants.
The acute neuropathic bladder

1. Immediately after spinal cord injury, ‘spinal shock’ occurs (see Chapter 35), which may last for days or months. The detrusor is not able to contract, the bladder distends and overflow incontinence occurs. Neglected bladder distension will lead to damage to the detrusor, infection and ultimately renal failure. Management is as follows:

2. The bladder must be emptied by aseptic intermittent catheterisation performed two or three times daily or the use of an indwelling urethral catheter on continuous drainage, making sure that the patient has a high urinary output (3 litres per day) to combat infection. Currently, intermittent catheterisation is preferred as soon as the patient’s spinal injury is stable.

3. Neurological examination must be performed to assess the level of sensory and motor loss. Ischaemic necrosis of the cord may extend below the upper level of cord injury. When sensory loss below the upper level is total, recovery is unlikely. Incomplete lesions may recover somatic and bladder function.

4. Demonstration of intact bulbocavernosus and anal reflexes indicates that the sacral cord and nerves are intact and that reflex bladder contractions are likely to develop, though they may be insufficient to empty the bladder. If there is persistent total loss of reflexes and perineal sensation then either the sacral cord or cauda equina is damaged. In such circumstances, an acontractile bladder is likely. In cauda equina lesions, there may be sensory, motor or mixed loss.

5. Full urodynamic assessment of bladder function should be undertaken when the injury is stable. This allows an accurate assessment of bladder and sphincter activity and will enable decisions to be made about further management; the prime aim is to prevent upper tract damage by promoting good bladder emptying (Summary box 76.5).

Summary box 76.5

Clinical management of spinal injury

- The bladder should be emptied during spinal shock by catheterisation
- Encourage high fluid intake
- Commence intermittent catheterisation
- When the patient is stable, undertake full urodynamic evaluation

The following situations represent the typical patterns of bladder function seen after spinal cord injury.

Lesions above T10

Usually leads to an ‘upper motor neurone’ bladder with reflexes intact but isolated from higher control mechanisms. Such patients are at risk of autonomic dysreflexia.

Because of detrusor–sphincter dyssynergia, bladder contractions are high pressure and ineffective in producing bladder emptying; the bladder neck is normally open. If left untreated, upper tract dilatation and renal failure may result. Bladder capacity is usually decreased with the development of trabeculation and a typical ‘ft-tree’ appearance. Patients are incontinent during high-pressure phasic contractions because the sphincter resistance suddenly diminishes.

Some patients with low-pressure bladders that empty may be managed by means of condom drainage. Others will require clean intermittent self-catheterisation (CISC), popularised by Lapides. Patients with poor emptying, low bladder capacity and upper tract dilatation require treatment with endoscopic sphincterotomy and condom drainage. Some carefully selected patients may require bladder reconstruction.

Lesions involving the sympathetic outflow (T11, T12, L1, L2)

These patients are usually similar to the group with lesions above T10.

Damage to the sacral centre S2, S3, S4 and cauda equina lesions

Usually leads to a ‘lower motor neurone’ bladder, also found in spina bifida (myelodysplasia); the detrusor is acontractile. Abdominal straining can produce reasonable emptying but the mainstay is CISC. Some patients may have sensation of filling through the hypogastric nerves, if T11 and T12 are intact. The bladder capacity may be good, but some patients have high resting pressures and high increases during bladder filling, which means that there is a risk to the upper urinary tract. The bladder neck is usually open and the distal sphincter mechanisms may be paralysed but of fixed resistance. Vesicoureteric reflux is common and upper tract damage is frequent in neglected cases. Patients who can achieve satisfactory bladder emptying by means of CISC usually have reasonable continence.

Bladder dysfunction after excision of the rectum or radical hysterectomy

Between 10 and 15 per cent of patients undergoing radical rectal excision for cancer sustain damage to the inferior hypogastric plexus, leading to impotence in the male and neurogenic bladder dysfunction. This type of bladder dysfunction is similar to the cauda equina lesion. Postoperative retention in other patients may also be caused by simple bladder outlet obstruction. The best plan is to catheterise the patient to allow postoperative recovery and then carry out urodynamic investigation to determine the appropriate treatment.

INCONTINENCE OF URINE

Overall, urinary incontinence occurs in 5 per cent of men and 20 per cent of women. Up to 40 per cent of women over the age of 60 years and 50 per cent of institutionalised elderly patients experience regular episodes of urinary incontinence. Health problems include skin breakdown and depression, and loss of esteem and sexual activity. Continence is dependent on normal mobility and brain function allowing a perception of when it is socially acceptable to void, normal bladder sensation, normal voluntary detrusor contraction producing good bladder emptying, a normally competent sphincter mechanism, which relaxes appropriately during a voluntary detrusor contraction allowing good bladder emptying, and good bladder capacity with normally low pressures during filling. This is clearly a fine balance and several factors can cause incontinence. In children, non-neurogenic incontinence is often associated with other dysfunctional conditions such as infections, constipation, psychological factors, increased fluid intake, intentional misconduct or an
Incontinence of urine

overactive bladder. Several investigations are required for diagnosis of urinary incontinence (Summary box 76.6).

**Summary box 76.6**

**Diagnosis of urinary incontinence**

The following investigations are required:

- A careful history and physical examination and completion of frequency voiding charts
- Urodynamic testing in most patients and in all patients in whom surgical intervention is proposed
- Urine culture to exclude infection and measurement of serum creatinine

In selected cases, IVU is carried out if a ureteric fistula is suspected, although ultrasound examination will often provide adequate details.

**Urodynamic testing**

The key to the practical management of lower urinary tract dysfunction, and particularly incontinence, lies with urodynamic investigation. The principle is to artificially simulate bladder filling and emptying while obtaining pressure measurements (Figure 76.14).

The patient attends with a full bladder and is allowed to void in private to measure the maximum urinary flow rate. After voiding, the residual urine is measured by ultrasound. A pair of catheters or a twin-lumen catheter is passed into the bladder, which allows the bladder to be filled at a rate of 50 mL/min while a continuous recording of intravesical pressure is made. To obtain ‘true’ detrusor pressure, a second channel is required to assess intra-abdominal pressure, measured by means of a small intrarectal or intravaginal balloon. The bladder is filled until the patient states that the bladder is full. X-ray screening may be carried out to assess bladder neck closure and urinary leakage during movement or coughing (stress incontinence) or during bouts of phasic detrusor pressure (detrusor instability). The patient is then asked to void at the end of bladder filling after the filling catheter has been removed (Figure 76.15).

The normal bladder will accept approximately 400–550 mL when filled at room temperature at a rate of <50 mL/min. The pressure increase in the bladder should be less than 15 cmH₂O. In addition, phasic pressure increases should not be seen. The normal voiding pressure should not exceed 60 cmH₂O in men and about 40 cmH₂O in women, with a flow rate of between 20 and 25 mL/s.

**Common abnormalities identified during urodynamic testing in incontinence**

**The overactive bladder**

Phasic increases in pressure give rise to urgency and urge incontinence (detrusor overactivity; Figure 76.16). This abnormality is found in patients with neurogenic bladder dysfunction, such as in multiple sclerosis (MS) or Parkinson’s disease or following a stroke or spinal injury, when it is known as detrusor hyperreflexia. About 50 per cent of men with bladder outflow obstruction have detrusor instability, and in about half of them the instability resolves after prostatectomy. Idiopathic detrusor overactivity is common and must be distinguished from genuine stress incontinence (GSI) in women before performing bladder neck suspension procedures. In children, overactive bladder symptoms must be carefully investigated and treated with conservative measures before initiating antimuscarinic therapy.

**Genuine stress incontinence**

This is defined as urinary leakage occurring during increased bladder pressure when this is solely due to increased abdominal pressure and not to increased true detrusor pressure (see Figure 76.15). It is caused by sphincter weakness.

**Chronic urinary retention**

Chronic urinary retention with overflow incontinence is recognised by a large residual volume of urine (Figure 76.17) and is usually associated with high pressures during bladder filling.
Bladder outflow obstruction

Bladder outflow obstruction is associated with increased voiding pressures, often in excess of 90 cmH₂O (Figure 76.18), coupled with low urinary flow rates.

Neurogenic dysfunction

Neurogenic bladder dysfunction may also be identified (Summary box 76.7).

Summary box 76.7

Uses of urodynamic testing

- To distinguish GSI (due to sphincter weakness) from detrusor instability in women (see Figure 76.15)
- For the classification of neurogenic bladder dysfunction
- To distinguish bladder outflow obstruction from idiopathic detrusor instability in men
- To investigate incontinence or other lower urinary tract symptoms

Causes of incontinence

There are various ways of classifying the causes of incontinence.

- Problems of social control. Patients with dementia often have incontinence because of uninhibited detrusor hyperreflexia and impaired social perception.
- Storage problems. Patients with a small bladder capacity owing to fibrosis (tuberculosis, radiotherapy or interstitial cystitis) can develop incontinence. Patients with a small functional capacity owing to severe detrusor instability, neurogenic dysfunction or infection can develop incontinence.
- Impairment of emptying. Patients with chronic retention or neurogenic bladder dysfunction have small functional bladder capacities with detrusor overactivity causing incontinence, despite having large residual volumes of urine.
- Weak sphincter. This leads to GSI and can follow surgical procedures such as radical prostatectomy in men.
- Fistulae. Leakage from fistulae or upper tract duplication with an ectopic ureter.
- In children, the causes must be carefully investigated and treated with conservative measures before initiating antimuscarinic therapy.

The common causes may be classified into male, female or mixed-sex groups.

Male incontinence

Chronic urinary retention with overflow

This may be due to benign prostatic hypertrophy, carcinoma...
of the prostate, urethral stricture and, in younger men, hypertrophy of the bladder neck. Examination may reveal that the bladder is distended, and it can be confirmed by ultrasound scanning. The treatment is discussed in Chapter 77.

Post-prostatectomy
Post-prostatectomy incontinence may result from injury to the external sphincter mechanism. Treatment should be conservative initially with pelvic floor exercises, and an anstomic sticture must be excluded. The condition may necessitate insertion of an artificial urethral sphincter (Figure 76.19).

Female incontinence

Stress incontinence
The most common cause is GSI, although in some parts of the world, vesicourethral fistulae as a result of neglected labour are common. It is usually found in multiparous women with a history of difficult labour. It can be found in normal young women who indulge in competitive trampolining and in patients with episadias. The classical symptom is urine loss during coughing, laughing, sneezing or a sudden change of posture. The symptoms may change with the menstrual cycle. The volume of urine loss can be measured during an exercise test, which is performed by putting the patient through a standard set of tests with 300 mL of fluid in the bladder; in GSI the fluid losses usually range from 10 to 50 mL. Urinary frequency and urgency are often found in such patients as they try to avoid incontinence by frequent voiding.

Idiopathic detrusor instability can mimic GSI and coexist with it. It is important to make a correct preoperative diagnosis by urodynamic measurements, as the outcome of surgery is suboptimal in women with idiopathic detrusor instability.

Minor to moderate stress urinary incontinence can be controlled by pelvic floor exercises. However, if this fails, surgery is indicated. Standard operations include open colposuspension or the use of a minimally invasive approach involving the insertion of a transvaginal tape (TVT procedure).

Open colposuspension
This operation is carried out through a Pfannenstiel incision with the patient in the Lloyd-Davies position. The vaginal fascia is identified by sweeping the bladder off the vagina and three sutures are placed on each side between the vaginal fascia and the iliopubic ligament. A suprapubic catheter is placed. Voiding difficulties are frequent but usually temporary. It is best to warn patients at five years. This operation is very successful for the treatment of GSI, with good results at one year in 90 per cent of patients, which are maintained in about 80 per cent of patients at five years.

Modifications of bladder neck suspension can also be achieved by minimally invasive approaches such as the transvaginal sling. This technique does reduce both hospital stay and postoperative morbidity.

Incontinence common to both sexes

Idiopathic detrusor overactivity
Phasic increases in bladder pressure may occur during filling in otherwise normal patients (idiopathic) or it may be found in neurogenic bladder dysfunction (when it is known as detrusor hyperreflexia) and bladder outflow obstruction. Idiopathic detrusor overactivity may be symptomless but usually results in symptoms of frequency, urgency, urge incontinence, nocturia or nocturnal incontinence (enuresis) depending on the severity of the instability. It must be distinguished from GSI and from bladder outflow obstruction before surgical treatment. Infection, tuberculosis or carcinoma in situ (CIS) should be excluded. The mainstay of treatment is the use of various anti-cholinergic medications (oxybutynin and tolterodine). Severe symptoms resistant to conventional conservative treatment resulting in major impairment of quality of life may need more aggressive treatment, such as enterocystoplasty or the injection of small doses of botulinum toxin (the toxin from Clostridium botulinum), known as BoTox, which blocks cholinergic neuromuscular transmission, at least for a time.

Ageing
Ageing can result in smooth muscle cell dysfunction, which can cause combinations of small functional capacity, detrusor overactivity, impaired bladder emptying and symptoms of lower urinary tract dysfunction.

Congenital
Congenital causes include ectopic vesicae and severe episadias. The abnormal entry of an ectopic ureter distal to the sphincter complex or into the vagina in a female patient should theoretically result in total urinary incontinence. This is discussed in Chapters 6 and 75.

Trauma
Trauma, whether from pelvic surgery or associated with pelvic fracture, may result in disruption of the nerve supply to the bladder or urethra, or in fistula formation.

Infection
Lower urinary tract infection (UTI) may be sufficient to induce urinary incontinence. A history of frequency, burning and a fever should prompt the diagnosis. Symptoms will usually settle with a course of antibiotics, but in the case of recurrent infection further investigation of the urinary tract will clearly be indicated.

Figure 76.19 The artificial urinary sphincter made by American Medical Systems.
Neoplasia
Locally advanced cancers in the pelvis, particularly carcinoma of the cervix in a woman and carcinoma of the prostate in a man, may result in direct invasion of the sphincter mechanism causing incontinence; occasionally, fistula formation may occur in women.

Other causes
Constant dribbling of urine coupled with normal micturition
This occurs when there is a ureteric fistula or an ectopic ureter associated with a duplex system opening into the urethra beyond the urethral sphincter in females or into the vagina. The history is diagnostic, and intravenous pyelography or ultrasound scanning may reveal the upper pole segment, which is often poorly functioning. Treatment is by excision of the aberrant ureter and portion of kidney. A ureteric fistula can be difficult to diagnose and its demonstration may require retrograde ureterography and a high degree of suspicion.

Nocturnal enuresis
This is a condition of young children and young adults. Of course, the time at which children become dry at night varies and, in some, nocturnal enuresis is merely a delayed onset of continence. In others, it persists until late adolescence and is classified into primary and secondary nocturnal enuresis. In children, once neurogenic dysfunction has been excluded, the condition can be associated with other symptoms such as intentional misconduct, infections, constipation and increased fluid intake. These causes must be ruled out before medication is considered.

Primary nocturnal enuresis occurs in patients with nocturnal symptoms alone, which are absent during the day. Often, they have been dry for a period, and the vast majority of patients will eventually become dry. In the meantime, a sympathetic approach to these children is essential. They often respond to a system of rewards using a ‘star’ chart. In addition, the use of DDAVP (a vasopressin analogue) can produce increased urinary concentration at night with a decrease in nocturnal incontinence. Other treatments include the use of an alarm that wakes the child (or at least the child’s parents) when incontinence occurs and medication in the form of an anticholinergic drug such as oxybutynin.

Treatments for incontinence
Treatments are listed below. Management is dependent on making a correct diagnosis.

Management and treatment
Following careful assessment and investigation, many cases of incontinence can improve with simple measures such as lifestyle interventions, pelvic floor exercises with biofeedback, bladder training and incontinence devices where necessary. In mixed urge and stress incontinence, the major component has to be treated first.

Problems of social functioning
Patients with dementia may respond to regular toileting. Anticholinergic agents can cause increased confusion in these patients and often, in severe cases, an indwelling catheter is needed.

Storage problems
Patients with a small bladder capacity because of fibrosis may require augmentation cystoplasty. Detrusor overactivity will require treatment with anti-cholinergic medication but, in severe cases, particularly in neuropathic patients at high risk of upper tract dilatation, bladder substitution (near-total supratrigonal cystectomy followed by the need for detubularised ileocoeical segment bladder substitution) or augmentation (enterocystoplasty) may be needed. These procedures should be carried out only after careful assessment in units used to dealing with such problems. Patients with very impaired mobility and MS may require ileal conduit diversion. The use of intravesical injections of BoTox has provided good improvements, and it may avoid or delay the need for major surgery.

Impaired bladder emptying
Patients with overflow incontinence because of bladder outflow obstruction will usually respond well to prostatectomy. Patients with impaired bladder emptying because of neurogenic bladder dysfunction should be treated in the first place by means of CISC.

Weak sphincter
Patients with GSI should be treated by means of pelvic floor exercises initially. Duloxetine can be used as medical treatment for GSI. Bulking agents, such as macroplastique, can be used and can provide good temporary solutions. Surgical treatment by means of colposuspension or TVT may be needed. Those with post-prostatectomy incontinence or neurogenic bladder dysfunction may need to be fitted with an artificial urinary sphincter (Figure 76.19), if they are well motivated and mobile, but careful assessment is required.

Use of appliances
An indwelling catheter drained constantly into a leg urinal may be a satisfactory solution although, in some instances, diversion via an ileal conduit is necessary. In men, a condom urinary appliance may be satisfactory and can avoid an indwelling catheter.

More major surgical treatments
Various types of urinary diversion
Urinary diversion may be required for the treatment of end-stage incontinence that is not otherwise treatable (see later in this chapter).

Bladder substitution procedures
The principle behind these operations is the creation of a low pressure, large-capacity reservoir, which can be made using any segment of bowel isolated on its vascular pedicle (Figures 76.20, 76.21 and 76.22). This is then detubularised by dividing its anti-mesenteric border and suturing this into a plate, which is then reconfigured into a spherical structure. This reservoir can then be anastomosed to the bladder remnant after excision of the fundus above the trigone. If necessary, the ureters can be reimplanted into the bowel segment. This new bladder will need to be emptied by means of CISC in up to 30 per cent of cases.
‘Clam’ enterocystoplasty
This procedure was originally described by Bramble for the treatment of nocturnal enuresis. It has been used in the treatment of idiopathic detrusor instability (Figure 76.23). This procedure can also be used as an augmentation procedure in patients with neurogenic bladder dysfunction and a reasonable bladder capacity (approximately 300 mL).

Fitment of artificial urinary sphincter
See Figure 76.19.

Summary
Treatments for incontinence can be summarised as follows:
1. Conservative measures such as lifestyle interventions, pelvic floor muscle and bladder training.
2. Devices for collection: external penile condom, or an indwelling urethral or suprapubic catheter.
3. Drugs: to decrease the strength of the bladder neck (e.g. adrenergic blockers); with mixed action on the bladder neck and central nervous system (e.g. tricyclic drugs); to inhibit bladder activity (e.g. anti-cholinergic drugs). Botulinum toxin A is used in selected patients. Duloxetine can be used as medical treatment for GSI – it is a serotonin–noradrenaline (norepinephrine) reuptake inhibitor.
5. Increasing outlet: pelvic floor physiotherapy; resistance colposuspension or TVT tapes or slings; periurethral injections of ‘bulking agents’ such as cross-linked collagen or other particles; use of the artificial urinary sphincter.
6. Denervation of bladder: S3 sacral nerve blockade, neurectomy or surgical transection of the bladder to inhibit bladder activity and improve functional capacity. These are rarely used nowadays because of the use of botulinum toxin and the clam cystoplasty or S3 nerve stimulation (see point 7).
7. Sacral nerve stimulation devices can improve incontinence. They involve percutaneous insertion of electrodes through the sacral foramina under radiological control and implantation of an electronic stimulator.

Figure 76.20 A vascularised ileocaecal segment being detubularised.

Figure 76.21 An ileocaecal segment being anastomosed to the trigone after near-total cystectomy; the left ureter is about to be implanted by means of a Camay–Le Duc anastomosis.

Figure 76.22 A capacious ileocaecal reservoir to be used in a patient requiring bladder substitution. These segments may be used for total bladder replacement, bladder substitution and the construction of continent diversion with a Mitrofanoff-type anti-incontinence mechanism (see later in the chapter).

Figure 76.23 A ‘clam’ cystoplasty being performed. The ureteric orifices can be seen with the interureteric bar; the defect will be filled by a segment of detubularised ileum, performing a bladder augmentation.

Frank James Bramble, formerly urologist, The Royal Victoria Hospital, Bournemouth, UK.
BLADDER STONES

Definition
A primary bladder stone is one that develops in sterile urine; it often originates in the kidney. A secondary stone occurs in the presence of infection, outflow obstruction, impaired bladder emptying or a foreign body.

Incidence
Until the twentieth century, bladder stone was a prevalent disorder among poor children and adolescents. Because of improved diet, especially an increased protein–carbohydrate ratio, primary vesical calculus is rare.

Composition and cystoscopic appearance
Most vesical calculi are mixed. An oxalate calculus is a primary calculus that grows slowly; usually, it is of moderate size and solitary, and its surface is uneven (Figure 76.24). Although calcium oxalate is white, the stone is usually dark brown or black because of the incorporation of blood pigment. Uric acid calculi are round or oval, smooth and vary in colour from yellow to brown (Figure 76.25). They occur in patients with gout but are also found in patients with ileostomies or with bladder outflow obstruction. A cystine calculus occurs only in the presence of cystinuria and is radio-opaque because of its high sulphur content. A triple phosphate calculus is composed of ammonium, magnesium and calcium phosphates and occurs in urine infected with urea-splitting organisms. It tends to grow rapidly. In some instances it occurs on a nucleus of one of the other types of calculus; more rarely it occurs on a foreign body (Figures 76.26 and 76.27). It is dirty white in colour and of chalky consistency. A bladder stone is usually free to move in the bladder and it gravitates to the lowest part of the bladder. Less commonly, the stone is wholly or partially in a diverticulum, where it may be hidden from view.

Clinical features
Men are affected eight times more frequently than women. Stones may be asymptomatic and found incidentally.

Symptoms
Frequency is the earliest symptom and there may be a sensation of incomplete bladder emptying. Pain (strangury) is most often found in patients with a spiculated oxalate calculus. It occurs at the end of micturition and is referred to the tip of the penis or to the labia majora; more rarely, it is referred to the perineum or suprapubic region. The pain is worsened by movement. In young boys, screaming and pulling at the penis with the hand at the end of micturition are indicative of bladder stone. Haematuria is characterised by the passage of a few drops of bright-red blood at the end of micturition, and is due to the stone abrading the vascular trigone. Interruption of the urinary stream is due to the stone blocking the internal meatus. Urinary infection is a common presenting symptom.

Figure 76.24 A rough bladder stone.

Figure 76.25 Smooth uric acid-type stones.
Examination
Rectal or vaginal examination is normal; occasionally, a large calculus is palpable in the female. Examination of the urine reveals microscopic haematuria, pus or crystals that are typical of the calculus, for example envelope-like in the case of an oxalate stone or hexagonal plates in the case of cystine calculi. In most patients, the stone is visible on ultrasound or on a plain x-ray (Figure 76.28). Imaging of the whole of the urinary tract should be undertaken to exclude an upper tract stone. Nearly all stones can be dealt with endoscopically. In men with bladder outflow obstruction, endoscopic resection of the prostate should be performed at the same time as the stone is dealt with.

Treatment
The cause of the stone should be sought and treated; this may include bladder outflow obstruction or incomplete bladder emptying in patients with neurogenic bladder dysfunction.

Litholapaxy
The blind lithotrite (Figure 76.29) was an early type of minimally invasive technique. Standard management now includes the optical lithotrite, electrohydraulic lithotrite, Holmium laser or ultrasound probe (Figure 76.30). Other devices include the stone punch, which is useful to crush small fragments further so that they can be evacuated with an Ellik evacuator. Contraindications to perurethral litholapaxy are extremely rare:

- urethral: a urethral stricture that cannot be dilated sufficiently; when a patient is aged below ten years;
- bladder: a contracted bladder;
- stone characteristics: a very large stone.

Ultrasound lithotripsy is extremely safe but appropriate only for small stones. Laser lithotripsy with the holmium laser can deal with most large stones. Once small fragments are produced, the optical lithotrite can be used to finish the job. For evacuation of the fragments, fluid (200 mL) is introduced into the bladder. The evacuator, filled with solution, is fitted on to the sheath. The bulb is compressed slowly and then permitted to expand; the returning solution carries with it fragments of stone.

Milo Ellik, b. 1905, American urologist. One of the original members of the Los Angeles Urological Society. In 1932 Dr Alcock, a pioneer of transurethral resection of prostate, persuaded one of his residents, Milo Ellik, to go to the Chemistry Department glass blowing shop where he devised his evacuator. Unfortunately he never had a patent on his device which was patented by Bard, the surgical company, in the 1940s.
Percutaneous suprapubic litholapaxy
It is possible to insert a needle into the bladder and then pass a guidewire. As in percutaneous nephrolithotomy, Alken metal dilators can be passed over the guidewire to dilate the track and an Amplatz sheath inserted followed by a large-bore nephroscope. This is the best method to use if it is not possible to carry out litholapaxy per urethram because of a narrow urethra.

Removal of a retained Foley catheter
A retained Foley catheter is usually caused by the channel that connects the balloon to the side arm becoming blocked, usually at the end near the balloon. The best way of dealing with this problem is to further inflate the balloon with 20 mL of water and then burst the balloon percutaneously using a needle under ultrasound screening. If the balloon bursts, it is important to subsequently cystoscope the patient to ensure that any fragments are removed before they can form a foreign body calculus. Cutting off the side arm and attempting to clear the channel with a wire is only occasionally successful.

FOREIGN BODIES IN THE BLADDER
The most common foreign body in the bladder is a fragment of catheter balloon (see above). Occasionally, a foreign body enters through the wall of the bladder, for example non-absorbable sutures used in an extravesical pelvic operation. Complications include:
- lower UTI;
- perforation of the bladder wall;
- bladder stone.

Treatment
A small foreign body can usually be removed per urethram by means of an operating cystoscope. Occasionally, a suprapubic approach using the percutaneous insertion of a cystoscope is needed.

DIVERTICULAE OF THE BLADDER
Definition
The normal intravesical pressure during voiding is about 35–50 cmH₂O; however, pressures as great as 150 cmH₂O may be reached by a hypertrophied bladder endeavouring to force urine past an obstruction. This pressure causes the lining between the inner layer of hypertrophied muscle to protrude, forming multiple saccules. If one or more, but usually one, saccule is forced through the bladder wall, it becomes a diverticulum (Figure 76.31). Congenital diverticula are the result of a developmental defect.

Aetiology of diverticulae
Congenital diverticula
These are situated in the midline anterosuperiorly and represent the unobliterated vesical end of the urachus.

Pulsion diverticula
The usual cause is bladder outflow obstruction.

Pathology
The mouth of the diverticulum is situated above and to the outer side of one ureteric orifice. Exceptionally, it is near the midline behind the interureteric ridge. The size varies from 2 to 5 cm, but they may be larger. Diverticula are lined by bladder mucosa and the wall is composed of fibrous tissue only (compare with a traction diverticulum). A large diverticulum enlarges in a downward direction and sometimes may obstruct a ureter – probably because of peridiverticular inflammation.

Complications
Recurrent urinary infection
As the pouch cannot empty itself efficiently, there remains a stagnant pool of urine within it. Peridiverticulitis can cause dense adhesions between the diverticulum and surrounding structures. Squamous cell metaplasia and leukoplakia are infrequent complications.

Bladder stone
This develops as a result of stagnation and infection. The stone often protrudes into the bladder.
**Diverticulae of the bladder**

Hydronephrosis and hydroureter

This is extremely rare and is a consequence of peridiverticular inflammation and fibrosis.

Neoplasm

Neoplasm arising in a diverticulum is an uncommon complication (<5 per cent). The prognosis is dependent on the stage of the tumour (see below).

**Clinical features**

An uninfected diverticulum of the bladder usually causes no symptoms. The patient is nearly always male (95 per cent) and over 50 years of age. Symptoms are those of associated urinary tract obstruction, recurrent infection and pyelonephritis. Haematuria (due to infection, stone or tumour) is a symptom in about 30 per cent. In a few patients micturition occurs twice in rapid succession (the second act may follow a change of posture).

**Diagnosis**

Diverticula are usually discovered incidentally on cystoscopy or ultrasound (Figures 76.32, 76.33 and 76.34).

**Indications for operation**

Operation is necessary only for the treatment of complications. Provided the diverticulum is small and associated outflow obstruction has been dealt with by prostate resection, there is no reason to resect the diverticulum. Even a large diverticulum may not require treatment in the absence of infection or other complications.

**Combined intravesical and extravesical diverticulectomy**

A ureteric stent is passed up the ureter on the affected side and the anterior bladder wall is exposed through a suprapubic incision. The bladder is incised in the midline and the diverticulum is packed with a strip of gauze. The neck of the diverticulum is separated from the ureter and, when the pouch is free, it is severed from the bladder. The resulting defect is closed in a single layer with 2/0 absorbable sutures. A suprapubic catheter is left in place and an extravesical drain is inserted. An alternative method, if the sac is densely adherent, is to carry the incision in the bladder down to the rim of the diverticular orifice, then to detach the diverticulum together with its fibrous rim. The incision in the bladder is closed and the diverticulum left in position with a corrugated drain placed into it for 2–3 days. The track fibroses rapidly after removal of the drain. If bladder outlet obstruction is present, prostatectomy should be carried out at the same time as the diverticulectomy, using any appropriate method (transurethral resection of the prostate (TURP), laser or open) (Summary box 76.8).

**Summary box 76.8**

**Bladder diverticula**

- Bladder diverticula are most frequently diagnosed incidentally by cystoscopy or urinary tract imaging
- The presence of a diverticulum – even quite a large one – is not an indication for diverticulectomy unless symptoms or cancer are present

---

Figure 76.32 Cystoscopic appearance of the orifice of a diverticulum and trabeculation of the bladder.

Figure 76.33 Occasional appearance of a diverticulum with inadequate distension of the bladder.

Figure 76.34 Bladder diverticulum demonstrated by ultrasound.
**Traction diverticulum (synonym: hernia of the bladder)**

A portion of the bladder protruding through the inguinal or femoral hernial orifice occurs in 1.5 per cent of such herniae treated by operation (Figure 76.35).

**URINARY FISTULAE**

**Congenital urinary fistulae**

The causes of congenital urinary fistulae include:
- ectopia vesicae;
- a patent urachus – the presence of a urinary leak from the umbilicus, present at birth or commencing soon after, suggests this diagnosis. In adult life, infection in a urachal cyst may produce a fistula and adenocarcinoma may occur (Figures 76.36 and 76.37). Treatment is by means of excision of the urachal tract and closure of the bladder once distal obstruction has been excluded;
- in association with imperforate anus (see Chapters 8 and 73).

**Traumatic urinary fistulae**

Perforating wounds, damage not recognised during surgery or poor healing and avascular necrosis following radiotherapy and surgery may lead to fistula formation. Also, clot retention occurring after an open bladder operation may lead to dehiscence of the wound and a fistula, which will heal quickly provided the bladder is kept empty with an indwelling catheter.

**Vesicovaginal fistulae**

**Aetiology**

- Obstetric. The usual cause is protracted or neglected labour.
- Gynaecological. The operations chiefly causing this complication are total hysterectomy and anterior colporrhaphy.
- Radiotherapy.
- Direct neoplastic infiltration. Exceptionally, carcinoma of the cervix ulcerates through the anterior fornix to implicate the bladder.

When an injury to the bladder is recognised and repaired, leakage is uncommon, but escape of urine will quickly follow if such damage passes unnoticed. However, most vesicovaginal fistulae are the result of ischaemic necrosis of the bladder because of prolonged pressure of the fetal head in obstetric cases. In gynaecological cases, the ischaemia is brought about by grasping the bladder wall in an artery forceps, including the bladder wall in a suture or perhaps even by local oedema or haematoma. Leakage because of necrosis of tissue seldom manifests itself before 7 days after the operation. An intractable fistula following radiotherapy for carcinoma of the cervix uteri may arise from avascular necrosis years after the apparent cure of the original lesion.

![Figure 76.35](a) Intraperitoneal, (b) paraperitoneal and (c) extraperitoneal hernia of the bladder, in relation to a hernial sac.

![Figure 76.36](An operative photograph showing a large urachal cyst in which adenocarcinoma formation has occurred. A partial cystectomy with total removal of the urachal remnant is about to be carried out.

![Figure 76.37](A computed tomography scan of the same patient as in Figure 76.36, showing a large urachal cyst closely approximated to the dome of the bladder.)
Clinical features
There is leakage of urine from the vagina and excoriation of the vulva. Vaginal examination may reveal a localised thickening on its anterior wall or in the vault. On inserting a vaginal speculum, urine will be seen escaping from an opening in the anterior vaginal wall.

The ‘three-swab test’
The differential diagnosis between a ureterovaginal and vesico-vaginal fistula can be made by placing a swab in the vagina and injecting a solution of methylene blue through the urethra; the vaginal swab becomes coloured blue if a vesico-vaginal fistula is present. Cystoscopy and bilateral retrograde ureterography provide a more reliable demonstration. An IVU should be performed to exclude a coincidental ureterovaginal fistula (ureterovaginal fistula occurs with vesico-vaginal fistula in about 10 per cent of cases). Usually, the IVU shows some upper tract dilatation resulting from partial obstruction.

Treatment
Just occasionally, conservative management of a vesico-vaginal fistula following hysterectomy, by urethral bladder drainage, is successful; however, the majority of fistulae will require definitive surgical repair. A low fistula (subtrigonal) is best repaired per vaginam. The fistula is exposed, the bladder is closed using absorbable sutures and the vagina subsequently closed with a separate layer. A urethral catheter should be left in situ for at least 10 days. For higher (supratrigonal) fistulae, a transvaginal approach can be difficult. These patients should always be cystoscoped before the repair procedure and bilateral ureterograms performed. For high fistulae, a suprapubic approach is the best method in most hands; however, some experts will aim to carry out vaginal closure in most cases that have not involved complex surgery or radiotherapy.

To repair a ureterovaginal fistula, an extraperitoneal approach to the ureter via the previous Pfannenstiel incision is made. Considerable adhesions will be encountered, but the ureter can usually be found above the level of the injury and followed down. Reimplantation into the bladder is often required. Depending on the amount of ureter lost, it may be possible to achieve reimplantation with a psoas hitch procedure. If the gap is too large, a Boari flap of anterior bladder wall should be cut and brought over to meet the ureter and a reimplant performed. The most important principle of ureteric reimplantation is that there should be no tension on the repair.

Fistulae from renal pelvis to skin or gut
Tuberculosis of a kidney may result in a fistula to the duodenum, colon or skin. Similarly, a pyonephrosis may discharge into the gut or onto the skin. Duodenal ulcer involving the pelvis of the right kidney, Crohn’s disease involving the renal pelvis or ureter, or cases of xanthogranulomatous pyelonephritis may cause fistulae. A longstanding urinoma will occasionally fistulate into the gut.

Fistulae arising from infection
The most common cause is diverticulitis of the colon. Fistulae may also follow Crohn’s disease, appendix abscess or pelvis sepsis after acute salpingitis, or pelvic surgery.

The onset of a fistula from diverticular disease may well be treated as a simple urinary infection. The diagnosis can be difficult to make, but on cystoscopy a patch of oedema on the left side of the vault is suggestive and bubbles of gas may be seen (Figure 76.38). A cystogram may reveal the fistula. The passage of gas per urethram in a patient is most suggestive (provided that diabetes resulting in urinary infection with a gas-forming organism is excluded).

Treatment of fistulae caused by diverticular disease
In most patients a single-stage operation is indicated provided that the surgeon is experienced in colonic surgery. At laparotomy, the communication is separated, the hole in the bladder being closed and patched with omentum, and the segment of diseased bowel resected; it is most important to ensure that the left colon and, if necessary, the splenic flexure are fully mobilised to facilitate a tension-free, well-vascularised anastomosis. The bladder is drained by a urethral catheter.

Fistulae caused by carcinoma
By the time that a fistula between the bowel and the bladder has developed, the tumour is usually locally advanced but may be operable.

Urethral fistulae in the male
These occur as the result of infection above a stricture producing a para-urethral abscess that ruptures into the urethra, allowing extravasation to occur suddenly into the scrotum and perineum. Urine and infection extend into the upper 2.5 cm of the thigh and lower abdominal wall. Widespread cellulitis and tissue necrosis (which may lead to Fournier’s gangrene) may occur unless drainage of urine is achieved by suprapubic cystotomy and the tissue planes are freely drained by inguinal and scrotal incisions.

Neoplastic fistulae
Primary bladder tumours very rarely produce fistulae. Involvement of the bladder by tumours of the cervix, uterus, colon and rectum can produce fistulae, as may sarcoma of the small gut. Carcinoma of the prostate rarely produces a rectal fistula. Treatment is difficult and in most cases only palliative
relief can be given. It is rarely in the patient’s interest to carry out urinary diversion, although minimally invasive techniques, such as placement of ureteric stents, can be helpful in palliating symptoms (Summary box 76.9).

### Summary box 76.9

**Fistulae**
- A fistula is a communication between two epithelium-lined surfaces
- Most urinary fistulae are vesicovaginal and result from obstetric trauma; an associated ureterovaginal fistula occurs in about 10 per cent of cases
- A ‘three-swab test’ is used to aid the diagnosis. An examination under anaesthesia, vaginoscopy, and cystoscopy and IVU should be performed and, if necessary, retrograde ureterography
- Conservative management is rarely successful
- The principles of repair include good exposure, excision of diseased tissue and tension-free vascularised repair in anatomic layers
- Fistulae caused by radiation, cancer and sepsis can be complex with multiple tracts
- The persistence of a fistula on the skin implies the presence of distal obstruction, chronic infection, such as tuberculosis, or a foreign body, such as a stone or non-absorbable ligature

### LOWER URINARY TRACT INFECTION AND CYSTITIS

Infection of the bladder gives rise to symptoms of frequency, urgency, suprapubic discomfort, dysuria and cloudy offensive urine. These symptoms are often known as ‘cystitis’. Lower UTIs are much more common in women than in men, particularly in the under 50s. It should be remembered that a lower UTI is often associated with upper tract colonisation and the presence of associated loin pain, pyrexia, rigors and malaise (these symptoms represent complicated infection and should be taken seriously as serious sepsis can ensue).

#### Isolated infection

A single episode of lower tract infection occurs frequently in females and is rarely complicated.

#### Recurrent infection

Recurrent infection may be associated with an underlying predisposing cause or may be a result of bacterial resistance. In healthy women, infection after intercourse can occur without any demonstrable abnormality of the urinary tract. Repeated attacks of UTI in women, or a single attack in a man or a child of either sex, should always be followed by investigation to discover and treat the cause; sometimes, however, no cause can be found. Asymptomatic bacteriuria is common and investigation may fail to demonstrate any underlying cause.

#### Infection in males

Although more common in female adults, the incidence of infection is higher in male infants as underlying urinary tract abnormalities are more frequent. Complicated or recurrent infection in adult males warrants prompt antibiotic therapy and investigation to exclude an underlying cause.

### Infection in pregnancy

The incidence of asymptomatic bacteriuria in pregnant women is twice as high as in non-pregnant women. Simple uncomplicated infection can be treated following urine culture with an appropriate antibiotic that is not contraindicated in pregnancy, such as cephalosporin or ampicillin. Non-responsive infection may require intravenous therapy and an ultrasound scan.

#### Predisposing causes of urinary tract infection

- Incomplete emptying of the bladder, secondary to bladder outflow obstruction, a bladder divverticulum, neurogenic bladder dysfunction or decompenation of the detrusor muscle.
- A calculus, foreign body or neoplasm.
- Incomplete emptying of the upper tract, dilatation of the ureters associated with pregnancy, or vesicoureteric reflux. In childhood, the mainstay of treatment of vesicoureteric reflux is antibiotic therapy; operation is reserved for those with recurrent infection despite antibiotics or with severe upper tract dilatation.
- Oestrogen deficiency, which may give rise to lowered local resistance.
- Colonisation of the perineal skin by strains of *Escherichia coli* expressing molecules that facilitate adherence to mucosa.
- Diabetes.
- Immunosuppression.

### Avenues of infection

Ascending infection from the urethra is the most common route (see Chapter 74). The organisms originate in the bowel, contaminate the vulva and reach the bladder. The passage of uraltral instruments may cause infection in either sex, especially when the bladder contains residual urine (Figure 76.39). Other routes are less common and include descending infection from the kidney (tuberculosis), haematogenous spread, lymphogenous spread and spread from adjoining structures (Fallopian tube, vagina or gut).

### Bacteriology

Bacterial virulence factors affect the ability of a pathogen to infect the host. The possession of pili (rod-shaped structures) that project from the outer membrane increases adhesiveness. The type of pilus can be used to classify the pathogen involved. *Escherichia coli* is the most common organism followed by *Proteus mirabilis, Staphylococcus epidermidis* and *Streptococcus faecalis*. Infection with other organisms or infection with mixed organisms is found in patients with neurogenic bladder dysfunction or those with a longstanding indwelling urethral catheter. These organisms include *Pseudomonas, Klebsiella, Staphylococcus aureus* and various streptococci. Tuberculous infection is considered below. The presence of pus cells without organisms calls for examination for *Mycobacterium tuberculosis* and *Neisseria gonorrhoeae*. Having eliminated these possibilities, the underlying condition may be abacterial cystitis, carcinoma in situ, renal papillary necrosis, stones or incomplete treatment of a urinary infection.
Clinical features
These include frequency, pain, haematuria and pyuria. Pyrexia and rigors are not associated with a simple UTI, but are a sign of upper tract infection or septicaemia.

Examination
On examination, there is tenderness over the bladder. Initial and midstream urine specimens should be collected in a male as acute prostatitis may be present (see below), which will lead to threads in the initial specimen. The midstream specimen must be subjected to microscopy and culture, and the sensitivity of any organisms assessed.

Treatment
Treatment should be commenced immediately and modified if necessary when the bacteriological report is to hand. The patient is urged to drink. Appropriate first-line antibiotics depend on local likely sensitivities, but would include trimethoprim or one of the quinolones. Failure to respond indicates the need for further investigation to exclude predisposing factors. It is important to check for associated allergies or other drugs or conditions that might preclude the use of some antibiotics (e.g. concomitant administration of methotrexate and trimethoprim (both inhibit tetrahydrofolate reductase)).

Investigation
Investigation may be needed in the male or when recurrent infection occurs. This includes measurement of urinary flow rates and post-void residual urine. IVU, ultrasound scan or CT scanning will usually be carried out together with cystoscopy.

Summary box 76.10

**UTI in adults**
- Isolated UTI in adults is not infrequent and is more common in women
- Recurrent or complicated infection (haematuria, rigors) warrants appropriate antimicrobial therapy and investigation
- Investigation to exclude a predisposing cause includes urinalysis, microscopy and culture, upper tract imaging and cystoscopy
- *Mycobacterium tuberculosis, Neisseria gonorrhoeae* or *Mycoplasma genitalium* should be suspected if pus cells are present but urine culture is negative
- Cancer, especially CIS, masquerading as infection may be diagnosed as abacterial cystitis

Difficult cases may require urodynamic investigation (Summary box 76.10).

**SPECIAL FORMS OF LOWER URINARY TRACT INFECTION**

**Acute abacterial cystitis (acute haemorrhagic cystitis)**
The patient presents with severe UTI. Pus is present in the urine but no organism can be cultured. It is commonly sexually acquired, but tuberculous infection and CIS must be ruled out. The underlying causative organism may be *Mycoplasma* or herpes simplex virus. Cyclophosphamide can also cause this problem.

**Frequency–dysuria syndrome (urethral syndrome)**
This consists of symptoms of lower tract infection but with negative urine cultures. CIS, tuberculosis and interstitial cystitis should be excluded. Most urologists advise patients to adopt general measures such as wearing cotton underwear, using simple soaps, adopting general perineal hygiene measures and voiding after intercourse. Other treatments include cystoscopy and urethral dilatation, although the benefits remain doubtful.

**Tuberculous urinary infection**
Tuberculous urinary infection is secondary to renal tuberculosis. Early tuberculosis of the bladder commences around the urethral orifice or trigone, the earliest evidence being pallor of the mucosa due to submucous oedema. Subsequently, tubercles may be seen and, in longstanding cases, there is marked fibrosis and the capacity of the bladder is greatly reduced (Figure 76.40).

**Treatment**
Tuberculous infection usually responds rapidly to anti-tuberculous drugs but occasionally the involved kidney and ureter have to be removed. If the bladder remains of low capacity, patients will have severe symptoms and the upper tracts are at risk because of high filling pressures and vesicoureteric reflux. Such
On cystoscopy, the characteristic ulcer is found in the fundus, but it may be absent. This area bleeds readily as the bladder is decompressed. Treatment is difficult and unsatisfactory. Hydrostatic dilatation under anaesthesia may give relief for some months. Instillation of dimethyl sulphoxide results in improvement in some patients. Other drugs that have been tried include intravesical heparin, oral ranitidine and steroid therapy. Patients with severe symptoms may well require cystectomy and orthotopic bladder substitution. In patients with severe inflammation involving the trigone and urethra, this operation may not result in complete relief and some type of urinary diversion may be needed.

**Alkaline encrusting cystitis**

Alkaline encrusting cystitis is rare and is due to urea-splitting organisms causing phosphatic encrustations on the bladder mucosa of elderly women. There are symptoms of chronic UTI and a plain x-ray shows the bladder outline. The encrustations may be removed by bladder irrigation and the infection treated with appropriate antibiotics.

**Cystitis cystica**

Under the influence of chronic inflammation, the surface epithelium sends down buds, resulting in minute cysts filled with clear fluid, most abundant on the trigone. This is frequently found in patients with recurrent frequency and dysuria.

### SCHISTOSOMIASIS OF THE BLADDER

**Geographical distribution**

The disease is endemic in Egypt, parts of Africa, Israel, Syria, Saudi Arabia, Iran, Iraq and the shores of China’s great lakes. Dwellers of the Nile valley have suffered for centuries. Marshes or slow-running fresh water provide the habitat for the freshwater snail (*Bulinus truncatus*) that is the intermediate host (see Chapter 6).

**Mode of infestation**

The disease is acquired through exposure of the skin to infected water, which usually occurs while bathing. The free-swimming, bifid-tailed embryos (cercariae) of the trematode *Schistosoma haematobium* penetrate the skin. Shedding their tails, they enter blood vessels and are swept to all parts of the body but they flourish in the liver where they live on erythrocytes and develop into male and female worms. Sexual maturity having been attained, the nematodes leave the liver and enter the portal vein. The male worm bends into the shape of a gutter (the gynaecophoric canal) into which a female worm nestles, and the pair makes its way towards the inferior mesenteric vein. *Schistosoma haematobium* has an affinity for the vesical venous plexus, which it reaches through the portosystemic anastomotic channels.

Having reached the bladder, the female worm eventually enters a submucous venule which is so small that it completely blocks it. It now proceeds to lay about 20 ova in a chain; each ovum is provided with a terminal spine that penetrates the vessel wall. A heavily infected subject passes hundreds of ova a day. If the ova reach fresh water, the low osmotic pressure causes rupture and the ciliated miracidium emerges. To survive, it must reach and penetrate the intermediate snail host within 36 hours. Within the snail’s liver, the miracidium enlarges and gives rise...
to myriads of daughter cysts, which are set free on the death of the snail. A single miracidium begets thousands of cercariae to complete the life cycle.

**Clinical features**

After penetration of the skin, urticaria lasting about 5 days can occur (swimmer’s itch). Following an incubation period of 4–12 weeks, a high evening temperature, sweating and asthma, together with leukocytosis and eosinophilia, occur. Usually, an asymptomatic period of several months supervenes before the ova are released, causing the typical early sign and symptom of intermittent, painless, terminal haematuria. Men are affected three times more frequently than women.

**Examination of the urine**

The last few millilitres of an early-morning urine specimen are collected and centrifuged. Examination on several consecutive days may be required, but a negative result does not exclude bilharziasis, especially in patients no longer resident in bilharzial districts. Antibody detection by enzyme-linked immunosorbent assay (ELISA) using *Schistosoma mansoni* adult microsomal antigen (MAMA) can be performed. The test is positive one month after infection and is specific for *Schistosoma mansoni* and *Schistosoma haematobium*.

**Cystoscopy**

Depending on the length of time for which the disease has remained untreated, cystoscopy will reveal one or more of the following:

1. **Bilharzial pseudotubercles** are the earliest specific appearance of the disease (Figure 76.41);
2. **Bilharzial nodules** (Figure 72.42) are caused by the fusion of tubercles;
3. ‘Sandy patches’ are the result of calcified dead ova with degeneration of the overlying epithelium (Figure 76.43);
4. **Ulceration** is the result of sloughing of the mucous membrane containing dead ova (Figure 76.44);
5. **Fibrosis** is mainly the result of secondary infection;
6. **Granulomas**. Bilharzial masses are caused by the aggregation of nodules;
7. **Papillomas** are more pedunculated (Figure 76.45);
8. **Carcinoma** is a common end result in grossly infected bilharzialis of the bladder that has been neglected for years.

**Treatment**

Safe and effective drugs are available for the treatment of schistosomiasis, including praziquantel taken in three doses of 20 mg/kg (total 60 mg/kg) 4 hours apart. It takes many months for dead ova to be expelled and, even after repeated courses and healing of the bladder lesion, living bilharzial worms have been found at necropsy in the portal system.

Other complications, requiring specific treatment, include the following:

- urinary calculi;
- stricture of the ureters;
- prostatoseminal vesiculitis;
- fibrosis of the bladder and bladder neck (Figure 76.46);
- bilharzial urethral strictures;
- squamous bladder cancer.

**NEOPLASMS OF THE BLADDER**

In total, 95 per cent of primary bladder tumours originate in transitional epithelium; the remainder arise from connective tissue (angiomatous, myoma, fibroma and sarcoma) or extra-adrenal phaeochromocytomas.

**Figure 76.41** Bilharzial tubercles [courtesy of N Makar].

**Figure 76.42** Bilharzial nodules [courtesy of N Makar].

**Figure 76.43** ‘Sandy patches’ [courtesy of N Makar].
Secondary tumours of the bladder are common and most frequently arise from the sigmoid and rectum, the prostate, the uterus or the ovaries, although bronchial neoplasms may also spread to the bladder.

Pathology

Benign papillary tumours

The papilloma consists of a single frond with a central vascular core with villi; it looks like a red sea anemone (Figures 76.47 and 76.48). Inverted papilloma is a condition in which the proliferative cells penetrate under normal mucosa so that the lesion is covered with smooth urothelium. It is benign.

CARCINOMA OF THE BLADDER

Histological types of bladder cancer include urothelial, squamous and adenocarcinoma (or mixed, as a result of metaplasia in a transitional cell carcinoma (TCC)). Over 90 per cent are urothelial in origin. Pure squamous carcinoma is uncommon (approximately 5 per cent), except in areas where bilharzia is endemic. Primary adenocarcinoma, which arises either from the urachal remnant or from areas of glandular metaplasia, accounts for 1–2 per cent of cases.

Urothelial cell carcinoma

Aetiology

Cigarette smoking is the main aetiological factor (40 per cent of cancers). Occupational exposure to urothelial carcinogens remains common. The first suspicion of a chemical cause for bladder cancer was raised by Rehn in 1895 when he recorded a series of tumours in workers in aniline dye factories. Hueper showed that 2-naphthylamine was carcinogenic in dogs. Subsequent investigation demonstrated that the following compounds may be carcinogenic:

- 2-naphthylamine;
- 4-aminobiphenyl;
- benzidine;
- chloranaphazine;
- 4-chloro-o-toluidine;
- o-toluidine;
- 4,4'-methylene bis(2-chloroaniline);
- methylene dianiline;
- benzidine-derived azo dyes.

Occupations associated with an increased risk of bladder cancer are:

- textile workers;
- dye workers;
- tyre rubber and cable workers;
- petrol workers;
- leather workers;
- shoe manufacturers and cleaners;
- painters;
- hairdressers;
- lorry drivers;
- drill press operators;
- chemical workers;
- rodent exterminators and sewage workers.

Figure 76.45 Bilharzial papilloma [courtesy of N Makar].

Figure 76.46 Bilharzial contracture of the bladder, with ureteric reflux [courtesy of H Talib, Baghdad, Iraq].
Bladder cancer became a prescribed industrial disease (No. 39) in 1953, and previously exposed workers may be entitled to compensation. Balkan nephropathy is associated with an increased incidence of upper tract urothelial tumours (see Chapter 75).

A series of genetic events has been clearly implicated in cancer formation but is outside the remit of this chapter. Activation of dominantly acting oncogenes such as ras and c-erbB-1 and -2, and transcription factors such as E2F3, have been reported in bladder cancer, as has the inactivation of tumour-suppressor genes such as p53, p21, p16 and the retinoblastoma gene. Activation of many other genes occurs including those coding for enzymes that dissolve the basement membrane, such as the metalloproteinases (stromelysin, collagenases and elastase), lysosomal enzymes such as the cathepsins and others including urinary plasminogen activators; angiogenic factors (e.g. vascular endothelial growth factor (VEGF)) and other peptide growth factors such as the epidermal growth factor and its receptor (EGFR) also have a role to play, as well as the fibroblast growth factor and its receptor-3 (FGFR-3) which was found to be altered mostly in non-muscle invasive disease. These changes are common to several tumour types, including prostate cancer (Summary box 76.11). More recently, new approaches through genome-wide association studies allowed the investigation of genetic susceptibility for urothelial cancer. Several new loci were identified, but to date, only two, NAT2 (N-acetyltransferase 2) and GSTM1 (glutathione S-transferase Mu 1) have been demonstrated to be consistent germline susceptibility markers. These genetic markers do not yet have sufficient discriminatory ability to be used for clinical decision making.

**Tumour staging and grading**

Study of the biological behaviour of transitional cell cancer of the bladder shows that cancers fall into the three following groups. Depth of invasion (T) from the tumour–node–metastasis (TNM) classification and grade (World Health Organization I, II or III) are important factors in planning treatment and determining prognosis in bladder cancer.

- Non-muscle-invasive pTa (Figure 76.48) and pT1 tumours account for 70 per cent of all new cases; the previous terminology of ‘superficial’ bladder cancer in this category has now been abandoned; it is important to distinguish however ‘low-risk’ urothelial cancers which are unlikely to progress, such as well differentiated (G1) pTa tumours (not invading lamina propria), from ‘high-risk’ cancers such as poorly differentiated (G3) pT1 cancers (invading lamina propria), which should be followed up carefully and treated aggressively as necessary. This can be determined by careful histological examination. Single papillary pTa tumours account for a significant proportion of bladder cancers and carry an excellent prognosis.

- Muscle-invasive disease (pT2) accounts for 25 per cent of new cases. Such tumours carry a much worse prognosis as they are subject to local invasion and distant metastasis.

- Flat, non-invasive CIS (primary CIS) accounts for 5 per cent of new cases. Unless diagnosed and treated promptly, it carries a poor prognosis (Summary box 76.12). The highest risk non-muscle invasive cancer is found with multifocal poorly differentiated tumours invading lamina propria (pT1G3) in the presence of CIS.
Non-muscle invasive bladder cancer

These are usually papillary tumours that grow in an exophytic fashion into the bladder lumen (Figures 76.47 and 76.48). They may be single or multiple and may appear pedunculated, arising on a stalk with a narrow base, but if the tumours are less well differentiated they are more solid with a wider base. The mucosa around the tumour is often rather oedematous, with angio-matous and velvety; this suggests a generalised 'field change' with the presence of widespread CIS. The most common sites for superficial tumours are the trigone and lateral walls of the bladder.

After initial complete treatment by endoscopic transurethral resection (TURT), patients with pTa or pT1 disease may develop two problems:

1. About 50–70 per cent develop recurrent tumours that may be single or multiple, and the recurrences may occur on one or on many occasions. The recurrent tumours are usually of the same stage or grade as the primary tumour. High-grade, multiple tumours with concomitant CIS are most likely to develop recurrent disease.

2. About 15 per cent will develop a recurrent tumour that invades the bladder muscle. The risk of such progression increases with high-grade disease, pT1 disease, multiple primary disease and concomitant CIS. Many urologists now regard the presence of pT1 grade 3 tumours as an indication for offering the patient immediate cystectomy because of the excellent outcome.

This behaviour provides the rationale for performing check cystoscopies. The factors that result in an increased recurrence and progression rate are:

- high grade;
- pT1 disease;
- concomitant CIS;
- multiple primary tumours;
- recurrent disease at the first check cystoscopy three months after diagnosis.

Patients presenting with a solitary grade 1 or grade 2 pTa tumour without concomitant CIS, which does not recur within the first six months, have an excellent outcome. Patients with recurrent low-grade disease can be treated with intravesical instillations of a chemotherapeutic agent such as mitomycin-C or epirubicin with regular cystoscopic checkups and repeat biopsies, or immunotherapy using regular intravesical instillations of Bacille Calmette–Guérin (BCG), an attenuated form of the anti-tuberculosis vaccine. Patients with high-grade pTa or pT1 disease are at high risk and should be counselled very carefully.

The options include immediate cystectomy or a more conservative approach with a course of BCG followed by careful cystoscopic assessment and maintenance instillations. assessment. The presence of persistent disease after BCG therapy is reason to offer cystectomy (Summary box 76.13).

Muscle-invasive bladder cancer

Muscle-invasive tumours are nearly always solid (Figure 76.49), although there may be a low tufted surface. These tumours are often large and broad based, having an irregular, ulcerated, appearance within the bladder. The incidence of metastases, whether from lymphatic invasion in the pelvis or blood-borne to the lung, liver or bones, is much more common and will cause the death of 30–50 per cent of patients (Summary box 76.14).

Summary box 76.12

Bladder cancer staging

- Cystoscopy and resection of tumour with separate resection of the tumour base is essential for accurate analysis of invasion into detrusor muscle
- Bimanual examination should be performed after resection of the tumour
- Complete urinary tract imaging is required using contrast CT urography, MR or intravenous urography where other techniques are not available. Cross-sectional imaging by CT or MR is essential in high-risk and muscle invasive disease to stage the tumor further including lymph node status for metastasis.

Summary box 76.13

Non-muscle-invasive bladder cancer (NMIBC)

- Does not invade the detrusor muscle but can extend to the lamina propria
- Extension to the lamina propria (pT1) is a significant risk factor for progression to invasive disease, especially if associated with high-grade disease and CIS
- The incidence of recurrence of this disease can be reduced by intravesical chemotherapy and immunotherapy
- High-risk superficial disease (any grade 3 disease) is best managed by BCG immunotherapy followed by radical treatment if disease persists

Summary box 76.14

Muscle-invasive bladder cancer

- Muscle-invasive bladder cancer should be staged by an accurate bimanual examination performed under anaesthesia before and after resection of the tumour
- Complete urinary tract assessment should be performed, including CT, MR or IV urography, as well as cross-sectional imaging identify lymph node involvement and distant spread
- Radical primary treatment options include radical cystectomy, urinary diversion and thorough lymph node dissection which tends to be offered as first line, or radical external beam radiotherapy
- Neoadjuvant chemotherapy improves survival rates as well as adjuvant chemotherapy in some cases particularly in the presence of nodal and distant disease
- Locally advanced disease may be downsized by radiotherapy or chemotherapy to enable salvage cystectomy
**In situ carcinoma**

The histological appearance of irregularly arranged cells with large nuclei and a high mitotic index replacing the normally well-ordered urothelium is known as CIS. It may occur alone (primary CIS) or in association with a new tumour (concomitant CIS) or it may occur later in a patient who has previously had a tumour (secondary CIS). It can only be diagnosed when a biopsy is examined under the microscope. It may cause severe symptoms of dysuria, suprapubic pain and frequency (hence its old name of malignant cystitis). It carries a risk for the patient of developing a malignant muscle-invasive cancer. Without treatment, 50 per cent will die of invasive bladder cancer. It can be treated initially with intravesical BCG, but failure of response is an indication for cystectomy. CIS cannot be treated with external beam radiotherapy.

**Pure squamous cell carcinoma of the bladder**

Squamous cell tumours tend to be solid and are nearly always associated with muscle invasion. This is the most prevalent form of bladder cancer in areas where bilharzia is endemic. Squamous cell tumours may be associated with chronic irritation caused by stone disease in the bladder as a result of metaplasia.

**Pure adenocarcinoma**

Adenocarcinoma accounts for approximately 1–2 per cent of all bladder cancers. It usually arises in the fundus of the bladder at the site of the urachal remnant. Occasionally, primary adenocarcinomas arise at other sites and probably originate from areas of glandular metaplasia. Such tumours need to be distinguished from secondary cancer, and can be treated with partial cystectomy.

**CLINICAL FEATURES OF BLADDER CARCINOMA**

Painless gross haematuria is the most common symptom and is indicative of a bladder carcinoma until proven otherwise. Often, however, the patient fails to declare the symptom to their GP. The bleeding may give rise to clot formation and clot urinary retention.

Constant pain in the pelvis usually heralds extravesical spread. There is often frequency and discomfort associated with urination. Pain in the loin or pyelonephritis may indicate ureteric obstruction and hydronephrosis. A late manifestation is nerve involvement causing pain that is referred to the suprapubic region, groins, perineum, anus and into the thighs.

It is also important to assess the patient as a whole. Many are elderly men who have been lifelong smokers and who suffer from chronic obstructive airway disease or cardiovascular disease. Their suitability for major surgery must be borne in mind.

**INVESTIGATION OF BLADDER CARCINOMA**

**Urine**

Urine should be cultured and examined cytologically for malignant cells. This is not a good screening test but a positive result is highly specific, and it is mostly helpful with high grade disease and CIS. New tests are being developed based on the presence of antigens such as nuclear matrix proteins (NMP22) or mini-chromosome maintenance (MCM) proteins, which may be able to detect new or recurrent tumours; and epigenetic events such as methylated panels of markers or microRNA fragments. These tests continue to be under evaluation and are not used routinely.

**Blood**

Estimation of haemoglobin and the level of serum electrolytes and urea should be carried out.

**CT, magnetic resonance, IVU or ultrasound scanning**

This should be performed on all patients with painless haematuria. Occasionally, the preliminary film shows a faint shadow of an encrusted neoplasm of the bladder. The most common radiological sign is a filling defect (Figure 76.50). Occasionally, irregularity of the bladder wall may herald the presence of an invasive tumour. Hydronephrosis may occur if a superficial tumour grows up the intramural ureter or if direct invasion of the ureteric wall occurs. Ultrasound scanning should be carried out if the kidney is non-functioning to determine its presence and the possibility of an obstructed system.

**Cross-sectional imaging**

Non-contrast CT or magnetic resonance (MR) imaging is being used in some centres instead of IVU or ultrasound scanning for the immediate management of patients with gross painless haematuria. For staging when a muscle-invasive bladder cancer is suspected, contrast-enhanced CT is used, ideally before TURBT. False-positive pT3 disease can be diagnosed if cross-sectional imaging is carried out soon after TURBT. Magnetic resonance imaging is being used more frequently (Figure 76.51) and can demonstrate lymph node metastasis or muscle invasion.

**Cystourethroscopy**

Cystourethroscopy is the mainstay of diagnosis and should always be performed on patients with haematuria. It can be carried out with a rigid instrument under general anaesthesia or with a flexible instrument under local anaesthesia. The urethra...
is inspected at the initial insertion of the instrument (urethroscope) and the bladder is then examined in a systematic fashion (cystoscopy). Conventional ‘white’ light cystoscopy has been improved recently by the introduction of photodynamic ‘blue’ light cystoscopy which relies on the photosensitiser hexamino-levulinate. It is now recommended in patients with high suspicion of the disease and negative initial findings and in follow up of patients with CIS.

**Bimanual examination**

A bimanual examination with the patient fully relaxed under general anaesthesia should be performed both before and after endoscopic surgical treatment of these tumours. The bladder should be empty. Once there is muscle invasion, the differentiation between pT2 and pT3 disease depends on whether a mass is palpable bimanually at the end of the procedure (pT3). When invasion has spread into the prostate in a man or the vagina in a woman, it is classified as pT4a. If the tumour is fixed to the lateral pelvic side wall, it is staged as pT4b.

**TREATMENT FOR CARCINOMA OF THE BLADDER**

**Non-muscle invasive tumours**

**Endoscopic surgery**

The tumour should be carefully resected in layers using a resectoscope. The base of the tumour is sent separately for histological examination. Small pinch biopsies are taken near to and distant from the primary lesion when CIS is suspected (inflamed or velvety appearance). After removal of the tumour, two or three further loops of tissue from the base should be sent separately so that the pathologist can accurately determine whether there is lamina propria or muscle invasion. The base of the tumour is then coagulated, so achieving haemostasis. The appearance of pale-yellow glistening fat will indicate a perforation of the bladder. Should this occur before the resection is complete, it may be prudent to stop the resection and leave a catheter in the bladder for a few days. In this instance, the procedure could be completed some 2 weeks later. The bimanual examination is repeated at the end of the endoscopic procedure. Following these procedures, an irrigating catheter is left in situ for 48 hours to prevent clot retention of urine. There is good evidence that a single dose of mitomycin (mitomycin C; 40 mg in 60 mL of fluid) instilled into the bladder before catheter removal decreases the risks of recurrence in patients with pTa and pT1 grade 1 and 2 disease.

Patients with larger solid tumours should have adequate material resected for histological staging and grading. If possible and straightforward, the mass of the tumour should be resected as completely as possible — even when pT2 or pT3 disease is suspected.

**Follow up**

Most urologists agree that patients with a single low- or medium-grade pTa tumour can safely be treated by resection alone plus a single instillation of mitomycin, followed up with regular cystoscopies.

The treatment of patients with multiple low- or medium-grade pTa tumours can be by either resection alone or resection followed by a 6-week course of intravesical chemotherapy with mitomycin, doxorubicin or epirubicin.

The treatment of pT1 disease is difficult. Approximately 30 per cent of tumours are understaged at first resection. For this reason, a repeat cystoscopy and resection of the tumour base is advocated within 6 weeks. Some urologists would offer immediate cystectomy to a patient with a high-grade pT1 tumour, particularly if it were multiple or accompanied by CIS, because of the 30–50 per cent risk of progression to muscle invasion. Others will treat such patients by endoscopy followed by immunotherapy with intravesical BCG. The most effective treatment of solitary medium-grade pT1 disease remains uncertain, but a reasonable approach would be endoscopic resection followed by resection of the area after 6 weeks, followed by intravesical BCG.

Follow-up cystoscopies are essential; they may be carried out under local anaesthesia with a flexible cystoscope or under general anaesthesia if the urologist feels that the patient is at high risk of recurrence. They should be performed at three-monthly intervals over the first year; following this the time interval between cystoscopies can be determined according to the presence or absence of further disease. In total, 30 per cent of patients will never develop another tumour so that, if the bladder has remained clear after two years, annual inspection...
Treatment for carcinoma of the bladder

1335

may be adequate. For patients who go on to develop multiple recurrences within the bladder at each examination, the cystoscopies need to be maintained at frequent intervals so that the growths can be resected. These patients are at a greater risk of their disease progressing; although intravesical chemotherapy can decrease the recurrence rate, no reduction in progression rates has been found.

Open surgical excision

This should be totally avoided. If by some error a bladder containing a tumour is entered, then the tumour may be removed with a diathermy needle and the base coagulated and the bladder closed. Postoperative radiotherapy to the wound will diminish the chance of tumour implantation.

Muscle-invasive tumours

The treatment of cancer with proven muscle invasion remains a subject for debate. Whatever the modality of treatment employed, few centres have five-year survival figures of more than 50 per cent. There is a move towards primary surgical treatment in most centres. The use of systemic chemotherapy with a combination of agents – cisplatin, methotrexate, doxorubicin and vinblastine (M-VAC) or cisplatin plus gemcitabine given before (neoadjuvant) radical cystectomy – has been shown to be of benefit. The current evidence is that neoadjuvant chemotherapy improves survival by about 5–7 per cent.

Radiotherapy

External beam radiotherapy is usually given at 60 Gy over a 4- to 6-week period. There is a complete response rate of 40–50 per cent. Unfortunately, some patients do not respond and others exhibit only a partial response, with pTa or pT1 tumour remaining in the bladder giving rise to a risk of recurrence. Patients with residual disease after radiotherapy should be offered ‘salvage cystectomy’ if they are fit. Proponents of radiotherapy claim that it avoids the need to remove the bladder in some patients and allows men to retain potency. Radiotherapy is not without complications, and during the course of treatment will cause urinary frequency and also diarrhoea. Late complications can leave the bladder contracted and fibrosed, in which case it may need to be removed for palliative reasons. Late complications affecting the rectum should be uncommon, especially if lateral fields of irradiation are employed.

Surgery

Partial cystectomy

This should be limited to the treatment of small adenocarcinomas of the bladder.

Radical cystectomy and pelvic lymphadenectomy

This is now standard treatment for localised pT2–pT3 disease without evidence of secondary spread or of CIS that has not responded to BCG. Before contemplating radical surgery to remove the bladder, it is important to have evidence that surgical cure is attainable. Cross-sectional imaging of the pelvis may locally overstage the bladder if a recent resection has been carried out, although the finding of grossly enlarged pelvic, iliac or para-aortic nodes or liver metastases will alter the decision for cystectomy. A bone scan (using technetium-99m (99mTc)) will help to show whether there is spread to bone, and a chest plain x-ray should be performed to exclude pulmonary metastases, although many centres now perform routine CT imaging of the chest preoperatively and it tends to be more sensitive than plain x-ray in detecting small lung lesions.

Operation

Alternative drainage for urine is necessary following removal of the bladder. The standard procedure is to perform an ileal conduit diversion. Male patients should be counselled about the onset of erectile impotence and absent ejaculation following the operation, although in some cases the nerve supply for erectile function can be preserved through careful dissection; they should also be told about alternative forms of urinary diversion, which include continent urinary diversions and orthotopic bladder replacement.

Patients should be seen by a stoma care therapist, who will help to advise the patient and will try different ileostomy bags to ensure that the correct site is chosen, avoiding skin creases so that one does not end up with the disaster of a leaking urinary

Figure 76.51 (a) Cross-sectional magnetic resonance imaging showing a ‘cystogram’ and a bladder cancer. (b) Cross-sectional magnetic resonance imaging showing invasive bladder cancer.
ileostomy. A decision is made about whether the male urethra is to be removed (depending on the estimated risk of recurrence within the urethra); a urethrectomy is usually indicated in patients with primary CIS or those with tumour invading the prostate stroma. Many surgeons are now offering total replacement of the bladder after cystectomy.

The patient should receive prophylactic antibiotics including metronidazole, cefuroxime and amoxicillin, and low-dose heparin or equivalent thrombo-embolic prophylaxis including physical means such as stockings and inflatable devices applied to the legs peroperatively to promote venous circulation.

The abdomen is opened through a midline incision extending down to the symphysis pubis. The liver and the retroperitoneum are checked for evidence of metastases, and the operability of the bladder is assessed. A bilateral pelvic lymphadenectomy is performed, removing external iliac nodes, internal iliac nodes and the nodes in the obturator fossae. Some surgeons will remove lymph nodes up to the aortic bifurcation or higher with some evidence of improved long-term oncological outcomes. The vessels passing to the bladder from the side wall of the pelvis are ligated and divided; these include the obliterated hypogastric vessels, the superior vesical artery, the middle vesical veins, and the inferior vesical arteries and veins. The ureters are then divided. The posterior ligaments extending from the pararectal area to the back of the bladder are ligated and divided, and the layer posterior to Denonvilliers’s fascia is opened up. The endopelvic fascia is then divided on each side and the puboprostatic ligaments are divided. A ligaure is passed between the dorsal vein complex and the urethra, and the former is ligated and divided. The urethra is then mobilised and divided. The ligaments lateral to the prostate are divided and the bladder is removed. In women, the uterus and anterior vaginal wall need to be included. Women must be counselled about the loss of ovarian and uterine function.

An isolated loop of ileum is then prepared on its own mesentery, and continuity of the small bowel restored. The ureters are then implanted into the bowel segment and the ileostomy is created. Metoculnic care must be taken to close all mesenteric windows, thus avoiding internal hernias. If the bladder is to be replaced orthotopically, a reservoir made from detubularised bowel (usually a segment of well vascularised ileum) is created and anastomosed to the ileostomy after implantation of the ureters.

The operative mortality rate associated with cystectomy used to be considerable but is now <2 per cent. Late complications include urethral recurrence (about 5–8 per cent), which is increased in the presence of multifocal tumours, CIS and, particularly, invasion of prostatic stroma (Figure 76.52).

Leukoplakia

This condition is simply squamous metaplasia of the bladder. Profuse production of keratin may result in the passing of white particles in the urine. It cannot be treated easily. Localised areas may be resected endoscopically. Diffuse leukoplakia of the bladder is pre-malignant and results in squamous cancer of the bladder. Careful cystoscopic assessment is required and the condition may require cystectomy.

Endometriosis

Endometriosis within the bladder wall is rare but can have the appearance of a vascular bladder tumour or a tumour that contains chocolate-coloured or bluish cysts. The swelling enlarges and bleeds during menstruation. If medical management fails, by means of danazol or luteinising hormone-releasing hormone (LHRH) agonists, further treatment is usually by means of partial cystectomy or full-thickness endoscopic resection, depending on its site. The condition may be part of more widespread disease. Endometriosis is also a cause of ureteric stricture.

**INTERNAL AND EXTERNAL URINARY DIVERSION**

**Indications**

Diversion of the urine may be either a temporary expedient to relieve distal obstruction or a permanent procedure when the bladder has been removed or has lost normal neurological control and in cases of incurable fistula or irremovable obstruction.

**Methods of urinary diversion**

Temporary methods use prosthetic materials, the most common being a urinary catheter. In elderly patients unfit for prostatectomy, and in some patients with terminal carcinoma of the prostate, an indwelling silicone urethral Foley catheter changed every three months is a satisfactory method of drainage. A suprapubic placement is an alternative to urethral placement. The major drawback of long-term catheterisation is infection secondary to the associated bacteriuria that invariably develops. Ureteric obstruction can be relieved by placement of internal ‘double-J’ pigtail ureteric stents, which can remain for 4–5 months, but are usually changed every three months. As an alternative, a nephrostomy tube, inserted percutaneously by ultrasound and fluoroscopic imaging, is effective when internal stent placement is not feasible.

**Permanent urinary diversion**

**External diversion**

**Ileal conduit**

Permanent urinary tract diversion is most commonly performed by conduit diversion. The ureters are implanted into a short, isolated segment of ileum (Figure 76.53a) or, less commonly, colon. The conduit diverts the urine onwards to a cutaneous stoma for collection in an ileostomy bag. This form of diversion is well established and associated with a low complication rate of less than 10 per cent. The main complication is ureteroileal stricture, which can be limited by spatulation of the distal ureters and an end-to-end anastomosis as described by Wallace (Figure 76.53a). Stenosis at the ileocutaneous site is
less frequent, and a short isoperistaltic conduit limits the formation of a residual urine volume, reducing infection and avoiding the problems of reabsorption of urine. In some cases, when the pelvic area has been subjected to radiation, the lower ureters may be unhealthy; a high division with insertion of the ureters into an ileal loop above the root of the mesentery may then be wiser (Figure 76.54).

The site for the stoma must be chosen before operation, in consultation with a stoma care therapist; the site is marked indelibly on the skin.

**Operative details**
A coil of ileum, approximately 15–20 cm long and 30 cm from the ileocaecal valve, with its blood supply intact, is isolated. The left ureter is brought behind the mesorectum. The ureters may be joined to the ileum either end-to-side or end-to-end after anastomosing of the distal spatulated ureters to form a plate (Wallace). The distal end of the coil is brought out through an incision made at the site identified before operation; a disc of skin and fat is removed, a cruciate incision is made in the fascia and the muscle is split. The stoma is made about 2–3 cm long. It is evaginated initially by means of four sutures passing through the skin, the ileal loop as it passes through the opening and the cut edge of the ileum.

**Internal urinary diversion**

**Colon and rectum**
The advantage of diverting urine into the colon is that no collecting apparatus is necessary. Clearly, however, the anal sphincter must be competent. Before ureterosigmoidostomy is undertaken, the patient must prove that he or she can control at least 200 mL of fluid in the rectum. The disadvantage of the operation is that the renal tract is exposed continuously to infection from the faeces; this can be minimised by constructing an anti-reflux procedure. Various diversions are described; the Mainz II ureterosigmoidostomy creates a cul-de-sac type low-pressure reservoir in the sigmoid into which the ureters are placed (see Figure 76.53b). This reduces reflux, and bowel content, although in contact with urine, takes a direct route to the rectum. In the long term, cancer can develop at long-standing ureterocolic junctions (Figure 76.55).

**Bladder reconstruction**
Over the past decade, several techniques have been developed to allow a near-spherical urinary reservoir to be formed out of various lengths of bowel that are detubularised. These may consist of ileum, ileum and caecum or sigmoid colon (see Figure 76.53c). The ureters can then be reimplanted in these reservoirs in an anti-reflux manner and the reservoir anastomosed to the membranous urethra in the male (see Figures 76.20, 76.21 and 76.22). This is only indicated when the urethra can be preserved, with no evidence of tumour at the junction between the urethra and the prostate in the male, and bladder neck in the female. About 15–30 per cent of patients cannot empty the neobladder completely and will need to perform intermittent self-catheterisation. The results are good after radical cystectomy, particularly in younger well motivated patients.

** Continent urinary diversion**
A similar concept is used in the construction of continent diversions. A urinary reservoir is made as described above and the

---

**Figure 76.53** Diversion of urine. Favoured methods: (a) ileal conduit; the ureters are spatulated and anastomosed to ileum end-to-side (insert); (b) ureterosigmoidostomy; (c) ileal neobladder with anti-reflux long afferent limb.

**Figure 76.54** Ureteroileostomy (after DM Wallace, FRCS).
ureters are attached to the reservoir. A continence mechanism is then made to connect the reservoir to the skin. This is the complication-prone part of the operation. The continence mechanism may be made of an invaginated loop of ileum supported by three rows of staples (Kock pouch) or from the appendix, buried in an anti-reflux manner in a submucosal tube (Mitrofanoff; Figure 76.56). Alternatively, a length of ileum can be made into a tube (of a similar size to the appendix) after excision of the antimesenteric ileum and buried in a submucosal tunnel in an antireflux way. Clearly, these operations are complex, with the potential for increased postoperative complications.

**Bladder substitution and augmentation**

In patients with contraction of the bladder because of tuberculosis or with neuropathic dysfunction and a small bladder capacity, the bladder may need to be augmented. Similar techniques to those used to perform a bladder replacement can be utilised to make a near-spherical pouch from detubularised bowel, which can then be attached to the trigone or bladder neck after near-total cystectomy (see Figures 76.20, 76.21 and 76.22). The ureters are then reimplemented. The facility to provide a continence mechanism must be available if needed in the neuropathic patient. This may comprise an artificial urinary sphincter or a colposuspension in the female.

**Complications of internal diversion**

**Stricture**

Ureterosigmoidostomy was first used by Chaput in 1894. Subsequent modifications included those made by Coffey and Grey Turner. In these methods, the ureters were cut obliquely and pulled into the gut by a stitch – the ends were not stitched to the gut wall – and stenosis was common. Nesbit, Cordonnier and Leadbetter all recognised that these strictures could be prevented by anastomosing mucosa to mucosa.

**Reflux of urine**

High-pressure activity within a segment of gut can cause reflux of potentially infected urine at high pressure to the kidneys. In the long term, this can cause renal impairment. The principle of a low-pressure reservoir for both neobladder and ureterosigmoidostomy (Mainz II) reduces this. In addition, an anti-reflux mechanism, used in neobladder construction, is created by anastomosing the ureters to a non-detubularised 20-cm segment of small bowel, which is in continuity with the neobladder (see Figure 76.53c).

**Metabolic consequences of internal diversion**

**Resorption of solutes**

This depends upon the following factors: (1) the area of bowel that is exposed to urine; and (2) the length of time that the urine is in contact with the bowel epithelium.

The biochemical changes associated with urinary diversion are due to a combination of reabsorption of chloride and urea and progressively diminishing tubular function as a result of pyelonephritis. Diarrhoea with loss of potassium-containing mucus may exacerbate the loss of potassium. The typical changes of a hyperchloraemic acidosis with potassium depletion occur more frequently with ureterosigmoid diversion than with a colonic and ileal neobladder. When severe, the patient develops loss of appetite, weakness, thirst and diarrhoea. Coma may ensue. Mild acidosis, unrecognised over a long period, produces osteomalacia. Bone pain and even pathological fracture can occur. Renal impairment from pyelonephritis and reabsorption from the mucosa are seen less frequently after ileal or colonic conduit formation, continent urinary diversion or orthotopic bladder substitution. In fact, they are seen very infrequently except in patients with pre-existing renal impairment and unsatisfactory emptying of the urinary reservoir. Malabsorption can occur with the loss of terminal ileum and small bowel. The loss of terminal ileum can result in vitamin B12 deficiency and so monitoring of vitamin B12 and folate is recommended after the first year.

**Treatment**

Patients should be instructed to empty the rectum or conti-
nent reservoir or neobladder 3-hourly by day. In patients who have undergone ureterosigmoidostomy and in whom acidosis is present, a rectal tube should be inserted at night to drain the urine continuously. The patient should take a mixture of potassium citrate and sodium bicarbonate three times a day (2 g of each, either as crystals or as tablets). Regular serum biochemical analyses, including calcium, are required.

Established hyperchloraemic acidosis is usually associated with marked dehydration and the mainstay of treatment is administration of intravenous saline. The patient may be given small doses of sodium bicarbonate to half-correct the pH deficit if it is severe and additional intravenous potassium. This should be coupled with appropriate systemic antibiotic treatment.

**Risk of malignancy**

There is a risk of cancer developing in bowel used to reconstruct the urinary tract. When the urine is not mixed with faeces, the incidence is small, becoming significant after 15–18 years. The major risk of malignancy was discovered when ureterosigmoidostomy construction enabled free mixing of urine and faeces. The development of sigmoid reservoirs into which the ureters are inserted has reduced this risk.

The prostate and seminal vesicles

---

**LEARNING OBJECTIVES**

To understand:
- The relationship of anatomical structure and biochemical function to the development and treatment of benign and malignant disease of the prostate
- The terminology used to describe lower urinary tract symptoms and to know their causes as well as the treatment options available
- Which investigations are appropriate for carcinoma of the prostate
- Clinical staging of carcinoma of the prostate and how staging contributes to the complex decision-making process for the best treatment option

---

**EMBRYOLOGY**

From the primitive urethra, a series of solid epithelial buds develop and become canalised in a matter of weeks. The surrounding mesenchyme forms the muscular and connective tissue of the gland and has a major role in differentiation (stromal epithelium interactions). Skene's tubules, which open on either side of the female urethra, are the homologue of the prostate.

---

**SURGICAL ANATOMY**

The contemporary classification of the prostate into different zones was based on the work of McNeal (Figure 77.1). He showed that it is divided into the peripheral zone (PZ), which lies mainly posteriorly and from which most carcinomas arise, and a central zone (CZ), which lies posterior to the urethral lumen and above the ejaculatory ducts as they pass through the prostate; the two zones are rather like an egg in an egg-cup. There is also a periurethral transitional zone (TZ), from which most benign prostatic hyperplasia (BPH) arises. Smooth muscle cells are found throughout the prostate but, in the upper part of the prostate and bladder neck, there is a separate sphincter muscle that subserves a sexual function, closing during ejaculation. Resection of this tissue during prostatectomy is responsible for retrograde ejaculation. There are also a periurethral transitional zone (TZ), from which most benign prostatic hyperplasia (BPH) arises. Smooth muscle cells are found throughout the prostate but, in the upper part of the prostate and bladder neck, there is a separate sphincter muscle that subserves a sexual function, closing during ejaculation. Resection of this tissue during prostatectomy is responsible for retrograde ejaculation. The distal striated urethral sphincter muscle is found at the junction of the prostate and the membranous urethra; it is horseshoe shaped with the bulk lying anteriorly and is quite distinct from the muscle of the pelvic floor (Figure 77.1).

The glands of the peripheral zone (Figure 77.2), lined by columnar epithelium, lie in the fibromuscular stroma, and their ducts, which are long and branched, open into posterolateral grooves on either side of the verumontanum. The glands of the CZ and TZ are shorter and unbranched. All these ducts, the common ejaculatory ducts and the prostatic utricle open into the prostatic urethra.

Benign prostate hypertrophy starts in the periurethral transitional zone and, as it increases in size, it compresses the outer PZ of the prostate, which becomes the false capsule. There is also the outer true fibrous anatomical capsule, and external to this lie condensations of endopelvic fascia known as the periprostatic sheath of endopelvic fascia. Between the anatomical capsule and the prostatic sheath lies the abundant prostatic venous plexus. The prostatic sheath is contiguous with the fascia of Denonvilliers, which separates the prostate and its coverings from the rectum. The neurovascular bundles supplying autonomic innervation to the corpora of the penis are in very close

levels. Thus, pharmacological levels of oestrogens cause atrophy by acting on the hypothalamus, decrease the secretion of LHRH, hence increase the risk of receptor desensitisation and forms the basis for androgen deprivation therapy in prostate cancer. Testosterone is converted to DHT by the enzyme 5α-reductase, which is found in high concentration in the prostate and the perigenital skin. DHT has five times the potency of testosterone.

**PHYSIOLOGY**

The prostate has a sexual function, but it is unclear how important its secretions are to human fertility. That the normal adult prostate undergoes atrophy after castration was known to John Hunter.

**Systemic hormonal influences (endocrine) and local growth factors (paracrine and autocrine)**

The growth of the prostate is governed by many local and systemic hormones whose exact functions are not yet known. The main hormone acting on the prostate is testosterone, which is secreted by the Leydig cells of the testes under the control of luteinising hormone (LH), itself secreted from the anterior pituitary under the control of hypothalamic luteinising hormone-releasing hormone (LH-RH). LH-RH has a short half-life and is released in a pulsatile manner. This pulsatile release is important, as receptors for LH-RH will become desensitised if permanently occupied. The administration of LH-RH analogues in a continuous, non-pulsatile manner exploits the concept of receptor desensitisation and forms the basis for androgen deprivation therapy in prostate cancer. Testosterone is converted to 1,5-dihydrotestosterone (DHT) by the enzyme 5α-reductase, which is found in high concentration in the prostate and the perigenital skin (type II). Other androgens are secreted by the adrenal cortex, but their effects are minimal in the normal male. Oestrogenic steroids are also secreted by the adrenal cortex and, in the ageing male, may play a part in disrupting the delicate balance between DHT and local peptide growth factors, and hence increase the risk of BPH. Increased levels of serum oestrogens, by acting on the hypothalamus, decrease the secretion of LH-RH (and hence LH) and thereby decrease serum testosterone levels. Thus, pharmacological levels of oestrogens cause atrophy of the testes and prostate by means of reductions in testosterone.

Other locally acting peptides are secreted by the prostatic epithelium and mesenchymal stromal cells in response to steroid hormones. These include epidermal growth factor, insulin-like growth factors, basic fibroblast growth factor and transforming growth factors alpha and beta. These undoubtedly play a part in normal and abnormal prostatic growth, but as yet their functions are unclear (Summary box 77.1).

**Summary box 77.1**

**Androgenic hormones**

- Androgenic hormones, which drive prostate growth, are derived from several sources
- The majority of testosterone (90 per cent) is secreted by the Leydig cells of the testes under the control of LH, secreted from the anterior pituitary
- Metabolised adrenal androgen accounts for the remaining 5–10 per cent of testosterone
- Testosterone is converted to DHT by the enzyme 5α-reductase type II, which is found in high concentration in the prostate and the perigenital skin
- DHT has five times the potency of testosterone

**Elaboration and secretion of prostate-specific antigen and acid phosphatases**

Prostate-specific antigen (PSA) is a glycoprotein that is a serine protease. Its function may be to facilitate liquefaction of semen, but it is a marker for prostatic disease. It is measured by an immunoassay, and the normal range can differ a little from laboratory to laboratory. There is no real normal upper limit. The levels increase with age, with prostate cancer and with BPH. There are age-related values but, in general, in men aged 50–69 years, a level of about 3–4 ng/mL would prompt a discussion about the need for prostate biopsy. Its level in men with metastatic prostate cancer is usually increased to >30 ng/mL and falls to low levels after successful androgen ablation. Men with locally confined prostate cancer usually have serum PSA levels <10–15 ng/mL. Although PSA is a reliable marker for the progression of advanced disease, it is neither specific nor sensitive in the differential diagnosis of early prostate cancer and BPH, as both diseases are compatible with PSA in the range of 3–15 ng/mL. PSA measurement has superseded measurement of serum acid phosphatase. In summary, about 25 per cent of men with a PSA of 4–10 ng/mL have prostate cancer (i.e. it is not very specific), and about 15–20 per cent of men with a PSA of 1–4 ng/mL have prostate cancer. In general, one would advise men aged 50–69 years to undergo prostate biopsy if the PSA was more than ~3 ng/mL. The threshold would be lower in younger men with a strong family history.

**BENIGN PROSTATIC HYPERPLASIA**

**Aetiology of benign prostatic hyperplasia**

**Hormones**

Serum testosterone levels slowly but significantly decrease with advancing age; however, levels of oestrogenic steroids are not decreased equally. According to this theory, the prostate enlarges because of increased oestrogenic effects. It is likely that the secretion of intermediate peptide growth factors plays a part in the development of BPH (Summary box 77.2).

---

**Figure 77.2** A transverse section of the prostate. The peripheral zone is the area from which most prostate cancers arise. The ‘adenomatous’ zone comprises the central and transitional zones.

**Summary box 77.2**

- In about 1/3 of men, who are >50 years of age, the prostate may become enlarged
- In about 1/3 of men who are >50 years of age, serum PSA is in the range of 4–10 ng/mL
- About 1/3 of men with serum PSA of 4–10 ng/mL have prostate cancer
- About 1/3 of men with serum PSA of 1–4 ng/mL have prostate cancer
- About 1/3 of men have enlarged prostate with normal serum PSA

---

Franz von Leydig, 1821–1908, Professor of Histology successively at Wurzburg, Tubingen and Bonn, Germany.
**Pathology**

BPH affects both glandular epithelium and connective tissue stroma to variable degrees. These changes are similar to those occurring in breast dysplasia (see Chapter 53), in which adenosis, epitheliosis and stromal proliferation are seen in differing proportions. BPH typically affects the submucosal group of glands in the transitional zone, forming a nodular enlargement. Eventually, this overgrowth compresses the PZ glands into a false capsule and causes the appearance of the typical 'lateral' lobes.

When BPH affects the subcervical CZ glands, a 'middle' lobe develops that projects up into the bladder within the internal sphincter (Figure 77.3). Sometimes, both lateral lobes also project into the bladder, so that, when viewed from within, the sides and back of the internal urinary meatus are surrounded by an intravesical prostatic collar.

**Effects of benign prostatic hyperplasia**

It is important to realise that the relationship between anatomical prostatic enlargement, lower urinary tract symptoms (LUTS) and urodynamic evidence of bladder outflow obstruction (BOO) is complex (Figure 77.4). Pathophysiologically, BOO may be caused in part by increased smooth muscle tone, which is under the control of \( \alpha \)-adrenergic agonists (Summary box 77.3).

**Summary box 77.3**

**Consequences of BPH**

- No symptoms, no BOO
- No symptoms, but urodynamic evidence of BOO
- Lower urinary tract symptoms, no evidence of BOO
- Lower urinary tract symptoms and BOO
- Others (acute/chronic retention, haematuria, urinary infection and stone formation)

Anatomically, the effects are as follows:

- **Urethra.** The prostatic urethra is lengthened, sometimes to twice its normal length, but it is not narrowed anatomically. The normal posterior curve may be so exaggerated that it requires a curved catheter to negotiate it. When only one lateral lobe is enlarged, distortion of the prostatic urethra occurs.

- **Bladder.** If BPH causes BOO, the musculature of the bladder hypertrophies to overcome the obstruction and appears trabeculated (Figure 77.5). Significant BPH is associated with increased blood flow, and the resultant veins at the base of the bladder are apt to cause haematuria.

**Lower urinary tract symptoms**

In both sexes, non-specific symptoms of bladder dysfunction become more common with age, probably owing to impairment of smooth muscle function and neurovesical coordination. Not all symptoms of disturbed voiding in ageing men should therefore be attributed to BPH causing BOO. Urologists prefer the term LUTS and discourage the use of the descriptive term 'prostatism'.

The following conditions can coexist with BOO, leading to difficulty in diagnosis and in predicting the outcome of treatment:

- idiopathic detrusor overactivity (see Chapter 76);
- neuropathic bladder dysfunction as a result of diabetes, strokes, Alzheimer’s disease or Parkinson’s disease (see Chapter 76);
parts of the prostate. This is a urodynamic concept based on the combination of low flow rates in the presence of high voiding pressures. It can

be diagnosed definitively only by pressure-flow studies. This is because symptoms are relatively non-specific and can result from detrusor instability, neurological dysfunction and weak bladder contraction. Even low measured peak flow rates (<10–12 mL/s) are not absolutely diagnostic because, in addition to BOO, weak detrusor contractions or low voided volumes (owing to instability) can be the cause. Nonetheless, flow rates provide a useful guide for everyday clinical management.

Urodynamically proven BOO may result from:

- BPH;
- bladder neck stenosis;
- bladder neck hypertrophy;
- prostate cancer;
- urethral strictures;
- functional obstruction due to neuropathic conditions.

The primary effects of BOO on the bladder are as follows:

- **Urinary flow rates decrease** (for a voided volume >200 mL, a peak flow rate of >15 mL/s is normal (Figure 77.6), one of 10–15 mL/s is equivocal and one <10 mL/s is low (Figure 77.7).
- **Voiding pressures increase** (pressures >80 cmH₂O are high (Figure 77.8), pressures between 60 and 80 cmH₂O are equivocal and pressures <60 cmH₂O are normal).

The long-term effects of bladder outflow obstruction are as follows:

- The bladder may decompensate so that detrusor contraction becomes progressively less efficient and a residual urine develops.
- The bladder may become more irritable during filling with a decrease in functional capacity partly caused by detrusor overactivity (see Chapter 76), which may also be caused by neurological dysfunction or ageing, or may be idiopathic.

Aside from symptoms, the complications of BOO are as follows:

- Acute retention of urine is sometimes the first symptom of BOO. Postponement of micturition is a common precipitating cause; overindulgence in beer and confinement to bed on account of intercurrent illness or operation are other causes.
- Chronic retention. In patients in whom the residual volume is >250 mL or so (Figure 77.9), the tension in the bladder wall increases owing to the combination of a large volume of residual urine and increased resting and
filling bladder pressures (a condition known as high-pressure chronic retention). The increased intramural tension results in functional obstruction of the upper urinary tract with the development of bilateral hydronephrosis (Figures 77.10 and 77.11). As a result, upper tract infection and renal impairment may develop. Such men may present with overflow incontinence, enuresis and renal insufficiency. These symptoms should alert the doctor to the presence of this condition.

- Impaired bladder emptying. If the bladder decompensates with the development of a large volume of residual urine, urinary infection and calculi are prone to develop.
- Haematuria. This may be a complication of BPH. Other causes must be excluded by carrying out an intravenous urography (IVU), cystoscopy, urine culture and urine cytological examination.
- Other than pain from retention, pain is not a symptom of BOO, and its presence should prompt the exclusion of acute retention, urinary infection, stones, carcinoma of the prostate and carcinoma in situ of the bladder.

**ASSESSMENT OF THE PATIENT WITH LOWER URINARY TRACT SYMPTOMS**

**History**

Symptom score sheets such as the International Prostate Symptom Score (IPSS) assign a score which gives information regarding the severity of symptoms at the outset and changes over time and following intervention. The IPSS assessment should include an assessment of quality of life, which is a reflec-
Assessment of the patient with lower urinary tract symptoms

1345

In addition to the IPSS, a frequency-volume diary completed by the patient before attending the clinic is invaluable in revealing fluid intake habits, diurnal variation in outputs and low-volume, frequent voiding. These assessments are routinely performed at lower urinary tract clinics but can be elicited by a thorough clinical history (Summary box 77.4).

Abdominal examination

Abdominal extension is usually normal. In patients with chronic retention, a distended bladder will be found on palpation, on percussion and sometimes on inspection with loss of the transverse suprapubic skin crease. General physical examination may demonstrate signs of chronic renal impairment with anaemia and dehydration. The external urinary meatus should be examined to exclude stenosis, and the epididymides are palpated for signs of inflammation.

Rectal examination

In benign enlargement, the posterior surface of the prostate is smooth, convex and typically elastic, but the fibrous element may give the prostate a firm consistency. The rectal mucosa can be made to move over the prostate. Residual urine may be felt as a fluctuating swelling above the prostate. It should be noted that, if there is a considerable amount of residual urine present, it pushes the prostate downwards, making it appear larger than it is.

The nervous system

The nervous system is examined to eliminate a neurological lesion. Diabetes mellitus, tabes dorsalis, disseminated sclerosis, cervical spondylosis, Parkinson's disease and other neurological states may mimic prostatic obstruction. If these are suspected then a pressure-flow urodynamic study should be carried out to diagnose BOO. Examination of perianal sensation and anal tone is useful in detection of an S2 to S4 cauda equina lesion.

Serum prostate-specific antigen

The difficulty here is the uncertain benefit of early detection and radical treatment of prostate cancer – this is dealt with in the section on prostate cancer. Certainly, men should be informed about the test, the risks of the prostate biopsy that might be required and the risks of the detection of a cancer that we are not certain how best to treat, as well as the positive aspects of the early discovery of a small prostate cancer. After suitable counselling, measurement of serum PSA may be helpful. Men in whom a diagnosis of early prostate cancer might influence treatment option (such as those under 70 years or those with a positive family history who might be offered radical treatment) should be offered a PSA measurement. If this is in excess of 2.5–4 nmol/L, then transrectal ultrasound scanning (TRUS) plus multiple transrectal biopsies (10 biopsies) should be considered.

If rectal examination is quite normal with no suspicion of cancer, and if no change in treatment policy would in any case result from the diagnosis of early prostate cancer, then there is little point in the routine measurement of PSA in men with uncomplicated BOO. However, because of the fear of future litigation, many find it easier to offer a PSA test.

Flow rate measurement

For this to be meaningful, two or three voids should be recorded, and the voided volume should be in excess of 150–200 mL. This usually means the patient attending a special flow rate clinic. A typical history and a flow rate <10 mL/s (for a voided volume of >200 mL; Figure 77.7) will be sufficient for most urologists to recommend treatment. Usually, a flow rate measurement will be coupled with ultrasound measurement of post-void residual urine.

There are pitfalls in the measurement of flow rates. The machine must be accurately calibrated. The patient must void volumes in excess of 150 mL, and two or three recordings are needed to obtain a representative measurement. Decreased flow rates and symptoms of prostatism may be seen in:
- BOO;
- low voided volumes (characteristically in men with detrusor instability);
• men with weak bladder contractions (low pressure-flow voiding).

**Pressure-flow urodynamic studies**
Details of these studies are outlined in Chapter 76 (see Figure 77.8). They should be performed on the following patients:
- men with suspected neuropathy (Parkinson’s disease, dementia, longstanding diabetes, previous strokes, multiple sclerosis);
- men with a dominant history of irritative symptoms and men with lifelong urgency and frequency;
- men with a doubtful history and those with flow rates in the near normal range (~ or >15 mL/s);
- men with invalid flow rate measurements (because of low voided volumes).

**Blood tests**
Serum creatinine, electrolytes and haemoglobin should be measured.

**Examination of urine**
The urine is examined for glucose and blood; a midstream specimen should be sent for bacteriological examination, and cytological examination may be carried out if carcinoma in situ is thought possible.

**Upper tract imaging**
Most urologists no longer carry out imaging of the upper tract in men with straightforward symptoms. Obviously, if infection or haematuria is present, then the upper tract should be imaged by means of intravenous urogram or ultrasound scan.

**Cystourethroscopy**
Inspection of the urethra, the prostate and the urothelium of the bladder should always be done immediately prior to prostatectomy, whether it is being done transurethrally or by the open route to exclude a urethral stricture, a bladder carcinoma and the occasional non-opaque vesical calculus. The decision of whether to perform prostatectomy must be made before cystoscopy. This should be based on the patient’s symptoms, signs and investigations. Direct inspection of the prostate is a poor indicator of BOO and the need for surgery.

**Transrectal ultrasound scanning**
There is no need to carry this out routinely. Accurate estimation of prostatic size is also possible by means of transrectal or transabdominal ultrasound scan.

---

**MANAGEMENT OF MEN WITH BENIGN PROSTATIC HYPERPLASIA OR BLADDER OUTFLOW OBSTRUCTION**

Strong indications for treatment (usually prostatectomy) include:
- **Acute retention** (see Chapter 76) in fit men with no other cause for retention (drugs, constipation, recent operation, etc.) (accounts for 25 per cent of prostatectomies).
- **Chronic retention and renal impairment**: a residual urine of 200 mL or more, a raised blood urea, hydroureter or hydronephrosis demonstrated on urography and uraemic manifestations (accounts for 15 per cent of prostatectomies).
- **Complications of bladder outflow obstruction**: stone, infection and diverticulum formation.
- **Haemorrhage**: occasionally, venous bleeding from a ruptured vein overlying the prostate will require prostatectomy to be performed.
- **Elective prostatectomy for severe symptoms**: this accounts for about 60 per cent of prostatectomies. Increasing difficulty in micturition, with considerable frequency day and night, delay in starting and a poor stream are the usual symptoms for which prostatectomy is advised. Frequency alone is not a strong indication for prostatectomy. The natural progression of outflow obstruction is variable and rarely gets worse after ten years. Severe symptoms, a low maximum flow rate (<10 mL/s) and an increased residual volume of urine (100–250 mL) are relatively strong indications for operative treatment. The exact cut-off for operative or non-operative treatment will depend on careful discussion between the patient and the urologist (Summary box 77.5).

---

**Summary box 77.5**

**Options for treatment of LUTS secondary to BPH**
- **Conservative measures** include watchful waiting in conjunction with fluid restriction and reduction in caffeine intake
- **Drug therapy** is with β-blockers or, in men with a large prostate, a 5α-reductase inhibitor, or both
- **Interventional measures** include transurethral resection of the prostate (TURP), which remains the ‘gold standard’; consider open prostatectomy for large glands

---

**Acute retention**
The management of retention is discussed in detail in Chapter 76. Once the bladder has been drained by means of a catheter, the patient’s fitness for treatment is determined. If retention was not caused by drugs or constipation, then prostatectomy would usually be the correct management. Unfit men or those with dementia may be treated by means of indwelling prostatic stents or a catheter. Similar comments apply to men with chronic retention once renal function has been stabilised by catheterisation. The role of α-adrenergic drugs followed by a trial of catheter has been tested and found to be successful in certain groups with a short history and a low residual volume of urine, but the recurrence rate becomes cumulatively high.

**Special problems in the management of chronic retention**

Men with chronic retention who have relatively low volumes of residual urine and who do not have symptoms suggestive of coexistent infection and with good renal function do not necessarily require catheterisation before proceeding to prostatectomy on the next available list. For those who are uraemic, urgent catheterisation is mandatory to allow renal function to recover and stabilise. Haematuria often occurs following catheterisation owing to collapse of the distended bladder and upper tract, but settles within a couple of days (see Chapter 76 for general management of retention).
Uraemic patients with chronic retention are often dehydrated at the time of admission. Owing to the chronic back pressure on the distal tubules within the kidney, there is loss of the ability to reabsorb salts and water. The result, following release of this pressure, may be an enormous outflow of salts and water, which is known as post-obstructive diuresis. It is for this reason that a careful fluid chart, daily measurements of the patient’s weight and serial estimations of creatinine and electrolytes are essential. Intravenous fluid replacement is required if the patient is unable to keep up with this fluid loss. These patients are often anaemic and may require a blood transfusion once fluid balance is stabilised (if haemoglobin is <9 g/L).

**Indications for elective treatment in men with LUTS secondary to BPH**

Following careful assessment (see above under Assessment of the patient with lower urinary tract symptoms), the following questions should be answered:

1. **Have they failed a preliminary trial of medical therapy?**
   - Commonly, men will have been treated with α-blockers or 5α-reductase inhibitors and will have failed treatment. They are then referred by their general practitioner to the urologist.

2. **Is BOO present?**
   - In many cases, the findings of significant symptoms (assessed by symptom scoring), a benign prostate supplemented by the finding of a low maximum flow rate (<10–12 mL/s for a good voided volume (>200 mL)) will suffice to make a reasonable working diagnosis of BOO. In some men, particularly those with irritative symptoms, suspected neurological disease or those with technically imperfect flow rate measurements, pressure–flow studies will need to be performed.

3. **How severe are the symptoms and what are the risks of doing nothing?**
   - Severe symptoms and a large residual volume of urine will usually require treatment. Men with mild symptoms, good flow rates (>15 mL/s) and good bladder emptying (residual urine <100 mL) may be safely managed by reassurance and review: such patients rarely develop severe complications such as retention in the long term.

4. **Is the man fit for operative treatment?**

5. **What treatments are available, what are the outcomes and do the side-effects justify treatment?**

**Treatment**

**Men with symptoms attending for elective treatment (excluding acute and chronic retention)**

**Conservative treatment**

It is in men with relatively mild symptoms, reasonable flow rates (>10 mL/s) and good bladder emptying (residual urine <100 mL) that careful discussion over the merits and side effects of operative treatment is warranted. Waiting for a period of six months after careful discussion of the diagnosis is indicated. After this, a repeat assessment of symptoms, flow rates and ultrasound scan is helpful; many men with stable symptoms will elect to leave matters be. Advice over limiting fluid intake in the evening and careful use of anti-muscarinics to help with irritative symptoms is also useful.

**Drugs**

In men who are very concerned about the development of sexual dysfunction after transurethral resection of the prostate (TURP), the use of drugs may be helpful. Two classes of drug have been used in the treatment of men with BOO. α-Adrenergic blocking agents inhibit the contraction of smooth muscle that is found in the prostate. The other class of drug is the 5α-reductase inhibitors, which inhibit the conversion of testosterone to DHT, the most active form of androgen. These drugs, when taken for a year, result in a 25 per cent shrinkage of the prostate gland. Both groups of drugs are effective; however, α-blockers work more quickly and, although the 5α-reductase inhibitors have fewer side effects, they need to be taken for at least six months, and their effect is greatest in patients with large (>50 g) glands. Drug therapy results in improvements in maximum flow rates by about 2 mL/s more than placebo and results in mild (20 per cent) improvement in symptom scores. TURP, however, results in improvements in maximum flow rates from 9 to 18 mL/s and a 75 per cent improvement in symptom scores. These drugs are expensive in comparison with their effectiveness, and a significant proportion of men who try these drugs will subsequently undergo TURP. They may be best targeted at men who have failed an initial trial of watchful waiting and who wish to avoid surgery for a period.

**Operative treatment**

Apart from the strong indications for operative treatment mentioned above, the most common reason for TURP is a combination of severe symptoms and a low flow rate <12 mL/s. The key is to assess symptoms carefully and to counsel men about side effects and likely outcome before advising operative treatment.

**Counselling men undergoing prostatectomy**

Men undergoing prostatectomy need to be advised about the following:

- **Retrograde ejaculation.** This occurs in about 65 per cent of men after prostatectomy.

- **Erectile impotence.** This occurs in about 5 per cent of men, usually those whose potency is waning.

- **The success rate.** On the whole, men with acute and chronic retention do well from the symptomatic point of view. Ninety per cent of men undergoing elective operation for severe symptoms and urodynamically proven BOO do well in terms of symptoms and flow rates. Only about 65 per cent of those with mild symptoms or those with weak bladder contraction as the cause of their symptoms do well. Men with unobstructed detrusor instability do not respond well to TURP. This is the reason for carefully documenting the severity of symptoms and flow rates (supplemented when necessary by pressure–flow studies) before deciding on treatment.

- **The risk of reoperation.** After TURP, this is about 15 per cent after 8–10 years.

- **The morbidity rate.** Death after TURP is infrequent (<0.5 per cent), severe sepsis is found in about 6 per cent and severe haematuria requiring transfusion of more than two units of blood occurs in about 3 per cent. After discharge, about 15–20 per cent of men subsequently require antibiotic treatment for symptoms of urinary infection. Risk factors for complications include admission with retention, prostate cancer, renal impairment and advanced age.
Methods of performing prostatectomy

The prostate can be approached (1) transurethrally (TURP), (2) retropubically (RPP), (3) through the bladder (transvesical; TVP) or (4) from the perineum (Figure 77.12).

Transurethral resection of the prostate

TURP has largely replaced other methods unless diverticulectomy or the removal of large stones necessitates open operation; over 95 per cent of men being treated by urologists can be dealt with by TURP. Perhaps the greatest advance in the history of transurethral surgery was marked by the development of the rigid lens system of Professor Harold Hopkins. His lenses, illuminated by a fibreoptic light source, permit unparalleled visualisation of the working field. Men with indwelling catheters, those with recent urinary infection, those with chronic retention or those with prosthetic material or heart valves should receive broad spectrum prophylactic antibiotics with amoxicillin plus cefuroxime or gentamicin intravenously at induction of anaesthesia.

Strips of tissue are cut from the bladder neck down to the level of the verumontanum (Figure 77.13). Cutting is performed by a high-frequency diathermy current, which is applied across a loop mounted on the hand-held trigger of the resectoscope. Coagulation of bleeding points can be accurately achieved, and damage to the external sphincter is avoided provided one uses the verumontanum as a guide to the most distal point of the resection. The ‘chips’ of prostate are then removed from the bladder using an Ellik evacuator. The risks of hyponatraemia are reduced by using 1.5 per cent isotonic glycine for irrigation, and the recent introduction of continuous-flow resectoscopes makes the procedure swift and safe in experienced hands. At the end of the procedure, careful haemostasis is performed, and a three-way, self-retaining catheter irrigated with isotonic saline is introduced into the bladder to prevent any further bleeding from forming blood clots. Irrigation is continued until the outflow is pale pink, and the catheter is usually removed on the second or third postoperative day. In men with small prostates or bladder neck dyssynergia or stenosis, it is better to divide the bladder neck and prostatic urethra with a diathermy ‘bee-sting’ electrode.

Retropubic prostatectomy [Millin]

Using a low, curved transverse suprapubic Pfannenstiel incision, which includes the rectus sheath, the recti are split in the midline and retracted to expose the bladder. With the patient in the Trendelenburg position, the surgeon separates the bladder and the prostate from the posterior aspect of the pubis. In the space thus obtained, the anterior capsule of the prostate is incised with diathermy below the bladder neck, care being taken to obtain complete control of bleeding from divided prostatic veins by suture ligation. The prostatic adenoma is exposed and enucleated with a finger. A wedge is taken out of the posterior lip of the bladder neck to prevent secondary stricture in this region. The exposure of the inside of the prostatic cavity is good, and control of haemorrhage is achieved with diathermy and suture ligation of bleeding points before closure of the capsule over a Foley catheter (inserted per urethram) draining the bladder.

Transvesical prostatectomy

The bladder is opened, and the prostate enucleated by putting a finger into the urethra, pushing forwards towards the pubes to separate the lateral lobes, and then working the finger between the adenoma and the false capsule. In Freyer’s operation (1901), the bladder was left open widely and drained by
a suprapubic tube with a 16-mm lumen in order to allow free drainage of blood and urine. Harris (1934) advocated control of the prostatic arteries by lateral stitches inserted with his boomerang needle, the bladder wall was closed and the wound drained.

**Perineal prostatectomy** (Young)

This has now been abandoned for the treatment of BPH.

**After treatment**

Most urologists irrigate the bladder with sterile saline by means of a three-way Foley catheter for 24 hours or so.

**Complications**

**Local**

Haemorrhage is a major risk following prostatectomy whatever the surgical approach. Care should be taken in diathermising arterial bleeding points after TURP; they are often better seen when the rate of inflow of fluid is decreased. In the recovery room, one should check that the bladder is draining adequately; if it is not, this may indicate that a clot is blocking the eye of the catheter. The bladder should be promptly washed out using strict aseptic technique. The catheter should be changed by the surgeon. Only rarely is it necessary to return the patient to the operating room.

Secondary haemorrhage tends to occur after the patient has been discharged. All men should be warned about this possibility and given appropriate advice to rest and to have a high fluid intake. It is usually minor in degree but if clot retention occurs, the patient will need to be readmitted, a catheter will have to be passed and the bladder washed out.

Perforation of the bladder or the prostatic capsule can occur at the time of transurethral surgery. This usually occurs from a combination of inexperience in association with a large prostate or heavy blood loss. If the field of vision becomes obscured by heavy blood loss, it is often prudent to achieve adequate haemostasis and abandon the operation, swallowing one’s pride on the understanding that a second attempt may be necessary. A large perforation with marked extravasation may require the insertion of a small suprapubic drain. Rectal perforation should be extremely rare.

**Sepsis**

Bacteraemia is common even in men with sterile urine and occurs in over 50 per cent of men with infected urine, prolonged catheterisation or chronic retention. Septicaemia can occur in these patients shortly after operation or when the catheter is removed. In men at high risk, the use of prophylactic antibiotics is recommended. Wound infection following open prostatectomy is common if a urethral catheter has been in situ for a number of days before the operation. The most worrying aspect of infection is the early rigor following surgery. If left undetected and untreated, this may progress to frank septicaemia with profound hypotension. A blood culture should be taken and broad spectrum antibiotics with Gram-negative activity given parenterally, e.g. augmentin and gentamicin.

**Incontinence**

Incontinence is inevitable if the external sphincter mechanism is damaged. The bladder neck is rendered incompetent by any prostatectomy and, therefore, an intact distal sphincter mechanism is essential for continence. Damage to the sphincter may occur at open prostatectomy and following transurethral surgery if the resection extends beyond the verumontanum. If pelvic floor physiotherapy is ineffective, then the only satisfactory treatment is the fitting of an artificial urinary sphincter. In some patients, detrusor instability contributes to the incontinence. The use of anti-cholinergic agents or imipramine or duloxetine may help.

**Retrograde ejaculation and impotence**

Impotence in men with good sexual function before surgery is uncommon, but retrograde ejaculation occurs commonly (>50 per cent) because of disruption to the bladder neck mechanism.

**Urethral stricture**

This may be secondary to prolonged catheterisation, the use of an unnecessarily large catheter, clumsy instrumentation or the presence of the resectoscope in the urethra for too long a period. These strictures arise either just inside the meatus or in the bulb urethra. An early stricture can usually be managed by simple bouginage but, later on, it may be necessary to cut the densely fibrotic stricture with the optical urethrotome. The routine use of an Otis urethrotomy prior to TURP reduces the incidence of postoperative stricture.

**Bladder neck contracture**

Occasionally, a dense fibrotic stenosis of the bladder neck occurs following overaggressive resection of a small prostate. It may be due to the overuse of coagulating diathermy. Transurethral incision of the scar tissue is necessary.

**Reoperation**

It is now well known that, after eight years, 15–18 per cent of men with BPH will undergo repeat TURP (the rate after open prostatectomy is about 5 per cent). The reasons include a technically imperfect primary procedure and a speculative repeat operation in men with symptoms who are cystoscoped after operation.

**General complications**

Death occurs in about 0.2–0.3 per cent of men undergoing elective prostatectomy. In very elderly men, in men with prostate cancer admitted as an emergency with acute or chronic retention or in those with very large prostates, the 30-day death rate may be in the order of 1 per cent.

**Cardiovascular**

Pulmonary atelectasis, pneumonia, myocardial infarction, congestive cardiac failure and deep venous thrombosis are all potentially life-threatening conditions that can affect this elderly and often frail group of men.

**Water intoxication (also known as TUR syndrome)**

The absorption of water into the circulation at the time of transurethral resection can give rise to congestive cardiac failure, hyponatraemia and haemolysis. Accompanying this, there is frequently confusion and other cerebral events often mimicking a stroke. The incidence of this condition has been reduced since the introduction of isotonic glycine for performing the
resections and the use of isotonic saline for postoperative irrigation. The treatment consists of fluid restriction.

**Osteitis pubis**
This is rare.

**Newer treatments**
In general, newer, minimally invasive treatments occupy a position intermediate between TURP and drug treatment. In the last decade, technological innovations led to the introduction of novel minimally invasive treatments for prostatectomy. Tissue ablative techniques using hyperthermia and laser energy were associated with minimal morbidity and could often be performed as outpatient procedures. Many of the initial studies reporting treatment success were poorly designed and over a short duration. Longer-term follow up and randomised controlled trials have failed to confirm significant benefit from these techniques. More recently, the holmium laser, a pulsed solid-state laser, has been used to enucleate the prostate adenoma. This approach involves excision of parts of the prostate using a cutting laser and then morcellating the excised prostate fragments, which fall back into the bladder so that they can be removed. Morbidity with this procedure is low and short-term results favourable; long-term follow up will be necessary to determine whether this treatment will have a role to play in the management of BOO. The green light laser is now being used to vapourise the prostate tissue, but has not yet been shown to be as durable as holmium laser treatment or TURP, because the amount of tissue removed is usually less. Recently, the development of bipolar resectoscopes, which allow irrigation with normal saline, has allowed the resection of larger prostates without the risk of causing water intoxication.

**Intraurethral stents**
These devices are possibly helpful in the management of men with retention who are grossly unfit (classified by the American Society of Anesthesiologists as ASA grade IV) (Figure 73.14). These men are rare cases.

### BLADDER OUTFLOW OBSTRUCTION CAUSED BY THE BLADDER NECK

**Aetiology**
This condition usually occurs in men, but can rarely affect children of both sexes and women. It may be due to muscular hypertrophy or fibrosis of the tissues at the bladder neck following TURP.

**Clinical syndromes**

**Owing to muscle hypertrophy or dyssynergia**
Marion described a series of cases in which muscular hypertrophy of the internal sphincter in a young person had resulted in the development of a vesical diverticulum or hydronephrosis (Marion’s disease or ‘prostatism sans prostate’). It is thought that dyssynergic contraction of the smooth muscle of the bladder neck (bladder neck dyssynergia) may account for some cases of BOO.

**Owing to fibrosis**
The symptoms are similar to those of prostatic enlargement but are a consequence of scarring after TURP.

**Treatment**
The management of these patients depends on achieving an accurate diagnosis. For this, urodynamic investigation is often necessary, which should demonstrate raised voiding pressures and diminished flow rate.

**Drugs**
The presence of **α**-adrenergic receptors in the region of the bladder neck and prostatic urethra allows pharmacological manipulation of the outflow to the bladder.

**α-Blocking drugs**
Alfuzosin, 2.5 mg bd to tds (to a total maximum of 10 mg/day), doxazosin, 1 mg nocte (up to a maximum of 8 mg/day), indoramin, 20 mg bd (increased to a total maximum of 100 mg/day in divided doses), prazosin 500 mg bd (maintenance up to 2 mg/day) and terazosin, 1 mg nocte (to a total maximum of 10 mg/day), can be very useful, causing relaxation of the bladder neck. Modified release tamsulosin 400 mg can be taken once daily. These drugs are not target specific, and patients must be warned of the possibility of postural hypotension.

**Transurethral incision**
Transurethral incision of the bladder neck is the operation of choice. Sometimes symptoms recur, but this is usually due to inadequate division of the fibres of the bladder neck.

**Congenital valves of the prostatic urethra**
See Chapter 78.

### PROSTATIC CALCULI

Prostatic calculi are of two varieties: endogenous, which are common, and exogenous, which are comparatively rare.

An exogenous prostatic calculus is a urinary (commonly ureteric) calculus that becomes arrested in the prostatic urethra. This is considered in Chapter 75.

Endogenous prostatic calculus are usually composed of calcium phosphate combined with about 20 per cent organic material.

**Clinical features**
Prostatic calculi are usually symptomless, being discovered on

---

*Jean Baptiste Camile Marion, 1869–1932, Professor of Urology, The Faculty of Medicine, Paris, France.*
Carcinoma of the prostate is the most common malignant tumour in men over the age of 65 years. In England and Wales in 2008, 37,000 men were registered and 10,000 died from it; the corresponding figures in the USA were 186,000 and 28,000, respectively. If histological section of prostates at autopsy is performed, increasingly frequent foci of microscopic prostate cancers are found with increasing age. These foci of prostate cancer have variable potential for progressing clinically to metastatic disease. About 10–15 per cent of younger men who develop prostate cancer have a positive family history of the disease, but the aetiology is unclear. Throughout the world, rates of microscopic foci of prostate cancer are constant, but rates of clinically evident disease are low in men in Japan and China. Carcinoma of the prostate usually originates in the PZ of the prostate (Figure 77.2), so ‘prostatectomy’ for benign enlargement of the gland confers no protection from subsequent carcinoma.

**Pathology**

Serial sections of prostates obtained at routine necropsy demonstrate prostate carcinoma in 25 per cent of men between 50 and 65 years of age. The incidence in men over 80 years is in the region of 70 per cent (Franks). Most of these neoplasms are tiny and (if life had continued) might have remained latent for years.

The following types of prostate cancer occur:

- microscopic latent cancer found on autopsy or at cystoprostatectomy;
- impalpable tumours found incidentally during TURP (T1a and T1b) or following screening by PSA measurement (T1c);
- early, palpable, localised prostate cancer (T2);
- advanced local prostate cancer (T3 and T4);
- metastatic disease, which may arise from a clinically evident tumour (T2, T3 or T4) or from an apparently benign gland (T0, T1), i.e. occult prostate cancer.

It should be noted that only the last two groups cause symptoms, and such tumours are not curable. Only screening or the treatment of incidentally found tumours can result in cure of the disease. The problem is that many such tumours would never progress during the patient’s lifetime; herein lies the problem with prostate cancer (Summary box 77.6).

**Summary box 77.6**

**Prostate cancer detection**
- The incidence has increased, and opportunistic PSA testing has enabled the detection of early-stage disease
- It is not yet clear whether national screening programmes for prostate cancer should be instigated
- Patients should be counselled about the investigations and treatment options available before a PSA test is performed

**Screening for prostate cancer**

The cancer detection rate using measurement of PSA is between 2 and 4 per cent, and approximately 30 per cent of men with an elevated PSA will have prostate cancer confirmed by biopsy. Unfortunately, 20 per cent of men with clinically significant prostate cancer will have PSA values within the normal range. There is therefore controversy over the usefulness of PSA alone as a screening procedure. One of the two recent prospective screening trials (the other was inconclusive due to contamination) suggests that screening with PSA does prevent death due...
to prostate cancer, but that a lot of men must be screened and treated to prevent one death. At present, in Europe, population-based screening is performed only within the confines of clinical trials.

**Histological appearances**

The prostate is a glandular structure consisting of ducts and acini; thus, the histological pattern is one of an adenocarcinoma. The prostatic glands are surrounded by a layer of myoepithelial cells. The first change associated with carcinoma is the loss of the basement membrane, with glands appearing to be in confluence. As the cell type becomes less differentiated, more solid sheets of carcinoma cells are seen. A classification of the histological pattern based on the degree of glandular de-differentiation and its relation to stroma has been devised by Gleason. Prostate cancers exhibit heterogeneity within tissue, and so two histological areas of prostate are each scored between 1 and 5. The scores are added to give an overall Gleason score of between 2 and 10; this (and the volume of the cancer) appears to correlate well with the likelihood of spread and the prognosis.

**Local spread**

Locally advanced tumours tend to grow upwards to involve the seminal vesicles, the bladder neck and trigone and, later, the tumours tend to spread distally to involve the distal sphincter mechanism. Further upward extension obstructs the lower end of one or both ureters, obstruction of both resulting in anuria. The rectum may become stenosed by tumour infiltrating around it, but direct involvement is rare.

**Spread by the bloodstream**

Spread by the bloodstream occurs particularly to bone; indeed, the prostate is the most common site of origin for skeletal metastases, followed in turn by the breast, the kidney, the bronchus and the thyroid gland. The bones involved most frequently by carcinoma of the prostate are the pelvic bones and the lower lumbar vertebrae. The femoral head, rib cage and skull are other common sites.

**Lymphatic spread**

Lymphatic spread may occur (1) via lymphatic vessels passing to the obturator fossa or along the sides of the rectum to the lymph nodes beside the internal iliac vein and in the hollow of the sacrum and (2) via lymphatics that pass over the seminal vesicles and follow the vas deferens for a short distance to drain into the external iliac lymph nodes. From retroperitoneal lymph nodes, the mediastinal nodes and occasionally the supraclavicular nodes may become implicated.

**Staging using the tumour, node, metastasis (TNM) system (Figure 77.16)**

1. **T1a, T1b and T1c.** These are incidentally found tumours in a clinically benign gland after histological examination of a prostatectomy specimen. T1a is a tumour involving less than 5 per cent of the resected specimen; these tumours are usually well or moderately well differentiated. T1b is a tumour involving >5 per cent of the resected specimen. T1c tumours are impalpable tumours found following investigation of a raised PSA.

2. **T2a disease** presents as a suspicious nodule (Figure 77.17) on rectal examination confined within the prostate capsule and involving one lobe. T2b disease involves both lobes.

3. **T3 tumour** extends through the capsule (T3a, uni- or bilateral extension. T3b, seminal vesical extension).

4. **T4** is a tumour that is fixed or invading adjacent structures other than seminal vesicles – rectum or pelvic side wall (Summary box 77.7).

**Summary box 77.7**

**The natural history of prostate cancer**

This depends on the stage and grade of disease:

- **T1 and T2**
  - The progression rate of well-differentiated T1a prostate cancer is very low: 10–14 per cent after eight years. For moderately differentiated tumours, the rate is about 20 per cent.
  - For T1b and T2 tumours, the rate is in excess of 35 per cent.

- **T3 and T4 (MO)**
  - About 50 per cent progress to bony metastases after 3–5 years.

- **M1**
  - The median survival of men with metastatic disease is about three years.

**Clinical features**

Only advanced disease gives rise to symptoms, but even advanced disease may be asymptomatic. Symptoms of advanced disease include:

- BOO;
- pelvic pain and haematuria;
- bone pain, malaise, ‘arthritis’, anaemia or pancytopenia;
- renal failure;
- locally advanced disease or even asymptomatic metastases, which may be found incidentally on investigation of other symptoms.

Early prostate cancer is asymptomatic and may be found:

- incidentally following TURP for clinically benign disease (T1);
- as a nodule (T2) on rectal examination (Summary box 77.8).

**Rectal examination**

Rectal examination can detect nodules within the prostate and advanced disease. TRUS may be used to access the local stage and can be combined with a needle core biopsy (Figure 77.18). Irregular induration, characteristically stony hard in part or in the whole of the gland (with obliteration of the median sulcus), suggests carcinoma. Extension beyond the capsule up into the
bladder base and vesicles (Figure 77.19 demonstrates normal vesicles) is diagnostic, as is local extension through the capsule (Figure 77.20).

**Prostatic biopsy**

If there is suspicion of prostate cancer, because of local findings, a raised PSA or metastatic disease, then a transrectal biopsy using an automated gun is recommended. Routine local anaesthetic is used to decrease pain. About ten systematic biopsy cores are obtained, as well as biopsy of any suspicious areas. Broad spectrum antibiotic cover is given to all patients to reduce the incidence of sepsis.

If there are associated symptoms of BOO, then either:

- a TURP can be performed, which will provide diagnostic material and symptomatic relief;
- a transrectal biopsy can be carried out. If the diagnosis is positive and there is locally advanced disease, then hormone ablation can provide good symptomatic relief without the need for operation.

**General blood tests**

These are normal in early disease but, in metastatic disease, there may be leuко-erythroblastic anaemia secondary to extensive marrow invasion, or anaemia may be secondary to renal failure. There may be thrombocytopenia and evidence of disseminated intravascular coagulopathy with increased fibrinogen degradation products (FDPs).

**Liver function tests**

These will be abnormal if there is extensive metastatic invasion of the liver. The alkaline phosphatase may be raised from either hepatic involvement or secondaries in the bone. These can be distinguished by measurement of isoenzymes or gamma-glutamyltransferase.

**Prostate-specific antigen**

This is discussed earlier in this chapter. It is good at following the course of advanced disease. It is lacking in sensitivity and specificity in the diagnosis of early localised prostate cancer. Nevertheless, the finding of a PSA >10 nmol/mL is suggestive of cancer and >35 ng/mL is almost diagnostic of advanced prostate cancer. A decrease in PSA to the normal range following hormonal ablation is a good prognostic sign.

**Acid phosphatase**

Acid phosphatase has been superseded by measurement of PSA.
Radiological examination

X-rays of the chest may reveal metastases in either the lung fields or the ribs. An abdominal x-ray may show the characteristic sclerotic metastases in lumbar vertebrae and pelvic bones (Figure 77.21). The bone appears dense and coarse, and it is sometimes difficult to distinguish the change from that in Paget’s disease of bone. Nevertheless, osteolytic metastases are very common in prostate cancer and may coexist with sclerotic ones. Information about the upper urinary tracts can be obtained by excretion urography or ultrasound.

Cross-sectional imaging with magnetic resonance imaging and TRUS

Magnetic resonance imaging (MRI) with a high tesla magnet (1.5–3 T) is the most accurate method of staging local disease. Transrectal ultrasound scanning can also be used. Locally extensive disease (T2) can be diagnosed with increased sensitivity by TRUS (Figure 77.17) compared with rectal examination, but many tumours will still be missed. This problem remains a real one in screening for early prostate cancer; in comparison with breast cancer, with mammography detecting 70–80 per cent of tumours, TRUS plus rectal examination and measurement of PSA will detect only 30–50 per cent of cancers that are known to be present on autopsy studies (although it may detect the larger, more significant cancers).

Bone scan

Once the diagnosis has been established, it would be normal to perform a bone scan as part of the staging procedure if the PSA were >10 nmol/mL or if the biopsy showed high-grade cancer. If the PSA is <10 nmol/mL, then a bone scan would be performed only on clinical indications. The bone scan is performed by the injection of technetium-99m, which is then monitored using a gamma camera. It is more sensitive in the diagnosis of metastases (Figure 77.22) than a skeletal survey, but false positives occur in areas of arthritis, osteomyelitis or a healing fracture.

Lymphangiography

This is no longer carried out. If accurate information is required, then pelvic lymphadenectomy can be performed by means of laparoscopic surgery.

Bone marrow aspiration

Sometimes, examination of the bone marrow will reveal the presence of metastatic carcinoma cells.

Treatment of carcinoma of the prostate

Early disease

Curative treatment can only be offered to patients with early disease (T1a, T1b, T1c and T2). T1a disease found incidentally at TURP is by definition low volume and usually well differentiated. This stage can often be managed by active surveillance, with three- to six-monthly digital rectal examination (DRE)
Carcinoma of the prostate

1355

and PSA measurement, considering treatment if there is evidence of disease progression. The options available for T1b, T1c and T2 disease need to take into account patient age, performance status and lifestyle preferences. The treatment of patients with advanced disease (T3, T4 or any M0) is only palliative (Summary box 77.9).

**Summary box 77.9**

**Treatment and stage**

- Treatment options for prostate cancer depend on stage of disease, life expectancy of the patient and patient preference
- PSA, DRE and biopsy Gleason grade are used to predict pathological stage
- Localised cancer can be treated by radical prostatectomy, radiation therapy and active monitoring
- Treatment of advanced disease is palliative, and hormone ablation remains the first-line therapy

**Radical prostatectomy**

Radical prostatectomy is only suitable for localised disease (T1 and T2) and should be carried out only in men with a life expectancy of >10 years. Exclusion of metastases would require a negative bone scan, chest x-ray and a serum PSA <20 nmol/mL. It is a procedure that should be performed only by experienced surgeons when there is a high chance of cure. It results in a high incidence of impotence, but a low incidence of severe stress incontinence (<2 per cent), which may require the fitting of an artificial urinary sphincter. It involves removal of the prostate down to the distal sphincter mechanism in addition to the seminal vesicles (Figure 77.23). The bladder neck is reconstituted and anastomosed to the urethra. Recent modifications to this operation by Professor Patrick Walsh of the Johns Hopkins Hospital in Baltimore have led to the realisation that careful dissection in early-stage disease can lead to preservation of the neurovascular bundles that lie behind the prostate. This modification has led to the preservation of erectile function in about 60–70 per cent of cases. Recently, laparoscopic approaches to radical prostatectomy, sometimes supported by robotic techniques, have been introduced.

**Radical radiotherapy for early prostate cancer**

External beam radiotherapy (EBRT) can be administered in fields that conform to the contours of the prostate, thereby limiting exposure of adjacent tissues. Survival rates following the treatment of T1 and low-volume T2 disease are not greatly different from those following radical prostatectomy, although histological evidence of persistent tumour is found within the prostate in about 30 per cent of treated patients. The treatment of T3 disease which has spread through the capsule of the gland is controversial. Surgery, radiotherapy, androgen ablation or combinations of the above are used. The treatment requires the patient to attend hospital on a daily basis for between 4 and 6 weeks. Some local complications are inevitable, namely irritation of the bladder with urinary frequency, urgency and sometimes urge incontinence and similar problems affecting the rectum with diarrhoea and, occasionally, late radiation proctitis. Development of erectile dysfunction occurs less frequently than following radical prostatectomy, but is present in up to 30 per cent of cases.

**Brachytherapy**

Under transrectal ultrasound guidance, radioactive seeds are permanently implanted into the prostate. A computer program converts accurate ultrasound measurements of the prostate gland to construct a plan of the gland. Under anaesthesia, the patient is placed in the lithotomy position and, according to the template plan, seeds are placed through transperineal needles.

**Figure 77.22** Bone scan showing multiple hot-spots suggestive of metastatic disease in a man with prostate cancer.

**Figure 77.23** Radical prostatectomy specimen for a T2a prostate cancer. Preoperative PSA was 6 ng/L; postoperative levels remained undetectable at eight years. The patient is fully continent.

Patrick C Walsh, Professor of Urology, Johns Hopkins Hospital, Baltimore, MD, USA. Recipient of 2007 National Physician of the Year Clinical Excellence Award.

12-77-B&L_26th-Pt12_Ch77-cc.indd   1355
10/09/2012   11:59
The radioisotopes commonly used are iodine-125 and palladium-103. These isotopes deliver an intense, confined radiation dose, which falls off rapidly to spare the surrounding structures. Brachytherapy is gaining widespread acceptance for the treatment of lower grade low-volume T1 disease. A major factor is the reduced peroperative complications and generally low morbidity. Long-term cancer survival results from institutions specialising in the procedure are encouraging.

**Advanced disease**

There is still debate about the timing of androgen ablation treatment in patients with locally advanced or metastatic disease without symptoms. The options are androgen deprivation at diagnosis or careful review, reserving active treatment for the later development of symptoms. Patients with poorly differentiated disease are at risk of a catastrophic event such as spinal cord compression; in these patients, early androgen ablation can prolong the time to complications. Also, patients with local or general symptoms should be offered androgen deprivation.

**Orchidectomy**

Orchidectomy is performed to carry out androgen ablation in the treatment of locally advanced (T3 or T4) disease or of metastatic disease. In 1941, prostate cancer was shown to be responsive to such treatment by Charles Huggins, the only urologist to win a Nobel Prize. Bilateral orchidectomy, whether total or subcapsular, will eliminate the major source of testosterone production.

**Medical castration**

Medical forms of androgen ablation have been available since the discovery of stilbestrol. The other commonly available treatment to reduce testosterone levels to the castrate range is LHRH agonists. These agents initially stimulate hypothalamic LHRH receptors but, because of their constant presence (rather than the normal diurnal rhythm), they then downregulate them, resulting in cessation of pituitary LH production and, hence, a decrease in testosterone production. In the first 10 days or so, serum testosterone levels may increase, and it is wise to give flutamide, bicalutamide or cyproterone acetate for this period. LHRH agonists may be given by monthly or three-monthly depot injection.

Other treatments that block the androgen receptor have become available recently. Cyproterone acetate also has some progestogenic effect, while flutamide and bicalutamide are pure anti-androgen. In general, oral anti-androgen monotherapy has not been shown to be as good as LHRH agonists or orchidectomy. New types of drugs affecting the LHRH–androgen axis, such as LHRH antagonists, superpotent androgen receptor antagonists and drugs inhibiting androgen biosynthesis, are in clinical trials. The role of these drugs is yet to be established.

**Complete androgen blockade**

Complete androgen blockade has been advocated as being likely to result in increased life expectancy and an increased time to progression in a fitter subgroup of men with advanced prostate cancer. The concept is that of abolishing the testicular secretion of testosterone by means of orchidectomy or the use of LHRH therapy and then inhibiting the effects of adrenal androgenic steroids by means of androgen receptor blockade with flutamide, bicalutamide or the use of cyproterone acetate. Recent overviews of randomised trials do not confirm earlier reports of effectiveness.

**General radiotherapy**

Radiotherapy for symptomatic metastases is an excellent form of palliative treatment, often producing dramatic pain relief in men with hormone-relapsed prostate cancer that can last up to six months. When multiple sites are involved, intravenous radiopharmaceuticals such as strontium-89 can be employed. Strontium is a bone-seeking isotope that delivers effective radiotherapy to metastatic areas. It appears to be as effective as hemibody irradiation in the treatment of men with metastatic hormone-relapsed disease; however, the duration of response has been disappointing.

**Chemotherapy**

Cytotoxic agents in the treatment of these men have proved disappointing, but whether this is because the tumour is inherently insensitive or because these elderly men will not tolerate effective doses is uncertain. Recent trials of docetaxel have shown improvements in survival, but only by a few months.

**Summary of treatment**

1. **Incidentally diagnosed T1a and T1b disease.** For men in their 70s, conservative treatment would usually be the correct approach. Radical surgical treatment might be considered in the younger (<70 years) man with this form of the disease, although even in this group, some men will elect to pursue a conservative course when counselled about risks versus benefits.

2. **Localised T1c and T2 disease.** In younger, fitter men (<70 years), this may be treated by radical prostatectomy or radical radiotherapy. Active monitoring remains an option, particularly for more elderly patients with low-grade disease. In the elderly patient with outflow obstruction, transurethral resection with or without hormone therapy is indicated. The benefit of radical treatment over a conservative approach is likely to be about 25 per cent, given that progression to metastatic disease is of this order of magnitude after 10 years.

3. **Locally advanced T3 and T4 disease.** These patients are at significant risk of disease progression. Early androgen ablation is favoured if close follow up is not possible. For the sexually active, a careful conservative approach with the adoption of androgen ablation when symptoms arise is reasonable. Androgen ablation coupled with radiotherapy is standard treatment for younger men with T3 disease.

4. **Metastatic disease.** Once metastases have developed, the outlook is poor. For patients with symptoms, there is no dilemma; androgen ablation will provide symptomatic relief in over two-thirds of patients. For patients with asymptomatic metastases, the timing of treatment is less clear. Systemic chemotherapy with docetaxel should be considered in younger, fitter men.

**PROSTATITIS**

In both acute and chronic prostatitis, the seminal vesicles and posterior urethra are usually also involved.
**Acute prostatitis**

**Aetiology**

Acute prostatitis is common, but underdiagnosed. The usual organism responsible is *Escherichia coli*, but *Staphylococcus aureus*, *Staphylococcus albus*, *Streptococcus faecalis*, *Neisseria gonorrhoeae* or *Chlamydia* may be responsible. The infection may be haematogenous from a distant focus, or it may be secondary to acute urinary infection.

**Clinical features**

General manifestations overshadow the local: the patient feels ill, shivers, may have a rigor, has ‘aches’ all over, especially in the back, and may easily be diagnosed as having influenza. The temperature may be up to 39°C. Pain on micturition is usual, but not invariable. The urine contains threads in the initial voided sample, which should be cultured. Perineal heaviness, rectal irritation and pain on defaecation can occur; a urethral discharge is rare. Frequency occurs when the infection involves the bladder. Rectal examination reveals a tender prostate; one lobe may be swollen more than the other, and the seminal vesicles may be involved. A frankly fluctuant abscess is uncommon.

**Treatment**

Treatment must be vigorous and prolonged or the infection will not be eradicated and recurrent attacks may ensue. Spread of infection to the epididymes and tests may occur. Prolonged treatment with an antibiotic that penetrates the prostate well is indicated (trimethoprim or ciprofloxacin).

**Prostatic abscess**

In addition to the foregoing symptoms and signs, the advent of a prostatic abscess is heralded by the temperature rising steeply with rigors. Antibiotics disguise these features. Severe, unrelenting perineal and rectal pain with occasional tenesmus often cause the condition to be confused with an anorectal abscess. Nevertheless, if a rectal examination is performed, the prostate will be felt to be enlarged, hot, extremely tender and perhaps fluctuant. Retention of urine is likely to occur and, in such men, suprapubic catheterisation is best.

**Treatment**

The abscess should be drained without delay:

- The abscess can be drained by perurethral resection – unroofing the whole cavity.
- The perineal route is rarely indicated unless there is marked periprostatic spread.

**Chronic prostatitis**

Many urologists find the diagnosis of chronic prostatitis and ‘prostatodynia’ very difficult, for many men present with perigenital pain, testicular pain, prostatic pain exacerbated by sexual intercourse or pain that apparently renders sexual intercourse out of the question. Psychosexual dysfunction in such patients may be the underlying problem. The diagnosis of chronic prostatitis has to be based on:

- persistent threads in voided urine;
- prostatic massage showing pus cells with or without bacteria in the absence of urinary infection.

**Aetiology**

This is thought to be the sequel of inadequately treated acute prostatitis. While pus is present in the prostatic secretion, the responsible organism is often difficult to find. Other organisms such as *Chlamydia* species may be responsible for chronic abacterial prostatitis.

**Clinical features**

The clinical features are extremely varied. Only men with symptoms of posterior urethritis, prostatic pain and perigenital pain accompanied by intermittent fever and pus cells or bacteria in the post-prostatic massage specimen should be diagnosed as having chronic prostatitis.

**Diagnosis**

The three-glass urine test is valuable. If the first glass with the initial voided sample shows urine containing prostatic threads, prostatitis is present.

Rectal examination of the prostate may be normal or may show a soft, boggy and tender prostate.

Examination of the prostatic fluid obtained by prostatic massage should show pus cells and bacteria.

Urethroscopy may reveal inflammation of the prostatic urethra, and pus may be seen exuding from the prostatic ducts. The verumontanum is likely to be enlarged and oedematous. In many men with the symptoms described above, all investigations are normal.

**Treatment**

Antibiotic therapy should be administered only in accordance with bacteriological sensitivity tests. Trimethoprim penetrates well into the prostate. If *Trichomonas* or anaerobes are the responsible agent, a rapid response is obtained from administration of flagyl (metronidazole, 200 mg tds for 7 days to both partners). If *Chlamydia* is suspected, doxycycline is the antibiotic treatment of choice. It is uncertain whether prostatic massage helps in eradicating the infection.

**Prostatodynia**

This diagnosis is made by the presence of perigenital pain in the absence of any objective evidence of prostatitis inflammation. Whether the syndrome has any relationship with the prostate is unclear.

**TUBERCULOSIS OF THE PROSTATE AND SEMINAL VESICLES**

Tuberculosis of the prostate and seminal vesicles is rare and associated with renal tuberculosis. In 30 per cent of cases, there is a history of pulmonary tuberculosis within five years of the onset of genitai tuberculosis.

Tuberculosis of one or both seminal vesicles may be found when examining a patient with chronic tuberculous epididymitis, no symptoms being referable to the internal genitalia. On rectal examination, the affected vesicle is found to be nodular.

When the prostate is involved, rectal examination reveals nodules in one or both lateral lobes. Patients with tuberculous prostatitis usually present with the following:

- urethral discharge;
THE PROSTATE AND SEMINAL VESICLES

- painful, sometimes blood-stained, ejaculation;
- mild ache in the perineum;
- infertility;
- dysuria;
- abscess formation.

**Special forms of investigation**

X-ray sometimes displays areas of calcification in the prostate and/or the seminal vesicles.

Bacteriological examination of the seminal fluid yields positive cultures for tubercle bacilli.

**Treatment**

The general treatment is that for tuberculosis. If a prostatic abscess forms, it should be drained transurethrally.

---

**SEMINAL VESICLES**

**Acute seminal vesiculitis**

Acute seminal vesiculitis occurs in association with prostatitis. Prior to the antibiotic treatment of gonorrhoea, gonococcal vesiculitis was common.

**Chronic seminal vesiculitis**

Chronic seminal vesiculitis usually presents with haematospermia and pain on intercourse. TRUS demonstrates the features of distension and thickening and the presence of turbid fluid. The treatment is the same as for chronic prostatitis.

**Tuberculous seminal vesiculitis**

The clinical features and treatment have been discussed above.

**Diverticulum of the seminal vesicle**

Diverticulum of the seminal vesicle occurs occasionally. In such cases, the kidney of that side is absent, and the diverticulum represents an abortive ureteric bud. It is a cause of persistent infection.

**Cyst of the seminal vesicle**

A cyst of the seminal vesicle is uncommon and rarely requires treatment. It may be removed by dissection through an incision similar to that for perineal prostatectomy, if it is large or giving rise to symptoms.

---

**FURTHER READING**

THE MALE URETHRA

Anatomy
The male urethra is a tubular structure extending from the bladder neck to the external urinary meatus at the tip of the glans penis. It has four components which are named (from proximal to distal), the prostatic, membranous, bulbar and penile urethra. The prostatic urethra extends from the bladder neck to the verumontanum and is compressed on either side by the lateral lobes of the prostate, giving it a slit-like configuration. The verumontanum is a small hillock of tissue indented at its crown by a pit called the urticulus masculinus which marks the proximal extent of the external urethral sphincter and is an important landmark for urologists performing transurethral resection of the prostate. The membranous urethra lies just distal to the verumontanum and is located where the urethra penetrates the pelvic floor and it is the usual site of urethral rupture at the time of a pelvic fracture. It is the primary location of continence as a consequence of the surrounding pelvic floor musculature and external urethral sphincter. The bulbar urethra extends from the membranous urethra to the penoscrotal junction and is anteriorly located within the corpus spongiosum. The penile urethra is normally flattened anteroposteriorly, but distends when filled with fluid. The penile urethra becomes dilated within the glans penis where it is named the ‘navicular fossa’.

The external urethral sphincter is composed of circular striated muscle within the urethral wall. The bladder neck contributes to maintenance of continence in the man, although its main role is as a genital sphincter that closes at the time of ejaculation.

Congenital abnormalities
Posterior urethral valves
Posterior urethral valves occur in around one in 5000–8000 live male births. The valves are membranes which typically lie just distal to the verumontanum and cause obstruction to the urethra of boys. They are flap valves and so although they are obstructive to antegrade urinary flow, a urethral catheter can be passed retrogradely without any difficulty. The diagnosis is commonly made antenatally with ultrasound which demonstrates bilateral hydronephrosis above a distended bladder. If the diagnosis is not made antenatally, then patients typically present with urinary infection in the neonatal period or with uraemia and renal failure. Rarely the valves are incomplete and the patient is symptom free until adolescence or adulthood when again urinary infection or renal impairment can supervene.

Diagnosis
Posterior urethral valves need to be detected and treated as early as possible to minimise the degree of renal failure. The valves can be difficult to see on urethroscopy because the flow of irrigant sweeps them into the open position. If the bladder is filled with contrast medium, the dilatation of the urethra above the valves can be demonstrated on a voiding cystogram (Figure 78.1). The bladder is hypertrophied and often shows diverticula. Typically, there is vesicoureteric reflux into dilated upper tracts (Summary box 78.1).

</tr>
</tbody>
</table>
Treatment

Initial treatment is by catheterisation to relieve the back pressure and to allow the effects of renal failure to improve. Definitive treatment is by endoscopic destruction of the valves with continuing supportive treatment of the dilated urinary tract, the recurrent urinary infections and the uraemia (Summary box 78.1).

Hypospadias

Hypospadias occurs in around one in 200–300 male live births and is the most common congenital abnormality of the urethra (see also Chapter 8). There are three characteristic features. Firstly the external meatus opens on the underside of the penis or the perineum, secondly the ventral aspect of the prepuce is poorly developed ('hooded prepuce') and thirdly there is a ventral deformity of the erect penis (chordee).

Hypospadias is classified according to the position of the meatus (Figure 78.2).

- **Glanular hypospadias.** The ectopic meatus is placed on the glans penis, but proximal to the normal site of the external meatus which is marked by a blind pit. Occasionally the two are connected by a channel.
- **Coronal hypospadias.** The meatus is placed at the junction of the underside of the glans and the body of the penis.
- **Penile and penoscrotal hypospadias.** The meatus is on the underside of the penile shaft.
- **Perineal hypospadias.** This is the rarest and most severe abnormality. The scrotum is bifid and the urethra opens between its two halves. There may be testicular maldescent, which may make it difficult to determine the sex of the child.

The more severe varieties of hypospadias represent an absence of the urethra and corpus spongiosum distal to the ectopic opening. The absent structures are represented by a fibrous cord, which deforms the penis in a downward direction (chordee).

Treatment

Hypospadias does not cause either obstruction or urinary tract infection. Surgery is indicated to improve sexual function, to correct problems with the urinary stream and for cosmetic reasons. A variety of plastic surgical procedures have been described to correct the chordee and to re-site the urethral opening. Some techniques utilise the foreskin and therefore circumcision should be avoided before the hypospadias has been repaired. Operations for hypospadias are best performed by a paediatric urologist and are typically undertaken before the age of one year (Summary box 78.2).

**Summary box 78.2**

</tr>
</tbody>
</table>

Epispadias

Epispadias is very rare. In penile epispadias, the urethral opening is on the dorsum of the penis and is associated with an upward curvature of the penis (Figure 78.3). Epispadias often coexists with bladder extrophy and other severe developmental defects.

Urethral diverticulum

This is usually congenital and represents a partial duplication of the urethra. Acquired cases are uncommon but are sometimes seen as a result of increased intraurethral pressure behind a stricture. Others are caused by the longstanding presence of a foreign body such as a stone or calculus in the urethra.

Typically, patients present in adult life with a history of post-micturition dribbling and diagnosis is made at cystoscopy (Figure 78.4) or via a urethrogram. Treatment is often unnecessary, but they can be treated endoscopically by incising the flap of urethral

Figure 78.1 A voiding cystogram showing a dilated bladder with a dilated prostatic urethra above an obstruction at the level of the posterior urethral valve.

Figure 78.2 Hypospadias classification.
mucosa between the two lumens, or in severe cases by excision of the diverticulum.

Injuries to the male urethra

Rupture of the bulbar urethra

There is a history of a blow to the perineum, usually due to a fall astride injury. The bulbar urethra is crushed upwards onto the pubic bone, typically with significant bruising. In the days of sailing ships, the common cause was falling astride a spar and the modern equivalent is seen among workers losing their footing on scaffolding. Cycling accidents, loose manhole covers and gymnasium accidents astride the beam account for a number of cases. Almost certainly King William I of England died in 1087 following a ruptured bulbar urethra that he sustained when falling off his horse. It is thought that he ruptured the urethra on the saddle’s pommel and he subsequently developed urinary retention and sepsis secondary to infection of the haematoma and he died some days after the accident.

Extravasation of urine is common and the extravasated urine is confined in front of the midperineal point by the attachment of Colles’ fascia to the triangular ligament and by the attachment of Scarpa’s fascia just below the inguinal ligament. The external spermatic fascia stops it getting into the inguinal canals. Extravasated urine collects in the scrotum and penis and beneath the deep layer of superficial fascia in the abdominal wall.

Clinical features

The signs of a ruptured bulbar urethra are perineal bruising and haematoma, typically with a butterfly distribution. There is usually bleeding from the urethral meatus and retention of urine is also typically present.

Management

If the diagnosis is suspected, the patient should be treated with appropriate analgesia and antibiotics should be administered. He should be discouraged from passing urine. A full bladder should be drained with a catheter placed by percutaneous suprapubic puncture (Figure 78.5). This reduces urinary extravasation and allows investigations to establish the extent of the urethral injury. If the patient has passed urine when first seen and there is no extravasation, the rupture, if any, is partial and a suprapubic catheter is not usually needed. Diagnosis is made by urethrography using water soluble contrast.

If there is significant extravasation, then the perineal collection should be drained.

If the urethral tear is complete, the suprapubic catheter should remain in situ while the bruising and extravasation settle down. A stricture will typically develop at the site of the injury. The optimal treatment is delayed anastomotic urethroplasty after the swelling and bruising have settled down (typically 8–12 weeks later), with excision of the traumatised section and spatulated end-to-end reanastomosis of the urethra (Summary box 78.3).

Summmary box 78.3

Bulbar urethral injury

- Suspect urethral injury after blunt perineal trauma when the man cannot void, when there is perineal bruising and when there is blood at the urethral meatus
- The safest initial management is to insert a suprapubic catheter
- Beware of urinary extravasation and sepsis in the perineal haematoma
- Delayed urethroplasty is the preferred definitive management of complete disruptions

Rupture of the membranous urethra

Rupture of the membranous urethra typically occurs in association with a fractured pelvis and may be associated with an extraperitoneal rupture of the bladder. When the pelvis fractures, the membranous urethra is ruptured as it passes through the bony ring of the pelvis. The urethra is elastic at this point, and if the fracture results in only a minor displacement, then the tear may only be partial, but more typically the rupture is complete, such that the two ends are completely displaced, with the develop-
ment of a significant interposing haematoma. About 5 per cent of cases of fractured pelvis have an associated urethral injury and such injuries are almost universally seen in men.

Clinical features
The most common causes of pelvic fracture are road traffic accidents, severe crush injuries and falls. Typically there are multiple associated injuries that may be immediately life-threatening and the overriding priority is to keep the patient alive by appropriate resuscitation. Under these circumstances, the management of the other injuries takes precedence.

The clinical features include urinary retention, blood at the urethral meatus and a high riding prostate on digital rectal examination. If the diagnosis is suspected, a urethrogram performed with water soluble contrast media is confirmatory (Figure 78.6).

A suprapubic catheter should be inserted as soon as practicable. The distended bladder may be palpable making suprapubic catheterisation straightforward, but often the bruising and swelling associated with the fracture makes this difficult and ultrasound guidance is required. In the presence of a coexistent extraperitoneal bladder injury, no bladder will be apparent on ultrasound examination, and surgical exploration, bladder repair, suprapubic catheter placement and drainage of the retro-pubic space are needed.

Complications
Urethral disruption injury
The two ends of the urethra, having been torn apart, become separated by a haematoma. With time, this haematoma resolves and is replaced by fibrosis. This pelvic fracture urethral disruption injury is technically not a stricture of the urethra but is often erroneously described as being one. The conventional management of such an injury is delayed surgical reconstruction with excision of the scar tissue and end to end anastomosis. This surgery should be delayed until the patient has recovered from any other injuries and is usually undertaken 3–6 months later. It is a highly challenging technical procedure and should be undertaken only in specialist centres. Some surgeons continue to undertake early attempts to realign the urethral ends endo-
The male urethra

1363

the urethral, prostatic or bladder rupture is required (Summary box 78.4).

**Summary box 78.4**

**Pelvic fracture urethral disruption injury**
- Suspect the diagnosis in cases of pelvic fracture, when the patient has not voided and when there is blood at the urethral meatus
- A water soluble urethrogram confirms the diagnosis
- Initial management is insertion of a suprapubic catheter
- Surgical exploration is needed if there is coexistent rupture of the bladder
- Delayed anastomotic urethroplasty is the preferred definitive management

**Inflammation of the urethra**

Inflammatory conditions of the urethra include:
- meatal ulcer
- urethritis
- gonococcal urethritis
- non-specific urethritis
- Reiter’s disease
- peri-urethral abscess.

**Ulcration of the urethral meatus**

Meatal ulcer is an uncommon complication of neonatal circumcision and may develop up to two years after the circumcision. Lack of protection by the prepuce seems to be the primary cause, with friction from clothing and ammoniacal dermatitis also being contributory factors. Devascularisation caused by ligation of the frenular artery may also possibly play a part. The ulcer forms a scab that blocks the meatus and the child can pass urine only by bursting the scab. This hurts, so the boy screams; a tiny amount of blood may be passed as well. The process causes fibrosis, which can result in an acquired pinhole meatus. Local measures to soften the scab and alkalinise the urine are often curative although a few do need meatotomy.

**Gonorrhoeal urethritis**

Gonorrhoea is a sexually transmitted disease caused by *Neisseria gonorrhoeae* (gonococcus), a Gram-negative kidney-shaped diplococcus that infects the anterior urethra in men, the urethra and cervix in women and the oropharynx, rectum and anal canal in both sexes, but especially men. It is transmitted by unprotected sexual intercourse.

Most men have symptoms typical of urethral discomfort and urethral discharge. There is often scalding dysuria. In women it is often asymptomatic. Symptoms, which are present in 50 per cent or less, usually consist of a mild dysuria or slight urethral discharge, which can go unnoticed by the patient. Cervicitis can occur with about 10 per cent suffering from pelvic inflammatory disease (salpingitis), which, if bilateral, may lead to infertility. A mother may transmit gonorrhoea to her newborn during childbirth with the risk that blindness of the child can result. In addition, in both men and women exposed orally or anally, gonococcal infections can cause a predominantly asymptomatic pharyngitis or proctitis.
Investigations
Traditionally the diagnosis was made by identification of pus and gonococci in a Gram-stained urethral smear with subsequent culture. However, more recently PCR-based techniques, which are more sensitive, are the norm.

Complications
Complications are prevented by effective early treatment. In men, complications include posterior urethritis, prostatitis (acute or chronic), acute epididymo-orchitis, periurethral abscess and urethral stricture. Gonococcal arthritis, iridocyclitis, septicemia and endocarditis are unusual.

Treatment
Treatment is with antibiotics, with ceftriaxone currently the treatment of choice as a consequence of the increasing prevalence of antibiotic resistance to more traditional antibiotics such as ciprofloxacin or penicillin. Contact tracing is important in controlling the spread of the disease and management is usually by a genitourinary physician.

Non-specific urethritis (synonym: non-gonococcal urethritis)
Non-specific urethritis (NSU) is a sexually transmitted infection that in around 40 per cent of cases is due to Chlamydia trachomatis with other cases being caused by Ureaplasma urealytica or Mycoplasma genitalium. The causative agent in up to 50 per cent of cases is unknown.

Clinical features
In men, dysuria and a white mucopurulent urethral discharge appear up to 6 weeks after sexual intercourse. The urine appears to be clear but may contain ‘threads’ or pus cells. Epididymitis is common and urethral stricture can result. In women, the condition is usually asymptomatic although it can present as vaginal discharge or as a form of urethrotrigonitis. It may result in cervicitis or pelvic inflammatory disease.

Treatment
Exclusion of gonorrhreal infection is important. Chlamydial infection is diagnosed by PCR techniques on a urethral swab or a urine sample. Treatment with oxytetracycline or doxycycline is usually effective although relapse is common, especially in men, in whom the prostate may act as a reservoir of infection. Azithromycin is an alternative treatment taken as a single oral dose. It is important to treat both partners as reinfection is probable if this is not done.

Reiter’s disease (synonym: sexually acquired reactive arthritis)
Reiter’s disease is an autoimmune disease characterised by the triad of urethritis or diarrhoea, conjunctivitis and polyarthritus. Common triggers include Chlamydial urethritis, less commonly gonococcal urethritis and diarrhoea secondary to Salmonella, Shigella or Campylobacter. It is an HLA-B27 associated condition. The conjunctivitis (present in around 50 per cent) and arthritis typically occur 1–3 weeks after the primary infection. Diagnosis is made on clinical grounds and treatment is largely symptomatic, although antibiotic treatment of the precipitating infection is important. The urethritis and conjunctivitis frequently subside after a few weeks but the arthritis may persist for months. Severe anterior uveitis and frequently recurrent attacks suggest a poor outlook.

Periurethral abscess
Periurethral abscesses can be penile, bulbar or chronic.

Penile periurethral abscess
A penile periurethral abscess arises as an acute gonococcal infection of one of the glands of Littre. The tender induration felt on the underside of the penis points and discharges externally, often leaving a fistula. An anterior urethrotomy will encourage the abscess to burst into the urethra. When the abscess lies behind a stricture, it should be opened externally.

Bulbar periurethral abscess
A bulbar periurethral abscess is a spreading cellulitis caused by infection with streptococci and anaerobic organisms, possibly associated with a stricture. Extravasation of urine is not unusual. There is perineal pain with pyrexia, rigors and tachycardia. Tenderness and swelling rapidly spread from the perineum to the penis and the anterior abdominal wall. Antibiotics are essential. Collections of pus should be drained and the urethra should be defunctioned by a suprapubic urinary catheter.

Chronic periurethral abscess
A chronic periurethral abscess sometimes results from a longstanding urethral stricture (Figure 78.7). The multiple loculi of pus should be drained and the stricture treated. Urethral fistula occurs either spontaneously or as a result of incision of the abscess.

Hans Conrad Julius Reiter, 1881–1969, President of the Health Service and Honorary Professor of Hygiene, Berlin, Germany, described this condition in 1916. He was subsequently convicted of war crimes as a consequence of his involvement in the death of hundreds of inmates in Buchenwald.
The male urethra

**Urethral stricture**

**Causes**
The common causes of urethral stricture are:

- **Inflammatory**
  - Secondary to urethritis
  - Secondary to balanitis xerotica obliterans
- **Traumatic**
  - Bulbar urethral injury
  - Pelvic fracture urethral disruption injury
- **Iatrogenic**
  - Secondary to urethral instrumentation
  - Secondary to transurethral prostatectomy
  - Secondary to radical prostatectomy
- **Idiopathic.**

**Pathophysiology**
Post-inflammatory strictures are less common since the introduction of effective antibiotic treatment of gonorrhoea. The stricture is most commonly seen in the bulbar urethra but submeatal strictures also occur. There is infection in the periurethral glands which persists after inadequately treated gonorrhoea. The infection spreads to cause a periurethritis, which heals by fibrosis. Most strictures appear within one year of infection but may not cause difficulty in micturition for some time later.

Balanitis xerotica obliterans is a rare condition characterised by fibrosis of the foreskin resulting in phimosis. In around 10 per cent of cases, the glans penis is also affected causing meatal stenosis and, in a proportion of these cases, there is also fibrosis and strictureting of the penile urethra. The cause of the condition is unknown, but the strictures produced are typically long and difficult to treat.

Post-traumatic strictures have been discussed previously.
Post-instrumentation strictures follow endoscopy or catheterisation and may affect any part of the urethra. Some surgeons recommend prophylactic dilatation or urethrotomy before transurethral prostatectomy in order to try to avoid this complication. Some cases of stricture seem to be due to sensitivity to chemicals from a catheter, but most are the result of a combination of trauma, infection and pressure necrosis.

Bladder neck stenosis can occur following transurethral resection of the prostate (TURP) and following radical prostatectomy for the treatment of prostate cancer. If it cannot be managed by dilatation, bladder neck stenosis should be treated by transurethral incision and resection of the stricture, although in the man who has undergone radical prostatectomy, this will result in urinary incontinence.

**Clinical features**
Symptoms are usually hesitancy of micturition, straining to void and a poor urinary stream. The relative youthfulness of the patient often rules out prostatic enlargement, which characteristically occurs after the age of 50. As the stream becomes narrower, micturition is prolonged and is followed by post-micturition dribbling as a result of urine trickling from the dilated urethra proximal to the stricture. Urinary frequency by day and night is common and is due to incomplete bladder emptying, coexistent detrusor overactivity or urinary infection. The urinary flow rate is typically prolonged and plateau shaped (Figure 78.8).

A well-established stricture may be palpable as scarring along the line of the urethra. If the stricture is tight enough, the patient will go into acute retention, although this is rare. If this happens there is a danger that clumsy attempts to pass a urethral catheter will result in a false passage. If a patient has gone into retention because of a urethral stricture, its lumen will be too narrow to pass even a tiny catheter and suprapubic catheterisation is required.

Urethroscopy allows the stricture to be viewed as a circumferential scar (Figure 78.9). Openings of false passages commemorate previous misguided attempts to pass a urethral catheter.

Urethrography using a water-soluble contrast medium will show the extent and severity of the stricture (Figures 78.10 and 78.11).
Complications
The most common complication of a urethral stricture is urinary tract infection, which usually responds to antibiotic treatment although there is a tendency for them to recur as a consequence of the increased residual urines within the bladder. Any of the complications of bladder outflow obstruction can occur, including bladder calculi and upper tract dilatation with renal impairment, although the latter is rare. Similarly, retention of urine is also rare, and should be treated by suprapubic catheterisation. Rare complications include urethral diverticulum and paraurethral abscess (Summary box 78.5).

Summary box 78.5
Diagnosis of urethral stricture
- Suspect the diagnosis of urethral stricture in a young man with poor urinary stream
- Diagnosis is made either by visualisation (urethroscopy) or radiologically (by urethrography)
- Urinary infection should be excluded

Treatment
The management of urethral strictures has changed considerably over the past 20 years. The old treatments of urethral dilatation have largely been superseded by endoscopic incision (internal urethrotomy) or by formal reconstruction (urethroplasty). Urethral dilatation still has a place in elderly men with short strictures that recur infrequently and when the stricture is intimately related to the continence mechanism (such as the bladder neck stricture that follows radical prostatectomy). In these patients, occasional dilatation may be preferable to more complex procedures.

Internal urethrotomy cures around 50 per cent of short strictures. Success rates are highest when the stricture is short and when it is present within the bulbar urethra. In contrast, failure rates are highest in long strictures, strictures within the penile urethra and in recurrent strictures. In patients with recurrent strictures who are unable or unwilling to undergo urethroplasty, then intermittent self-dilatation with soft hydrophilic catheters on a regular (daily) basis can prevent stricture recurrence, although such self-dilatation is needed lifelong.

Short strictures with a clear traumatic history should be treated by urethroplasty since cure rates in excess of 90 per cent can be achieved by excision of the stricture with end to end anastomosis. Therefore, a conventional therapeutic algorithm is to offer an internal urethrotomy to all newly diagnosed strictures (excluding post-traumatic strictures), and to reserve the more major urethroplasty procedures for recurrent strictures.

Urethral dilatation
This is the old treatment for stricture. Under aseptic conditions, the urethra is stretched using graduated dilators. With care and gentleness, the procedure can be performed under local urethral anaesthesia with lignocaine gel. The drawback of dilatation is that it is performed ‘blind’, so there is always a danger of causing a false passage. This is most likely with an inexperienced operator unfamiliar with the complexities of an individual patient’s urethra.

Strictures have been treated by surgeons for centuries and there are many different dilating instruments. A simple stricture may be dilated using metal sounds (Figure 78.12), so called because they were originally used to ‘sound’ for stones in the bladder. These must be wielded with great care as it is easy to make a false passage.

Endoscopic (internal) urethrotomy
Internal urethrotomy is performed using the optical urethrotome. The stricture is cut under visual control using a knife passed through the sheath of a rigid urethroscope. The stricture is usually cut at the 12 o’clock position, taking care not to cut too deeply into the vascular spaces of the corpus spongiosum that surrounds the urethra. Other cuts can be made...
Urethroplasty
The simplest urethroplasty involves excision of the stenosed length of urethra and reanastomosis of the spatulated cut ends. This operation is possible only if the stricture is relatively short because there must be no tension at the suture line. If an end-to-end anastomosis is not feasible, a large number of different surgical procedures can be used to reconstruct the fibrosed urethra. The operations using myocutaneous flaps of penile and scrotal skin that dominated the field 20 years ago have largely been replaced by operations that utilise free grafts, usually of buccal mucosa, but also occasionally of penile skin, lingual mucosa and bladder mucosa. The advantage of buccal mucosa is that there is a plentiful supply (approximately 6–7 cm can be obtained from each cheek), it is tough with an excellent vascular plexus, it is easy to manipulate, it is tough with an excellent vascular plexus, and the donor site is minimal. Indeed, the morbidity associated with the donor site is minimal.

Urethroplasty should be considered when the stricture has arisen following trauma, and when a stricture has recurred following endoscopic treatment. The actual technique used should depend upon the site of the stricture, the length of the stricture and the cause of the stricture. Careful preoperative assessment with ascending and descending urethrography is vital.

Anastomotic urethroplasty has a success rate of around 90 per cent while substitution urethroplasty has success rates at ten years of around 80 per cent (Summary box 78.6).

Other conditions of the urethra

Treatment of urethral strictures

- Newly diagnosed strictures are best treated initially by internal urethrotomy with a 50 per cent success rate
- Intermittent self-dilatation increases the success rate of internal urethrotomy alone
- Urethroplasty should be considered in traumatic strictures and in recurrent strictures
- Treatment by intermittent self-dilatation should be considered in strictures closely related to the external sphincter mechanism

OTHER CONDITIONS OF THE URETHRA

Urethral fistula
The most frequent cause of urethral fistula is bursting or incision of a periurethral abscess. If the fistula arises behind a tight stricture, there may be multiple openings (watering-can perineum). A fistula can also follow urethroplasty if there is necrosis of part of the graft or flap. The stricture should be treated, in which case some fistulae heal themselves. Occasionally, formal urethroplasty is indicated.

Urethral calculi
Urethral calculi can arise primarily behind a stricture or in an infected urethral diverticulum. More commonly, the stone is a renal calculus that has migrated to the urethra via the bladder.

Clinical features
Migratory calculi cause sudden pain in the urethra soon after an attack of ureteric colic. There is blockage to the flow of urine and, if the stone is small, the force of the jet will usually expel it from the urethral meatus. Larger stones get stuck and must be removed endoscopically. It is sometimes possible to feel the calculus as a hard lump in the urethra, but if there is doubt the diagnosis is confirmed by urethroscopy.

A stone formed within the urethra is less likely to cause recognised symptoms and is usually detected during urethroscopy or bouginage.

Treatment
A stone lodged within the prostatic urethra should be displaced back into the bladder and treated by lithotripsy or supraperineal cystotomy as if it were a bladder stone. Calculi in more distal parts of the urethra are removed by basketing under vision or fragmented in situ using the electrohydraulic or ultrasonic lithotripter. It may be necessary to perform a meatusotomy to deliver the stone. Open removal by external urethrotomy is rarely necessary.

Neoplasms
Polyps are a relatively common finding in the prostatic urethra, where they may result from chronic infection. Genital warts acquired by sexually transmitted infection are sometimes found in the anterior urethra as an extension of warts on the skin of the glans penis. Angioma of the urethra is a very rare cause of urethral bleeding.
Carcinoma of the urethra is relatively rare. Multifocal transitional cell cancers of the bladder are sometimes associated with tumours in the prostatic urethra and occasionally more distally. Though superficial and susceptible to local ablation by diathermy or laser, they are associated with a tendency to distant spread. Squamous carcinoma can develop in an area of squamous metaplasia sometimes seen with a urethral stricture. It carries a poor prognosis even if the patient is treated by radical surgery. Bloody urethral discharge without infection should raise the suspicion that the patient has a urethral tumour.

**THE FEMALE URETHRA**

**Anatomy**

The female urethra is around 2–3 cm long, extending from the bladder neck to the external urethral meatus. Continence is maintained by the external striated urethral sphincter, which in women extends for almost the whole length of the urethra. There is extra support from the surrounding pelvic floor musculature. In contrast to men, the female bladder neck has little role in the maintenance of continence.

Abnormalities of the female urethra include:

- prolapse
- stricture
- Fowler’s syndrome (dysfunction of the striated urethral sphincter)
- diverticulum
- caruncle
- papillomata acuminata
- carcinoma.

**Prolapse (synonym: urethrocele)**

Weakening of the tissues that hold the urethra in place can cause it to move and to put pressure on the vagina, leading to the prolapse of the anterior distal wall of the vagina. Urethrocese often occur with cystoceles. Prolapse occurs in later life and is usually, in part, due to the trauma of childbirth. Prolapse of the urethral lining also occurs as a congenital abnormality, when it causes discomfort proportional to the degree of prolapse.

**Stricture**

Urethral strictures are uncommon in women but may follow urethritis or more commonly the trauma of a difficult labour. Urinary retention is an occasional consequence and is usually chronic. True urethral strictures in women respond well to dilatation.

**Fowler’s syndrome**

This condition, which was described by Fowler and Kirby, is associated with an abnormal myotonic discharge in the striated urethral sphincter, which can be detected by electromyography. It causes urinary retention in women and should not be confused with a urethral stricture. Urethral dilatation is ineffective and the retention is best treated by intermittent self-catheterisation. There is some evidence that sacral neuromodulation can be effective.

**Diverticulum**

A urethral diverticulum is more commonly seen in women than in men. Some seem to be congenital while others are acquired by rupture of a distended urethral gland or injury of the urethra during childbirth. Urine within the diverticulum becomes infected, causing local pain and repeated bouts of cystitis. Purulent urine is discharged if the urethra is compressed with a finger placed in the vagina. Diagnosis is by magnetic resonance imaging (MRI) or by transvaginal ultrasound. Excision of the diverticulum through the anterior vaginal wall is effective, but care must be taken not to damage the urethral sphincter.

**Caruncle**

This is common in elderly women. It presents as a soft, raspberry-like, pedunculated granulomatous mass about the size of a pea, attached to the posterior urethral wall near the external meatus. It is composed of highly vascular connective tissue stroma infiltrated with pus cells. There may be frequency of micturition and urethral pain afterwards. Occasionally, there is bleeding. A urethral prolapse is less tender and is not pedunculated. Treatment is by excision and diathermy coagulation of the base of the stalk. The patient should be given antibiotics to treat the underlying chronic urethritis.

**Papillomata acuminata**

Papillomata acuminata are the same as the sexually transmitted warts that occur on the penis. They are treated in the same way. In African women, papillomata acuminata are common and may grow to such a large size during pregnancy that they obstruct labour and necessitate a caesarean section.

**Carcinoma of the urethra**

This occurs twice as often in women as in men. Whether a caruncle can become malignant is disputed, but caruncules and tumours often occur close together. Malignant swellings of the urethra feel harder than benign ones. Treatment by radiotherapy or radical surgery is often ineffective. The overall prognosis is poor.

**THE PENIS**

**Anatomy**

The penis is composed of three tubular structures. The upper two structures, which are apposed to each other, are called the corpora cavernosa and are anchored posteriorly onto the pubic rami. They provide the erectile function. The third tubular structure is the corpus spongiosum, which contains the urethra and it expands distally to form the glans penis. The corpora cavernosa have an outer covering of tunica albuginea which is relatively inelastic and which also forms the septum between them. The tunica albuginea encloses the erectile tissue itself which has

---

**Note:**

A caesarean section is the operation of delivering the fetus by an incision into the uterus, usually through the abdominal wall. More than one explanation has been given as the origin of the term. The word ‘caesarean’ could be a derivative of the Latin term ‘caedo’, which means to cut. The thought that it derives from the name of the Roman Emperor Julius Caesar is untrue as his mother Aurelia successfully gave birth to her son by natural means and later was an advisor to him. The most plausible explanation is that the Roman or Caesarean Law (law during Caesar’s time) demanded that when a pregnant woman died, her body could not be buried until the fetus had been removed.)

a trabecular structure with a network of sinusoidal spaces lined by endothelium within which the blood pools during erection. The central arterial blood supply (the central penile artery) is a branch of the internal pudendal artery. Erection occurs when the parasympathetic nerves that innervate the penis cause smooth muscle relaxation with increased arterial inflow and dilatation of the sinusoids, such that blood accumulates within the trabecular spaces.

**DISEASES OF THE FORESKIN**

**Phimosis**
Phimosis is overdiagnosed in children (see also Chapter 8). At birth, the foreskin is normally adherent to the glans penis. These physiological adhesions between the foreskin and the glans penis may persist until six years of age or more, giving the false impression that the prepuce will not retract. This condition (sometimes known as physiological phimosis) should not be confused with true phimosis in boys, with scarring of the prepuce such that it will not retract without fissuring of the foreskin (Figure 78.13). In these cases, the aperture in the prepuce may be so tight as to cause urinary obstruction. Urinary difficulty with residual urine and back pressure effects on the ureters and kidney is far more commonly caused by meatal stenosis, which may be masked by the prepuce.

In adults, phimosis is due to scarring of the foreskin as a consequence of balanitis (inflammation of the glans penis), posthitis (inflammation of the foreskin), forcible retraction of the foreskin or lichen sclerosus et atrophicus (synonym: balanitis xerotica obliterans or BXO).

BXO is an uncommon condition in which the normally pliant foreskin becomes thickened. It typically becomes whitish in appearance and forms a constricting band (cicatrix) which prevents retraction (Figure 78.14a,b). BXO may also affect the glans penis (causing meatal stenosis) (Figure 78.15) and the penile urethra (causing urethral stricture). As a consequence it is difficult to keep the penis clean, there may be recurrent attacks of balanitis and there is both a problem with hygiene and, in later life, an increased susceptibility to carcinoma.

**Treatment.**
In a young child with a non-retractile foreskin, no treatment is necessary or appropriate. When the foreskin is mildly scarred, then preputioplasty is possible. For all other cases, circumcision is the appropriate treatment. In cases of BXO, circumcision is often curative, although when the condition affects the glans penis, topical steroid cream may be helpful. In resistant cases, formal meatotomy is necessary. In emergency situations, such as when catheterisation is required, but is impossible, then it is possible to divide the foreskin dorsally under local anaesthetic (a so-called dorsal slit).

**Preputioplasty**
This is an application of the Heineke Mikulicz principle whereby the tight ring of the foreskin is divided longitudinally and sewn transversely, thereby allowing retraction of the preserved foreskin. There is a recurrence rate and it is only indicated in mild cases with minimal scarring. If it fails, then circumcision is indicated.

**Circumcision**
Apparently, circumcision did not originate among the Jewish people: they took the practice either from the Babylonians or from African tribes, probably the latter. It had been practised in West Africa for over 5000 years.

**Indications**
In infants and young boys, circumcision is most usually performed at the request of the parents for social or religious reasons. Medical indications for circumcision in boys include true phimosis, BXO (rare under the age of five years), recurrent attacks of balanoposthitis and recurrent urinary tract infections with an abnormal upper urinary tract. Phimosis may result from misguided attempts by parents to expose the glans forcibly.

In adults, circumcision is indicated because of an inability to retract the foreskin for intercourse, for splitting of an abnormally tight frenulum or for recurrent balanitis.

Recently evidence has emerged that circumcision protects against the spread of human immunodeficiency virus (HIV), and a large scale programme of adult circumcision under the auspices of the World Health Organisation is planned for some African countries where HIV is a major health problem.

**Technique in an infant**
Applying a clamp or bone forceps across the prepuce distal to the glans with blind division of the foreskin is to be condemned. To see one boy with partial or total amputation of the glans is enough to realise the folly of this technique. It is far better to perform a proper circumcision under direct vision as in an adult.
The Plastibel device can be used in infants (Hollister) and its use is shown in Figure 78.16a–c: the ring separates between 5 and 8 days postoperatively.

**Technique in adolescents and adults**

In adolescents and adults, the following method is preferable. The prepuce is held in artery forceps and put on a gentle stretch. A circumferential incision in the penile skin is made at the level of the corona using a knife. Marking the skin with a pen is often helpful prior to the incision to ensure that excess skin is not removed. The prepuce is then slit dorsally in the midline to within 1 cm of the corona. This converts the foreskin into two flaps connected at the midline anteriorly. When the under-surface of the prepuce has been separated from the glans, the inner layer of each flap is incised with a second circumferential incision, leaving about 0.5 cm of the inner layer of the preputial skin. Cutting the remaining connective tissue completes the excision (Figure 78.17a–e). Monopolar diathermy must be avoided in operations on the penis in small boys because there is a danger that the current path will cause coagulation at the base of the penis. Haemostasis is important in circumcision however, and vessels should be secured with bipolar diathermy or with absorbable ligatures. The cut edges of the skin are approximated using interrupted sutures being certain that the frenular vessels are ligated (Summary box 78.7).

**Summary box 78.7**

**Circumcision**
- Is most commonly performed for cultural reasons
- Is not indicated for failure of retraction caused by congenital adhesions between the glans penis and the prepuce
- Is indicated when there is true phimosis with balanoposthitis or obstruction to urinary flow
- Never use monopolar diathermy when performing circumcision

**Frenulum breve**

Phimosis should not be confused with this condition, where the frenulum is short, such that it causes pain when the foreskin is retracted. Another possible presentation is tearing of the frenulum during sexual activity. Treatment is by frenuloplasty, which utilises the Heineke Mikulicz principle to ‘lengthen’ the frenulum.

**Paraphimosis**

A tight foreskin once retracted may be difficult to return and a paraphimosis results. In this condition, the venous and lymphatic return from the glans and distal foreskin is obstructed and these structures swell, causing even more pressure within.
the obstructing ring of prepuce. Icebags, gentle manual compression and injection of a solution of hyaluronidase in normal saline may help to reduce the swelling. Such patients can be treated by circumcision if careful manipulation fails. A dorsal slit of the prepuce under local anaesthetic may be enough in an emergency.

**Balanoposthitis**

Inflammation of the prepuce is known as posthitis; inflammation of the glans is balanitis. The opposing surfaces of the two structures are often involved, hence the term ‘balanoposthitis’. Skin conditions such as lichen planus and psoriasis affect the penis and, indeed, may be localised there. Drug hypersensitivity reactions can affect the skin of the penis. In mild cases, the only symptoms are itching and some discharge. In more severe inflammation, the glans and foreskin are red-raw and pus exudes. Balanoposthitis is associated with penile cancer, diabetes and phimosis. Monilial infections are quite common under the prepuce. Treatment is by broad-spectrum antibiotics and local hygiene measures. If there is associated phimosis, then a circumcision is required.

**Preputial calculi**

Later in life, chronic posthitis may lead to adhesions between the prepuce and the glans and closure of the orifice of the preputial sac. Preputial calculi result from the accumulation beneath a non-retractable foreskin of inspissated smegma, urinary salts or both.
INJURIES OF THE PENIS

Avulsion of the skin of the penis
Entanglement of clothing in rotating machinery is the usual cause. Repair is effected by burying the shaft of the penis in the scrotum with subsequent release at the time of a definitive plastic surgical repair.

Fracture of the penis
Fracture of the penis is an uncommon accident, usually occurring when the erect penis is bent violently downwards during intercourse. The forced deformity results in a rupture of the tunica albuginea with immediate extravasation of blood from within the penis. There is typically a loud cracking sound with immediate loss of the erection, and the rapid development of a large bruise around the penis and extending onto the scrotum (Figure 78.18). There may occasionally be an associated urethral injury. Optimal management involves early exploration of the penis with surgical repair of the ruptured tunica albuginea.

Strangulation of the penis
Strangulation of the penis by rings placed on the penis, usually for sexual reasons, can cause venous engorgement which prevents their removal. It may help to aspirate the corpora cavernosa but often the ring must be cut off with a ring cutter or hacksaw.

Other abnormalities of the penis

Erectile dysfunction
Failure to attain or maintain an erection is called erectile dysfunction (ED). It is a symptom, rather than a condition in itself. It can arise as a consequence of psychological issues, but the most common cause is vascular disease, and as such ED is associated with diabetes, hypertension, dyslipidaemia and smoking. Other rarer causes include endocrine disease (hypogonadism and prolactin secreting pituitary tumours), neurological disease (multiple sclerosis, spinal cord injury and prolapsed intervertebral disc), iatrogenic damage to the cavernosal nerves due to radical pelvic surgery (e.g. radical prostatectomy, abdominoperineal excision of the rectum and radical cystectomy), neuropathic secondary to pelvic radiotherapy and drug-induced cases (including anti-hypertensive agents, antidepressants and antipsychotics).

Assessment involves confirmation of the diagnosis by taking a careful history, assessing the patient for underlying risk factors, and trying to identify the rare case that can be cured as opposed to being treated. Physical examination of the genitalia, the blood pressure and assessment of the secondary sexual characteristics is required and biochemical assessment of the blood sugar, the serum lipid profile and the serum testosterone is necessary in all cases.

Treatment for most patients involves the use of the phosphodiesterase type 5 inhibitors (such as sildenafil) with intracavernosal injection of prostaglandin, vacuum pumps and penile implants reserved for resistant cases (Summary box 78.8).

Peyronie’s disease
Peyronie’s disease is characterised by penile deformity (Figure 78.19), palpable penile plaques within the penis, erectile dys-

Summary box 78.8

Erectile dysfunction
- The most common cause of erectile dysfunction is atherosclerosis
- Appropriate investigation involves identification of vascular risk factors
- Phosphodiesterase inhibitors are the first line treatment for most men

function and pain on erection. The cause is unknown, but probably involves minor injury to the erect penis with secondary microhaemorrhage beneath the tunica albuginea and secondary fibrosis. The latter results in the palpable plaques that can be identified on examination. The plaques may rarely be calcified (Figure 78.20). The presence of these relatively inelastic plaques causes the erect penis to bend, often dramatically, towards the side of the plaque. The most common direction of deformity is dorsally (towards the abdomen) and the deformity may be so great as to prevent penetrative sexual intercourse.

While the aetiology is uncertain, there is an association with Dupuytren’s contracture. The natural history of the condition is that it typically progresses for 18–24 months before stabilising. During this active phase of the disease, surgery is not indicated, and a variety of medical treatments have been tried, although none with any good evidence of benefit.

When the disease has stabilised, the crucial issue is whether the patient is still able to have sexual intercourse. If he cannot then no treatment is indicated, while if the deformity prevents penetration, or makes it difficult, then corrective surgery is indicated. Using this criterion, only around a quarter of men come to surgery. The most common procedure is the Nesbitt procedure which corrects the deformity by plicating the convex side of the deformity, thereby straightening the penis, with some accompanying loss of length (Summary box 78.9).

François de la Peyronie, 1678–1747, surgeon to King Louis XIV of France, and founder of the Royal Academy of Surgery, Paris, France.

Reed Nesbitt, urological surgeon, Nashville, TN, USA.

Figure 78.18 Penile fracture. Note the extensive bruising of penis and scrotum.
Summary box 78.9

Peyronie’s disease

- Medical treatments during the active phase have little evidence of efficacy
- The disease has a natural history of 18–24 months active disease before it stabilises
- Surgery may be indicated to correct deformity that interferes with sexual activity
- Surgical treatment will shorten the erect penile length

Chordee

Chordee (French = corded) is a fixed bowing of the penis caused by hypospadias or, more rarely, chronic urethritis. Erection is deformed and sexual intercourse may be impossible. Treatment is usually surgical.

Priapism

Priapism means persistent erection lasting longer than 4 hours and it is a surgical emergency. There are two main types of priapism, ischaemic and non-ischaemic.

Ischaemic priapism

Ischaemic or venogenic priapism is the more common and is due to venous congestion, with consequent thrombosis and ischaemia. The penis remains erect and becomes painful. This is a pathological erection and the glans penis and corpus spongiosum are not involved. The condition is most commonly seen as a side effect of medication, most notably anti-psychotic medication and intracavernosal injections, but it can also arise as a complication of a hypercoagulable blood disorder such as sickle cell disease or leukaemia. A tiny proportion of cases are caused by malignant disease in the corpora cavernosa or the pelvis.

Summary box 78.10

Ischaemic priapism

- The characteristic clinical features are a painful erection not involving the glans penis
- Blood gas analysis from the penis shows hypoxia, hypercapnoea and acidosis
- Detumescence should be ideally achieved within 6–12 hours to avoid long-term erectile dysfunction

Non-ischaemic priapism

The rarer form of priapism arises as a consequence of traumatic damage to the central penile artery, usually as a consequence of blunt perineal trauma. A fistula develops between the artery and the sinusoidal space which results in a persistent erection, which in contrast to the ischaemic priapism is painless. Blood gas analysis shows arterial blood and Doppler scanning demonstrates the fistula (Figure 78.21a,b). Treatment is not an emergency, since there is no ischaemia, and is most appropriately achieved by selective arterial embolisation.

Carcinoma of the penis

Penile cancer is rare in the UK, with only around 600 cases being recorded annually. It is much more common in other parts of the world, most notably South America, where it is one of the most common cancers.
Aetiology
Circumcision soon after birth confers immunity against carcinoma of the penis. Later circumcision does not seem to have the same benefit, with the assumption that smegma is in some way carcinogenic. Human papillomavirus infection with penile warts is a risk factor, as is BXO and smoking. Phimosis and chronic balanoposthitis are known to be contributory factors, and there are definite precancerous states including leukoplakia of the glans, which is similar to the condition seen on the tongue, and carcinoma in situ of the penis.

Carcinoma in situ of the penis (synonym Bowen’s disease, erythroplasia of Queyrat)
Carcinoma in situ of the penis is typically seen as a red cutaneous patch on the penis. When it occurs on the glans penis, it is known as erythroplasia of Queyrat and when it occurs on the shaft of the penis it is called Bowen’s disease. There are several other benign causes of red patches on the penis, and when in doubt a biopsy is indicated. When the diagnosis of carcinoma in situ is confirmed, treatment is by means of topical 5-FU cream, CO2 laser ablation or surgical excision.

Pathology
Carcinoma of the penis is most typically a squamous cell carcinoma arising in the skin of the glans or the prepuce. It may be flat and infiltrating or warty in appearance (Figure 78.22). The former often starts as leukoplakia and the latter results from an existing papilloma. Local growth continues for months or years. T1 tumours are confined to the skin, with T2 tumours invading the corpus spongiosum or the corpus cavernosum. T3 tumours invade the urethra and T4 tumours invade adjacent structures. The earliest lymphatic spread is to the inguinal (N1 and N2 disease) and then to the iliac nodes (N3 disease) (Figure 78.23). Distant metastatic deposits are infrequent.

Clinical features
Many patients present late (Figure 78.24), either because of embarrassment or because of misdiagnosis. About 10 per cent of patients are under 40 years of age. By the time the patient presents, the growth is often large and secondary infection causes a foul bloody discharge. There is typically little or no pain.

Around 50 per cent have inguinal lymph node enlargement at presentation, but the nodal enlargement often reflects infection. In many, the prepuce is non-retractile and must be split to view the lesion. A biopsy should be performed to make the diagnosis. Untreated, the whole glans may be replaced by a fungating offensive mass. Later, the inguinal nodes can erode the skin (Figure 78.23) of the groin and in rare cases death of the patient can result from erosion of the femoral or external iliac vessels.

Treatment
Management is divided into treatment of the primary tumour and treatment of the inguinal nodes. For the primary tumour surgical excision is the mainstay of treatment, with the tradi-
tional view that a 2 cm margin of normal tissue be removed being superceded by a more recent, more conservative view, such that penile preserving surgery with excision of much lower margins of normal tissue are now accepted. Tumours affecting the glans penis require glansectomy, with more advanced tumours requiring partial penectomy. In advanced cases, total penectomy is required with formation of a perineal urethrotomy. Such surgery is indicated even in advanced metastatic disease for reasons of local control.

Treatment of any associated enlarged inguinal lymph nodes should be delayed until at least 3 weeks after local treatment of the primary lesion. Enlargement caused by infection will usually show signs of subsiding with antibiotic treatment. For palpable nodes, ultrasound-guided fine needle aspiration will confirm the diagnosis and a block dissection of both groins should be undertaken. The management of the nodes when there is no palpable disease is more controversial with most protocols dictating prophylactic lymph node dissection for tumours that are T2 or greater and for those that are poorly differentiated because of the risk of microscopic disease. A recent development is the use of sentinel node biopsy for impalpable nodes in high risk cases. Management of the pelvic nodes is even more controversial. When they are involved on computed tomography (CT) scanning, surgery probably has little role, but when the iliac nodes are not enlarged in the presence of N2 disease, the options are observation, pelvic lymphadenectomy or radiotherapy. The prognosis for tumours confined to the penis is good with five-year survival rates in excess of 80 per cent. With nodal involvement, the five-year survival rate falls to around 40 per cent (Summary box 78.11).

**Buschke–Löwenstein tumour**

Buschke–Löwenstein tumour is uncommon. It has the histological pattern of a verrucous carcinoma. It is locally destructive and invasive but appears not to spread to lymph nodes or to metastasise. Treatment is by surgical excision.

**Genital ulcers**

The most common cause of a genital ulcer is genital herpes. Other less common causes include syphilis and chancroid.

**Genital herpes**

Genital herpes is caused by sexual transmission of the herpes simplex virus (usually type 2, occasionally type 1). Recurrent attacks occur in 50 per cent or more of cases. Pain along the distribution of the sensory nerve, usually the genitofemoral nerve, precedes the eruption by 2 days and may be particularly severe around the anus. A group of tiny vesicles rapidly erodes to form shallow ulcers which are painful. The first attack is typically accompanied by fever and myalgia. In female patients, the ulcers often spread on to the thighs during the attack. Involvement of the urethra may cause retention of urine, which may persist for
up to 14 days if there is radiculitis of the S2 and S3 nerve roots. The diagnosis is made clinically, or when there is doubt by either cell culture or by PCR-based techniques. Acyclovir and valacyclovir have been shown to be effective in treating genital herp-uses but they do not prevent recurrences.

A child born to a mother with active infection is susceptible to a fatal generalised herpes infection in the neonatal period. Caesarean section should be considered in these circumstances. There is an increased risk of carcinoma of the cervix and annual cytology for life is recommended.

**Syphilis**

Syphilitic ulcers are typically painless, rubbery and indurated. Due to the spirochaete *Treponema pallidum*, diagnosis was traditionally achieved by dark field microscopy, but modern serological techniques are nowadays more appropriate. The incidence of syphilis is increasing since the advent of the retrovirals used to treat HIV in mid-1990s. Treatment is by use of a long-acting penicillin.

**Lymphogranuloma venereum**

Lymphogranuloma venereum is a sexually transmitted disease caused by *Chlamydia trachomatis* (Chlamydia A) types L1–L3 and is primarily an infection of the lymphatics and lymph nodes. The primary lesion is a fleeting, painless, genital papule or ulcer which is often unnoticed by the patient. It can affect both sexes. While it was considered rare in developed countries, some recent outbreaks in Europe have occurred, usually in conjunc-
tion with HIV.

The inguinal glands become enlarged and painful between two and four months after infection. The masses of nodes mat together above and below the inguinal ligament to give the ‘sign of the groove’. The overlying skin reddens and there may be fluctuance. There may be a proctitis, which can go on to produce a rectal stricture if untreated. Lymphatic obstruction leads to lymphoedema in the perineum and occasionally the lower limbs. Urethritis and urethral strictures occur in men.

The diagnosis is confirmed clinically and by the detection of antibodies against the organism. Treatment is by a combination of antibiotics, which may include sulphonamides, oxytetracycline and erythromycin. The multilocular lymphatic masses should not be incised; aspiration is permissible to reduce discomfort.

**Granuloma inguinale**

This is a chronic and slowly progressive ulcerative tropical disease affecting the genitals and surrounding tissue but occa-
sionally occurring elsewhere in the body. It is usually sexually transmitted and is caused by *Klebsiella granulomatis* and is most commonly seen among socially deprived people. The incubation period varies greatly but is typically between 7 and 30 days.

A painless vesicle or indurated papule, usually on the external genitals but occasionally elsewhere on the skin, gradually erodes into a slowly extending ulcer with a beefy-red, granulomatos base. More chronic lesions may become greyish, especially at the edges, where, after months or years, malignant change may develop. The ulcerated area may bleed if touched but is usually surprisingly painless. Without treatment, healing is only partial and keloid is common.

Diagnosis is by microscopy of material from the edges of the ulcer, which shows the presence of short Gram-negative rods within the cytoplasm of the large mononuclear cells. Treatment is by erythromycin, oxytetracycline or streptomycin.

**Condylomata acuminata** (*synonym: genital warts*)

Genital warts are caused by infection with human papillomavirus (HPV) and are sexually transmitted. Infection is very common with only a small proportion of infected patients actually having visible warts. Most commonly due to HPV types 6 and 11, these viruses do not cause cervical cancer. Ordinary skin warts can occur on the genitals by direct contact with a finger lesion, but they are less moist and soft and less often pedunculated than the genital variety. The lesions most commonly occur under the prepuce in the coronal sulcus but may be found elsewhere, including inside the urinary meatus (Figure 78.25).

In women, genital warts are most commonly found on the vulva but they may line the vagina and occur on the cervix. Perianal warts are common.

Other associated sexually transmitted diseases should be excluded: in women mainly candidiasis and *Trichomonas* infection and in men syphilis or gonorrhoea. Genital warts may complicate HIV infection.

Treatment is by chemical or physical means. Podophyllin is often effective as a topical application. It is applied to the wart, taking great care to avoid the surrounding skin, and washed off after 6 hours or so. An alternative agent is Imidaquod. If chemical methods fail, the warts can be excised or they can be ablated with cryosurgery, electrosurgery or laser. Circumcision is sometimes advised if there are florid lesions under the foreskin.

**Figure 78.25 Penile warts.**

EMBRYOLOGY AND ANATOMY OF THE TESTIS

The testes develop in the retroperitoneum below the kidneys at around the 10th thoracic level. During the 7th week of fetal development, the gubernaculum forms within the folds of the peritoneum. The upper end is attached to the developing testis and the lower end is attached to the fascia between the developing abdominal wall muscles. At the same time an evagination of the peritoneum itself, the processus vaginalis, develops adjacent to the gubernaculum and over the subsequent weeks evaginates through the abdominal wall to create the inguinal canal. The processus vaginalis initially picks up fibres of the internal oblique (which become the cremasteric muscle) and then fibres of the external oblique (which become the external spermatic fascia). As it elongates, the processus carries with it the gubernaculum, which contains muscle fibres, although it is not fully clear what part it plays in testicular descent. What is clear is that the testes lie at the internal inguinal ring at three months' gestation and descend to the scrotum between seven and nine months. This latter descent into the scrotum is accompanied by shortening of the gubernaculum. Final descent from the external ring to the base of the scrotum takes 4–6 weeks and is usually complete by birth.

The mechanisms that result in testicular descent are poorly understood but probably involve Müllerian inhibiting substance. Maternal chorionic gonadotrophin stimulates growth of the testis and may stimulate its migration. Imperfectly developed testes tend to descend incompletely.

The anatomy of the adult testis reflects its embryonic development. The testicular arteries originate high up in the retroperitoneum from the abdominal aorta, just below the renal arteries. The testicular veins drain into the renal vein on the left and the inferior vena cava on the right. For much of their course, the testicular artery and vein run parallel to the ipsilateral ureter, for which they may be mistaken during retroperitoneal surgery.

The epididymis lies on the posterior aspect of the testis and is palpable as a separate structure, with a head, a body and a tail. The seminiferous tubules enter the epididymis at the upper end of the epididymis (the head). From the head, sperm travel through the body and tail of the epididymis to enter the vas deferens at the lower pole of the testis. The vas curves up behind the testis and can be felt above the testis as a firm tubular structure entering the external inguinal ring. In the inguinal canal, the vas deferens is invested by the cremasteric muscle along with the other components of the spermatic cord.

INCOMPLETELY DESCENDED TESTIS

Definitions

Incomplete descent of the testis occurs when the testis is arrested in some part of its normal path to the scrotum. An ectopic testis is a testis that is abnormally placed outside this path (see also Chapter 8).

Incidence

About 4 per cent of boys are born with one or both testes incompletely descended. About two thirds of these reach the scrotum during the first three months of life, but full descent after that is uncommon. The incidence of testicular maldescent at the age of one year is around 1 per cent. The condition is sometimes missed in the neonatal period and only discovered later in life. In a few cases, the presence of a hernia, testicular pain or acute torsion directs attention to the abnormality. In 10 per cent of unilateral cases, there is a family history.

Kaspar Friedrich Wolff, 1733–1794, Professor of Anatomy and Physiology, St Petersburg, Russia.
Pathology

The condition is more common on the right and is bilateral in 20 per cent of cases. In adults, secondary sexual characteristics are typically normal.

The testis may be:

- intra-abdominal; usually lying extraperitoneally just inside the internal inguinal ring;
- intra-canalicular; it may or may not be palpable (Figure 79.1);
- extra-canalicular; usually at the scrotal neck;
- ectopic; the most common site is within the superficial inguinal pouch which lies just inferior and medial to the superficial inguinal ring. Other rarer ectopic sites include the femoral triangle, the root of the penis and perineum.

Incompletely descended testes are often macroscopically normal in early childhood, but by puberty the testis is typically smaller compared with its intrascrotal counterpart. Microscopic changes are apparent from 1–2 years, including loss of Leydig cells, degeneration of Sertoli cells and decreased spermatogenesis. The higher the testis, the greater the degree of histological change.

Consequences

Infertility

Impaired fertility is a well-recognised consequence of testicular maldescent with paternity rates around two-thirds of normal for unilateral undescended testes and one-third of normal for bilateral undescended testes. Although there has been a recent tendency to undertake surgical orchidopexy earlier in life, evidence to show that this might benefit fertility is currently lacking.

Malignancy

The cancer risk for adults after cryptorchidism in childhood is 5–10 times greater than normal. The most common cancer is a seminoma and, as with fertility, it is unclear whether early orchidopexy reduces the risk of malignancy. However, if a testicular tumour does develop, it is undoubtedly easier to identify in a testis that is within the scrotum.

Hernia

Around 90 per cent of boys with an undescended testis have a patent processus vaginalis, although the incidence of a clinically apparent hernia is much lower.

Testicular torsion

The undescended testis is more prone to testicular torsion, largely as a consequence of a developmental abnormality between the testis and its mesentery (Summary box 79.1).

Summary box 79.1

Undescended testis

- Testes that are absent from the scrotum after three months of age are unlikely to descend
- Histological changes in the testis can be seen from one year of age
- An incompletely descended testis tends to atrophy as puberty approaches
- Boys with undescended testes are at greater risk of infertility, testicular malignancy, hernia and testicular torsion

Clinical features

During childhood, the testes are mobile and the cremasteric reflex is active. In some boys, any stimulation of the skin of the scrotum or thigh causes the testis to ascend and to temporarily disappear into the inguinal canal. This is called a retractile testis. In comparison to a true undescended testis, the scrotum of a boy with a retractile testis is normal as opposed to underdeveloped. When the cremaster relaxes, the testis reappears only to vanish when the scrotal skin is touched again. A retractile testis can be gently milked from its position in the inguinal region to the bottom of the scrotum. A diagnosis of true incomplete descent should be made only if this is not possible. It is helpful to have the boy as relaxed as possible and for him to be examined in a warm room, usually in a supine position.

When the testis is impalpable, ultrasound may be helpful in identifying the intracanalicular testis, while laparoscopy may be needed to differentiate between the abdominal testis and a truly absent testis (Summary box 79.2).

Summary box 79.2

Retractile testis

- Retractile testes should be differentiated from true undescended testes
- This is most easily done with the child relaxed in a warm room
- Retractile testes are more common than true undescended testes
- Retractile testes require no treatment

Surgical treatment

Orchidopexy

Orchidopexy is usually performed before the boy reaches 12 months of age in an attempt to prevent the consequences described earlier. The testis and spermatic cord are mobilised
and the testis is repositioned in the scrotum. The operation is performed through a short incision over the deep inguinal ring. The inguinal canal is exposed by division of the external oblique aponeurosis in the direction of its fibres.

Three manoeuvres help to gain the length required to bring the testis down into the bottom of the scrotum. First the patent processus vaginalis should be identified, separated and ligated. Second the coverings of the spermatic cord (including the cremasteric muscle) should be divided and third, lateral fibrous bands just inside the internal inguinal ring should be divided. Although these techniques are usually effective, the tiny vas and testicular vessels are vulnerable to injury. The empty hemiscrotum is stretched with a finger passed into it through the inguinal incision to give enough room for the testis which is placed in a pouch constructed between the dartos muscle and the skin (Figure 79.2).

**Failure to bring the testis down**

Sometimes for a high undescended testis a two-stage surgical procedure is necessary. The testis is mobilised as far as possible and anchored with a suture and the mobilisation is completed six months later. An alternative approach involves initial division of the gonadal artery (which is usually ‘tighter’ than the vas deferens), such that the testis becomes dependent for its blood supply upon the vasal artery. The second stage procedure involves conventional orchidopexy. Orchidectomy should be considered if the incompletely descended testis is atrophic, particularly in the post-pubertal boy if the other testis is normal.

**INJURIES TO THE TESTIS**

The testis can be damaged either by blunt or by penetrating trauma. Injuries can range from simple bruising, through significant intra-testicular haematoma to rupture of the tunica albuginea with very significant collections of blood within the tunica vaginalis (haematocoele) (Figure 79.3). If the tunica ruptures, the blood can track into the groin and perineum. Ultrasound examination is a useful adjunct to clinical examination and surgical exploration is indicated for significant injuries including testicular rupture. The objective is to repair the tunica albuginea and preserve the testis, but on occasions orchidectomy is necessary (Summary box 79.3).

### Summary box 79.3

**Scrotal trauma**
- Scrotal exploration should be considered when there is massive swelling and pain after scrotal trauma
- Ultrasound is valuable in the assessment of the injury

**ABSENT TESTIS**

‘Vanishing’ testis describes a condition in which a testis develops but disappears before birth. The most likely cause for this is prenatal torsion. True agenesis of the testis is rarer. Laparoscopy is useful in distinguishing these causes of clinically absent testis from intra-abdominal maldescent.

**TORSION OF THE TESTIS**

**Pathophysiology**

Testicular torsion is a condition whereby the testicle twists in such a way that its blood supply becomes compromised. If left untreated, the blood flow to the testicle ceases and the testicle dies. The earlier the surgery to untwist the testis can be undertaken the better the results, with a testicular salvage rate of 100 per cent if the testicle can be untwisted within 6 hours of the torsion taking place compared with an approximate 20 per cent salvage rate if the surgery is delayed for 24 hours.

Torsion of the testis is uncommon because the normal testis is anchored and cannot rotate. For torsion to occur, one of several abnormalities must be present:

- Inversion of the testis is the most common predisposing cause. The testis is rotated so that it lies transversely or upside down.
- High investment of the tunica vaginalis causes the testis to hang within the tunica like a clapper in a bell (Figure 79.4).
- Separation of the epididymis from the body of the testis permits torsion of the testis on the pedicle that connects the testis with the epididymis (Figure 79.5).

Normally, when there is a contraction of the abdominal muscles, the cremaster contracts as well. In the presence of one of the abnormalities described above, the spiral attachment of...
the cremaster favours rotation of the testis around the vertical axis. Straining on stool, lifting of a heavy weight and coitus are all possible precipitating factors. Alternatively, torsion may develop spontaneously during sleep.

**Clinical features**

Testicular torsion is most common between 10 and 25 years of age, although a few cases occur in infancy. Typically, there is sudden agonising pain in the groin and the lower abdomen. The patient feels nauseated and may vomit. Torsion of a fully descended testis is usually easily recognised. The testis seems high and the tender twisted cord can be palpated above it. The cremasteric reflex is lost.

**Differential diagnosis**

Redness of the skin and a mild pyrexia may result in the condition being confused with epididymo-orchitis in the older patient; however, in epididymo-orchitis there will usually be dysuria associated with the accompanying urinary infection. Elevation of the testis reduces the pain in epididymo-orchitis and makes it worse in torsion.

Torsion of a testicular appendage cannot always be distinguished with certainty from testicular torsion. The most common structure to twist is the appendix of the testis (the pedunculated hydatid of Morgagni). The twisted testicular appendages can sometimes be visible through the scrotal wall. If the diagnosis is made clinically, then conservative management is possible, but if in doubt then surgical exploration should be undertaken with ligation and amputation of the twisted appendage.

In mumps orchitis the cord is not particularly thickened and the condition is often bilateral.

Idiopathic scrotal oedema is an oddity that occurs between the age of four and 12 years and must be differentiated from torsion. The scrotum is very swollen but there is little pain or tenderness. The swelling is usually bilateral and may extend into the perineum, groin and penis. It is thought to be an allergic phenomenon; occasionally there is eosinophilia. The swelling subsides after a day or so but may recur (Figure 79.6).

Very occasionally, torsion can be convincingly mimicked by a small tense strangulated inguinal hernia compressing the cord and causing compression of the pampiniform plexus.

**Management**

The management of the case should be determined primarily on clinical grounds. If there is any doubt as to the diagnosis, then urgent scrotal exploration is indicated. While Doppler ultrasound scanning can confirm the absence of the blood supply to the affected testis, false positive results can be seen, so it is not routinely recommended.

Exploration for torsion should be performed through a scrotal incision. If the testis is viable when the cord is untwisted it should be prevented from twisting again by fixation with non-absorbable sutures between the tunica vaginalis and the tunica albuginea. The other testis should also be fixed because the anatomical predisposition is likely to be bilateral. An infarcted testis should be removed – the patient can be counselled later about a prosthetic replacement.

In cases where there is a history of pain for several days, the affected testis will be dead. It is not possible to recover such a testis and although little is gained (other than pain relief) by immediate exploration it is necessary to fix the contralateral testis (Summary box 79.4).

**VARICOCELE**

A varicocele is a varicose dilatation of the veins draining the testis.

**Surgical anatomy**

The veins draining the testis and the epididymis form the pampiniform plexus. The veins gradually join each other as they traverse the inguinal canal and, at or near the inguinal ring, there are only one or two testicular veins, which pass upwards
within the retroperitoneum. The left testicular vein empties into the left renal vein, the right into the inferior vena cava below the right renal vein. The testicular veins usually have valves near their terminations, but these are sometimes absent. There is an alternative (collateral) venous return from the testes through the cremasteric veins, which drain mainly into the inferior epigastrics.

**Aetiology**

Varicoceles are common, affecting perhaps 15–20 per cent of males. Ninety per cent are left-sided, reflecting the proximal venous anatomy. In some cases, the dilated vessels are cremasteric veins and not part of the pampiniform plexus. The usual cause is absence or incompetence of valves in the proximal testicular vein. While most varicoceles are idiopathic, obstruction of the left testicular vein by a renal tumour or nephrectomy is a cause of varicocele in later life; characteristically, in such cases the varicocele does not decompress in the supine position.

**Clinical features**

While most varicoceles are asymptomatic, those that are symptomatic tend to present in adolescence or early adulthood when there may be an annoying dragging discomfort that is worse on standing at the end of the day. This presumably reflects distension of the testicular veins. When examined in the erect position, the scrotum on the affected side hangs lower than normal (Figure 79.7), and on palpation, with the patient standing, the varicose plexus feels like a bag of worms. There may be a cough impulse. If the patient lies down the veins empty by gravity and this provides an opportunity to ensure that the underlying testis is normal to palpation. In longstanding cases, the affected testis is smaller and softer than its fellow owing to a minor degree of atrophy.

Ultrasonography can be helpful in the diagnosis of small varicoceles (Figure 79.8) and in older men with an apparently recent onset of varicocele, ultrasonography of the kidneys is important in excluding a left renal tumour.

**Varicocele and spermatogenesis**

Of all the possible causes of primary infertility, oligozoospermia (reduced numbers of sperm in the ejaculate) is one of the most difficult to treat. Because varicoceles are relatively common, some men with oligozoospermia will have a varicocele, and it is tempting to blame this for the infertility. Certainly the varicocele will tend to ‘warm’ the testis, which is usually around 2.5°C below rectal temperature, and there is conflicting evidence regarding the effect of this temperature difference upon spermatogenesis. Unfortunately, there is little evidence that varicocelectomy improves semen quality or the rate of conception.

**Treatment**

Operation is not indicated for an asymptomatic varicocele. When the discomfort is significant, then embolisation of the gonadal veins is the usual first line intervention. If this is not possible, or if the varicocele recurs (as it does in around 20 per cent after embolisation), then surgical ligation of the testicular veins is the appropriate treatment, although recurrence can occur even after such surgery (Summary box 79.5).

---

**Summary box 79.4**

**Testicular torsion**

- If the diagnosis of testicular torsion is possible, then surgical exploration is indicated
- Prompt exploration, untwisting and fixation is the only way to save the torted testis
- The patient should be counselled and consented for orchidectomy before exploration
- The anatomical abnormality is bilateral and the contralateral testis should also be fixed

---

**Summary box 79.5**

**Varicocele**

- Varicocele is a common condition and 90% are left sided
- Development of a left-sided varicocele in later life may indicate the presence of a renal tumour
- They are usually asymptomatic and as such rarely need treatment
- First-line treatment is embolisation in symptomatic cases
- Varicoceles often recur, even after surgical treatment
- The association of varicoceles with subfertility is controversial
HYDROCELE

A hydrocele is an abnormal collection of serous fluid in a part of the processus vaginalis, usually the tunica vaginalis. Acquired hydroceles are primary or idiopathic, or secondary to epididymal or testicular disease.

Aetiology

A hydrocele can be produced in four different ways (Figure 79.9):

1. By excessive production of fluid within the sac, e.g. a secondary hydrocele
2. By defective absorption of fluid; this appears to be the explanation for most primary hydroceles, although the reason why the fluid is not absorbed is obscure
3. By interference with lymphatic drainage of scrotal structures
4. By connection with the peritoneal cavity via a patent processus vaginalis (congenital).

Hydrocele fluid contains albumin and fibrinogen. If the contents of a hydrocele are allowed to drain into a collecting vessel, the liquid does not clot; however, the fluid coagulates if mixed with even a trace of blood that has been in contact with damaged tissue.

A secondary hydrocele is most frequently associated with acute or chronic epididymo-orchitis. It is also seen with torsion of the testis and with some testicular tumours. A secondary hydrocele is usually lax and of moderate size: the underlying testis is palpable. If a tumour is suspected, the hydrocele should not be punctured for fear of needle-track implantation of malignant cells. A secondary hydrocele subsides when the primary lesion resolves.

Clinical features

Hydroceles are typically translucent and it is possible to ‘get above the swelling’ on examination of the scrotum. The swelling usually surrounds the testis and epididymis such that they may become impossible to palpate separately.

A primary vaginal hydrocele is seen most commonly in middle and later life but can also occur in older children. The condition is particularly common in hot countries. Because the swelling is usually painless it may reach a prodigious size before the patient presents for treatment. The testis may be palpable within a lax hydrocele, but an ultrasound scan is necessary to visualise the testis if the hydrocele sac is tense. Be wary of an acute hydrocele in a young man since there may be a testicular tumour.

In congenital hydrocele, the processus vaginalis is patent and connects with the peritoneal cavity. The communication is usually too small to allow herniation of intra-abdominal contents. Pressure on the hydrocele does not always empty it but the hydrocele fluid may drain into the peritoneal cavity when the child is lying down; thus, the hydrocele may be intermittent. Ascites should be considered if the swellings are bilateral.

Encysted hydrocele of the cord is a smooth oval swelling near the spermatic cord, which is liable to be mistaken for an inguinal hernia. The swelling moves downwards and becomes less mobile if the testis is pulled gently downwards.

Hydrocele of the canal of Nuck is a similar condition in females. The cyst lies in relation to the round ligament and is always at least partially within the inguinal canal.

Treatment

Congenital hydroceles are treated by herniotomy if they do not resolve spontaneously (see Chapter 8).

Small acquired hydroceles do not need treatment. If they are sizeable and bothersome for the patient, then surgical treatment is indicated. Established acquired hydroceles often have thick walls. Unless great care is taken to stop bleeding after excision of the wall, haemorrhage from the cut edge is liable to cause a large scrotal haematoma. Lord’s operation is suitable when the sac is reasonably thin-walled (Figure 79.10). There is minimal dissection and the risk of haematoma is reduced. Eversion of the sac with placement of the testis in a pouch prepared by dissection in the fascial planes of the scrotum is an alternative (Jaboulay’s procedure) (Figure 79.11).

Aspiration of the hydrocele fluid is simple, but the fluid always reaccumulates within a week or so. It may be suitable for men who are unfit for scrotal surgery, although hydrocele surgery can be undertaken under local anaesthetic. Aspiration can result in bleeding into the hydrocele sac and haematoma formation. Injection of sclerosants such as tetracycline is effective but painful (Summary box 79.6).

Filarial hydroceles and chyloceles

Filarial hydroceles and chyloceles account for up to 80 per cent of hydroceles in tropical countries where the parasite Wucheria bancrofti is endemic. Filarial hydroceles follow repeated attacks...
Cysts associated with the epididymis

There are several types of cyst associated with the epididymis including epididymal cysts and spermatoceles.

Summary box 79.6

Hydrocele
- A hydrocele is a collection of fluid within the tunica vaginalis
- Primary hydroceles surround the testis and transilluminate brightly
- Ultrasound examination is valuable when the testis and epididymis are impalpable
- Hydroceles can be treated conservatively unless they are large and symptomatic
- Surgery is the mainstay of treatment
- Testicular malignancy is an uncommon cause of hydrocele that can be excluded by ultrasound examination

Haematocele
The most common cause of a haematocele is vessel damage during needle drainage of a hydrocele. Prompt refilling of the sac associated with pain, tenderness and reduced transillumination will confirm the diagnosis. Acute haemorrhage into the tunica vaginalis sometimes results from testicular trauma with or without testicular rupture. If the haematocele is not drained, the blood within it clots (Figure 79.12). It becomes painless and may be mistaken for a testicular tumour. Indeed, a tumour may present as a haematocele. Ultrasound scanning usually helps with the differential diagnosis.

Cysts of the testicular appendage
Cysts of a testicular appendage are usually unilateral and are felt as small globular upper pole swellings. Such cysts are liable to torsion and should be removed if they cause symptoms. They are usually very small.

Spermatocele
This is a unilocular retention cyst derived from some portion of the sperm-conducting mechanism of the epididymis. A spermatocele typically lies in the epididymal head above and behind the upper pole of the testis. It is usually softer and laxer than other cystic lesions in the scrotum but, like them, it transillumines. The fluid contains spermatozoa and resembles barley water in appearance. Spermatoceles are usually small and unobtrusive. Small spermatoceles can be ignored. Larger ones should be aspirated or excised through a scrotal incision (Summary box 79.7).

Figure 79.12. A longstanding haematocele. The testis has been flattened by prolonged pressure.
Cysts associated with the epididymis

- Lie posterior to and separate from the testis and they transilluminate
- Diagnosis can be confirmed by ultrasound examination
- Can be treated conservatively unless large or uncomfortable

EPIDIDYMO-ORCHITIS

Inflammation confined to the epididymis is epididymitis; infection spreading to the testis is epididymo-orchitis.

Pathophysiology

Infection reaches the epididymis via the vas from a primary infection of the urethra, prostate or seminal vesicles. A general rule is that epididymitis arises in sexually active young men from a genital infection, while in older men it more usually arises from a urinary infection or may be secondary to an indwelling urethral catheter.

In young sexually active men, the most common cause of epididymitis is now Chlamydia trachomatis, but gonococcal epididymitis is still occasionally seen. In older men with bladder outflow obstruction, epididymitis may result from a urinary infection – it is proposed that a high pressure in the prostatic urethra might cause reflux of infected urine up the vasa. Bloodborne infections of the epididymis are less common but may be suspected when there is Escherichia coli, streptococcal, staphylococcal or Proteus infection without evidence of urinary infection and are presumably the only possible mechanism in men who have previously undergone a vasectomy. Acute epididymo-orchitis can follow any form of urethral instrumentation. It is particularly common when an indwelling catheter is associated with infection of the prostate

Clinical features

While there may be initial symptoms of a urinary or a genital infection, such symptoms are not always seen. The development of an ache in the groin and a fever can herald the onset of epididymitis. The epididymis and testis swell and become painful. The scrotal wall, at first red, oedematous and shiny, may become adherent to the epididymis. Urinalysis will usually show leucocytes and may show a formal urinary tract infection. Ultrasound is useful in the initial assessment of epididymitis and will identify abscess formation. In young men, urethral swabs should be taken for chlamydial testing.

In adolescents the differential diagnosis is testicular torsion and if there is any clinical doubt as to the diagnosis then testicular exploration should be performed.

Resolution may take 6–8 weeks to complete. Occasionally, an abscess can form that needs surgical drainage. Other complications include testicular atrophy, development of a chronic epididymitis and infertility.

Treatment

Either doxycycline (100–200 mg daily) or a quinolone should be the initial treatment in young men. There should be contact tracing of the partner and treatment if necessary.

In older men, quinolones are the usual initial treatment but if there is evidence of systemic sepsis, then intravenous antibiotics directed at urinary pathogens may be valuable. If an organism is isolated from the urine, this simplifies the choice of antibiotic.

All patients should drink plenty of fluid. Local measures including scrotal support and analgesia are helpful. Antibiotic treatment should continue for at least 2 weeks or until the inflammation has subsided. If suppuration occurs, drainage is necessary.

Chronic disease

Chronic non-tuberculous epididymitis usually follows the failure of resolution of an acute episode of epididymitis. Patients typically complain of intermittent episodes of discomfort and the epididymis feels thickened and tender. Treatment involves use of antibiotics (usually quinolones or doxycycline) and anti-inflammatory agents for 4–6 weeks. Epididymectomy or orchidectomy can be considered if there is no resolution although some patients continue to suffer from pain despite such surgery (Summary box 79.8).

Summary box 79.8

Acute epididymo-orchitis

- In young men usually arises secondary to a sexually transmitted genital infection
- In older men usually arises secondary to urinary infection
- May be a complication of catheterisation or instrumentation of the urinary tract
- May need aggressive treatment with parenteral antibiotics

TUBERCULOUS EPIDIDYMO-ORCHITIS

Chronic tuberculous epididymo-orchitis usually begins insidiously. The frequency with which the lower pole of the epididymis is involved first indicates that the infection is retrograde from a tuberculous focus in the seminal vesicles.

Clinical features

Typically, there is a firm, uncomfortable discrete swelling of the lower pole of the epididymis. The disease progresses until the
whole epididymis is firm and craggy behind a normal-feeling testis. There is a lax secondary hydrocele in 30 per cent of cases, and a characteristic beading of the vas may be apparent as a result of subepithelial tubercles. The seminal vesicles feel indurated and swollen. In neglected cases, a tuberculous ‘cold’ abscess forms, which may discharge. The body of the testis may be uninvolved for years, but the contralateral epididymis often becomes diseased. In two-thirds of cases, there is evidence of renal tuberculosis or previous disease. Otherwise, patients typically appear healthy.

The urine and semen should be examined repeatedly for tubercle bacilli in all patients with chronic epididymo-orchitis. A chest x-ray should be performed as should imaging of the upper urinary tract. Ultrasound will demonstrate a thickened epididymis.

**Treatment**

Secondary tuberculous epididymitis may resolve when the primary focus is treated.

Treatment with anti-tuberculous drugs is less effective in genital tuberculosis than in urinary tuberculosis. If resolution does not occur within two months, epididymectomy or orchidectomy is advisable. A course of anti-tuberculous chemotherapy should be completed even if there is no evidence of disease elsewhere.

**Tumours of the testes**

Testicular cancer represents around 1–1.5 per cent of male neoplasms and there is clear evidence of an increased incidence of these tumours in the past 30 years. The vast majority are germ cell tumours and the peak incidence of seminomas is in the fourth decade of life with the non-seminomatous germ cell tumours being more common in the third decade of life. They are the most common form of tumour in young men. Risk factors include a history of testicular maldescent, a history of a contralateral testicular tumour and Klinefelter’s syndrome. Confirmed bilateral testicular tumours may be uninvolved for years, but the contralateral testicular tumour and Klinefelter’s syndrome.

**Classification and pathology**

Tumours of the testis are classified according to their predominant cellular type:

- **Germ cell tumours** (90–95% per cent) (these include seminoma, embryonal cell carcinoma, yolk sac tumour, teratoma, and choriocarcinoma);
- **Interstitial tumours** (1–2 per cent) (these include Leydig cell tumours);
- **Lymphoma** (3–7 per cent);
- **Other tumours** (1–2 per cent).

**Seminoma**

A seminoma typically has a cut surface which is homogeneous and pinkish cream in colour. It appears to compress neighbouring testicular tissue (Figure 79.14). It consists of oval cells with clear cytoplasm and large, rounded nuclei with prominent acidophilic nucleoli. Sheets of cells resembling spermatocytes are separated by a fine fibrous stroma. Active lymphocytic infiltration of the tumour suggests a good host response and a better prognosis. There are two histological variants, one with a more anaplastic appearance and another that is characterised by cells which closely resemble different phases of maturing spermatogonia (spermatocytic seminoma).

Seminomas metastasise mainly via the lymphatics (Figure 79.15) and haematogenous spread is uncommon. The lymphatic drainage of the testes is to the para-aortic lymph nodes near the origin of the gonadal vessels. The contralateral para-aortic lymph nodes are sometimes involved by tumour spread, but the inguinal lymph nodes are affected only if the scrotal skin is involved.

**Non-seminomatous germ cell tumours (NSGCT)**

These tumours may be tiny but can reach the size of a coconut. The smaller tumours may not even distort the tunica albuginea (Figure 79.16). The usual type of teratoma is yellowish in colour with cystic spaces containing gelatinous fluid (Figure 79.17). There are a number of histological types of non-seminomatous germ cell tumours (NSGCT), which may coexist within a single tumour:

- **Embryonal carcinoma**. Highly malignant tumours that occasionally invade cord structures.
- **Yolk sac tumour**. Tumours with this component secrete alpha fetoprotein (AFP).
- **Choriocarcinoma**. Often produces human chorionic gonadotrophin (HCG). This is a highly malignant tumour that metastasizes early via both the lymphatics and the bloodstream.
- **Teratoma**. These tumours contain more than one cell type with components derived from ectoderm, endoderm, and mesoderm. Tumours may range from ‘mature’ with...
well-differentiated tissue elements to ‘immature’ with undifferentiated primitive tissues. All can metastasise.

**Interstitial cell tumours**

Interstitial cell tumours arise from Leydig or Sertoli cells. A Leydig cell tumour masculinises; a Sertoli cell tumour feminises. They are typically small well circumscribed tumours with a yellow cut surface. Microscopically, the cells are usually uniform and closely packed. Approximately 10 per cent are malignant. Most prepubertal tumours (which account for around 25 per cent of cases) produce androgens, which cause sexual precocity including prominent external genitalia, suprapubic hair growth and a deep masculinised voice. Regression of the symptoms after orchidectomy may be incomplete. Most post-pubertal interstitial cell tumours produce feminising hormones leading to gynaecomastia, erectile dysfunction, loss of libido and azoospermia.

**Clinical features**

Usually the patient presents with a painless testicular lump. A sensation of heaviness can occur if the testis is two or three times its normal size, but only a minority of patients experience pain. In a few cases, an episode of trauma calls attention to the swelling. Some cases may simulate epididymo-orchitis and rarely some patients present with severe pain and acute enlargement of the testis because of haemorrhage into the tumour. Such cases can occasionally mimic testicular torsion.

Rarely, the predominant symptoms are those of metastatic disease. Intra-abdominal disease may cause abdominal or lumbar pain and the mass may be discovered in the epigastrium. Lung metastases are usually silent but they can cause chest pain, dyspnoea and haemoptysis in the later stages of the disease. The primary tumour may not have been noticed by the patient, and indeed may be so tiny that it can be detected only by ultrasonography (Figure 79.16).

On examination, there is an intratesticular solid mass. If present, a lax secondary hydrocele does not usually obscure the underlying tumour. The epididymis becomes more difficult to feel when it is flattened or incorporated in the growth. The vas is never thickened and rectal examination is normal. Around 5 per cent of cases have gynaecomastia (mainly the NSGCT). Metastatic disease is rarely apparent clinically and is more usually identified by formal staging investigations. In 1–2 per cent of cases, the tumour is bilateral at the time of diagnosis.

**Investigation and staging**

The diagnosis is confirmed by ultrasound scanning of the testis (Figure 79.18) which is also able to assess the contralateral testis. It is a mandatory test in all suspected cases of testicular tumour.

In confirmed cases, staging is an essential step in planning treatment. Blood is taken prior to orchidectomy to measure the levels of tumour markers which are raised in around 50 per cent of cases. A rise in AFP is seen in around 50–70 per cent
of NSGCTs and a rise in HCG is seen in 40–60 per cent of NSGCTs and around 30 per cent of seminomas. When raised, these markers are used to monitor the response to treatment. The mean serum half-lives of AFP and HCG are 5–7 days and 2–3 days, respectively, and reassessment of the markers following orchidectomy can indicate whether all the tumour tissue has been removed.

While a chest x-ray will occasionally demonstrate the ‘classical’ cannon ball metastases (Figure 79.19), computed tomography (CT) of chest and abdomen has taken over as the most useful means of detecting metastatic disease and for monitoring the response to therapy. Such imaging is usually undertaken after the affected testis has been removed.

**Staging of testicular tumours**

While TNM staging is the most widely used system for the staging of testicular cancer, the older staging system of stages I–IV is still considered valuable in determining the treatment options:

The stages are:

- Stage I: the tumour is confined to the testis;
- Stage II: nodal disease is present but is confined to nodes below the diaphragm;
- Stage III: nodal disease is present above the diaphragm;
- Stage IV: nonlymphatic metastatic disease (most typically within the lungs) (Summary box 79.9).

### Summary box 79.9

**Testicular tumours**

- A solid testicular lump that cannot be felt separately from the testis may be a malignant tumour
- Lymphatic spread is to the para-aortic lymph nodes
- Ultrasound is a mandatory investigation in all cases of suspected testicular tumour
- Tumour markers (AFP and HCG) should be measured prior to orchidectomy

---

**Treatment**

**Scrotal exploration and orchidectomy for suspected testicular tumour**

The orchidectomy is undertaken via an inguinal incision. The spermatic cord is displayed by dividing the external oblique aponeurosis and a soft clamp is placed across the cord to stop dissemination of malignant cells as the testis is mobilised into the wound. If necessary, the testis should be bisected along its anterior convexity to examine its internal structure. If there is a tumour, the cord should be double transfixed and divided at the level of the internal inguinal ring and the testis removed.

**Management by staging and histological diagnosis (after orchidectomy)**

The treatment of patients with testicular tumours is usually successful, even in cases that are advanced at presentation. This largely reflects the excellent response of these tumours to platinum-based chemotherapy and (for seminomatous tumours) to radiotherapy. Indeed in recent years the emphasis of clinical trials has been focused upon the identification of those patients who do not need chemotherapy, and who therefore will escape the side effects of treatment.

**Stage I tumours**

Seminomas are radiosensitive and for many years adjuvant radiotherapy to the para-aortic nodes was the mainstay of treatment for stage I disease. Some years ago, the excellent response to platinum-based chemotherapy led to chemotherapy being introduced for most men with stage I seminoma. However, current practice uses CT and tumour marker-based surveillance protocols with chemotherapy being reserved for men who demonstrate relapse.

NSGCTs are not radiosensitive, but they are highly sensitive to combination chemotherapy with bleomycin, etoposide and cis-platinum (so called BEP chemotherapy). Some good prognosis NSGCTs can be managed by surveillance protocols (using regular CT scanning and tumour marker measurement) with the more high risk cases receiving chemotherapy.
Stage II–IV tumours
Combination BEP chemotherapy is the mainstay of treatment for stages II–IV seminoma and NSGCT. Retroperitoneal lymph node dissection is sometimes needed in some cases of NSGCT when retroperitoneal masses remain after chemotherapy (Figure 79.20). The tissue removed may contain only necrotic tissue, but some patients have foci of mature teratoma or active malignancy. The operation can be formidable if the tumour mass is large, and retrograde ejaculation is likely unless steps are taken to preserve the sympathetic outflow to the bladder neck.

Prognosis
The prognosis of testicular tumours depends on several factors including the histological type and the stage at presentation. For seminoma, if there are no metastases, 90–95 per cent of patients will be alive five years after diagnosis. If there are poor prognostic features, the survival rate drops to around 70 per cent. For NSGCTs, a five-year survival rate of more than 90 per cent is achievable in patients with good prognosis tumours while for more advanced tumours the five-year survival rate is about 60 per cent (Summary box 79.10).

Summary box 79.10
Testis tumour staging and treatment
- Tumour markers help to make the diagnosis and to follow the response to treatment
- CT scanning of chest and abdomen is central to the staging of testicular tumours
- Testicular tumours are extremely sensitive to platinum-based chemotherapy
- Prognosis is excellent when the patient is treated with combination chemotherapy in a cancer centre

TESTICULAR TUMOURS IN CHILDREN
These are usually anaplastic teratomas. They occur before the age of three years and are often rapidly fatal.

TUMOURS OF THE EPIDIDYMIS
These may be benign mesothelioma or malignant sarcoma or secondary carcinoma. They are extremely rare but should not be forgotten when the patient presents with a non-cystic lump in the epididymis.

THE SCROTUM

Fournier’s gangrene
Fournier’s gangrene is an uncommon and nasty condition (Figure 79.21) of infective origin that is characterised by sudden scrotal inflammation, with rapid onset of gangrene leading to exposure of the scrotal contents. Although it can occur in conjunction with sepsis of the testis, epididymis or perianal region, an obvious cause is absent in over half the cases. It can arise following minor injuries or procedures in the perineal area, such as a bruise, scratch, urethral dilatation, injection of haemorrhoids or opening of a periurethral abscess. Many patients have concurrent illnesses that diminish their defences, most notably diabetes mellitus and alcoholism.

There is a mixed infection of aerobic and anaerobic bacteria in a fulminating inflammation of the subcutaneous tissues, which results in an obliterative arteritis of the arterioles to the scrotal skin which in turn results in gangrene. The condition can spread rapidly to involve the fascia and skin of the penis, perineum and abdominal wall.

Clinical features
There is sudden pain in the scrotum associated with prostration, pallor and pyrexia. Cellulitis spreads rapidly (within hours) and progresses to necrosis until the entire scrotal and penile coverings slough, leaving the testes exposed but healthy.

Treatment
Treatment of a case of Fournier’s gangrene is a surgical emergency. Urgent wide surgical excision of the dead and infected tissue is essential. This should be accompanied by intravenous antibiotics. Supportive care is essential, because the patients often become severely septic. Early review of the wounds is helpful to confirm that all dead tissue has been removed, and if the patient survives the acute episode, skin grafting is often necessary. Despite best therapy, mortality rates as high as 50 per cent are often reported (Summary box 79.11).

Summary box 79.11
Fournier’s gangrene
- Fournier’s gangrene requires early and aggressive treatment if the patient is to survive
- Treatment involves urgent surgical debridement of necrotic tissue in combination with intravenous antibiotics

Filarial elephantiasis of the scrotum
Filarial elephantiasis of the scrotum is caused by obstruction of the pelvic lymphatics by worms of which Wuchereria bancrofti accounts for 90 per cent of cases. The condition is common in the tropics and is transmitted by mosquitoes. It is often
accompanied by superadded infection and lymphangitis, resulting in swelling of the genital skin and skin of the lower limbs. In longstanding cases, the enormously swollen scrotum may bury the penis (Figure 79.22). Associated symptoms and signs include fever, epididymitis, hydrocele and chyluria. The diagnosis is usually made clinically, although immunological testing can be helpful.

Medical treatment involves the use of diethylcarbamazine (DEC), ivermectin and albendazole, with the exact regime depending upon geographical location. Surgical treatment is rarely helpful, although a range of procedures has been devised to remove redundant skin and to reconstruct the enlarged scrotum.

**Non-filarial elephantiasis**

Elephantiasis can occur in the absence of filariasis, most notably in sub-Saharan Africa. Non-filarial elephantiasis can result from fibrosis of the lymphatics caused by lymphogranuloma venereum, but in many cases it is thought to arise as a consequence of persistent contact with irritant soils.

**Sebaceous cysts**

Sebaceous cysts are common in the scrotal skin. They are usually small and multiple (Figure 79.23).

**Carcinoma of the scrotum**

Chimney sweeps cancer was the first reported occupational cancer (described by Percival Pott in 1775). It is a rare cancer that has also been seen in other workers who come into contact with oil and coal products. Animal studies suggest that aromatic cyclic hydrocarbons are the aetiological factor. Nowadays, this tumour is rarely associated with any obvious aetiological factor. Unlike carcinoma of the penis, carcinoma of the scrotum is almost unknown in India and Asiatic countries.

The growth starts as a wart or ulcer (Figure 79.24) and as it grows it may involve the testis. The tumour should be excised with a margin of healthy skin. The management of the inguinal nodes parallels the management of penile cancer and if nodal enlargement does not settle with antibiotics following treatment of the primary, then a bilateral groin dissection is indicated.

**MALE FACTOR INFERTILITY**

For couples of unknown fertility status, approximately 15 per cent are unable to achieve a pregnancy within one year. The inability to conceive may be due to female factor infertility, male factor infertility or a combination of these two factors and approximately 20 per cent of cases of infertility are caused entirely by the male factor.

**Aetiology**

The two main causes of male factor infertility are testicular causes and vasal or epididymal obstruction. A few cases reflect endocrinological abnormalities, such as hypogonadism or hyperprolactinaemia.

---

**Percival Pott**

Percival Pott, 1714–1788, surgeon, St Bartholomew’s Hospital, London, UK, described the ‘Puffy tumour’ in 1760. In 1756 he sustained a broken leg after a fall from his horse. As he lay on the ground, he sent a servant to buy a door which acted as a stretcher. While his surgeons were contemplating amputating his leg, he persuaded them to splint the leg instead as a result of which he recovered completely. Although some think that Pott’s fracture of the ankle was described after this injury of his, it is not so. He sustained a compound fracture of the femur. Nevertheless, history can be controversial. Other authorities feel that Pott actually suffered a fracture-dislocation of the ankle from whence the fracture gets its name. Pott was the first to link an environmental factor to the aetiology of cancer when he demonstrated that chimney sweeps developed squamous cell scrotal cancer. In those days, the chimney sweep’s apprentice climbed up inside the chimney...
Testicular causes include chromosomal problems (e.g., Klinefelter’s syndrome), microdeletions of the Y chromosome, cryptorchidism, mumps orchitis, drugs and radiation damage. In most cases, however, the cause is unclear. In these cases, there may be reduced numbers of sperm in the ejaculate (oligozoospermia) or a complete absence of sperm in the ejaculate (azoospermia). Obstructive causes include congenital absence of the vasa (often in association with cystic fibrosis), surgical damage to the vasa, epididymitis and azoospermia is inevitable in these cases.

Assessment and investigation

Given the interplay between male and female factors, the man should not be investigated in isolation from his female partner. A careful history is the mainstay of the assessment with a careful search for aetiological factors. Physical examination is usually normal, but occasionally the testes may feel small (suggestive of a testicular cause), the vasa may be absent, there may be evidence of endocrine abnormalities (gynaecomastia or abnormal hair distribution) or there may be a varicocele. The relation of any varicocele to the infertility is controversial and treatment is not usually indicated.

The female should also be assessed. It is important to remember that female fertility declines from the age of 35 years in a way that is not true of men. The age of the female is therefore important and the regularity of menstruation should be confirmed either by temperature testing or by endocrinological testing.

The assessment of the male includes semen analysis, which should be tested within 2 hours of the semen being produced. Two or three samples should be tested. The volume of the ejaculate, the numbers of sperm, their motility and the percentage of abnormal or damaged sperm are all predictive of the male fertility. An endocrine screen should be performed including serum testosterone, prolactin, FSH and LH.

**Treatment**

Sperm counts of less than 20 million sperm per mL are defined as oligozoospermia. If there is a reversible cause, it should be treated. However, in many cases, some form of assisted conception is required.

Azoospermia (the complete absence of sperm from the ejaculate) is either due to obstruction of the pathway of spermatozoa from the testis to the ejaculatory ducts or due to severe testicular failure. In the latter, the serum FSH is typically raised, while in obstructive cases, the FSH is typically normal. If there is doubt as to the cause, then testicular biopsy is mandated to check for the presence of spermatogenesis combined with vasography to assess the presence and location of any obstructive lesion. If the site of the obstruction can be identified, it may be possible to perform a bypass operation. Unfortunately, even in the best hands, the results of epididymovasostomy are poor.

Assisted conception including in vitro fertilisation (IVF) and intracytoplasmic sperm injection (ICSI) has revolutionised the management of male factor infertility regardless of the cause of the problem. In ICSI, spermatozoa harvested from the ejaculate, by aspiration of the epididymis or even from testicular biopsy, can be injected in vitro into ova obtained from the mother. Embryos are then transferred into the mother’s uterus at the four- to six-cell stage (Summary box 79.12).

**Vasectomy for sterilisation**

Vasectomy for sterilisation is a common and effective contraceptive procedure. It should be undertaken only after the couple has been carefully counselled. Both partners need to know that the operation is performed to make the man permanently...
sterile. They should be warned that normal contraceptive precautions should continue until the success of the operation is confirmed by semen analysis performed 12–16 weeks after surgery. They should also be warned of the possibility of spontaneous recanalisation, which may restore fertility unexpectedly and of the possibility of chronic testicular pain which may occur in up to 5 per cent of men.

Vasectomy is easily and painlessly performed under local anaesthetic. The vasa are delivered through tiny bilateral scrotal incisions or through a single midline scrotal incision. For medico-legal reasons, it is wise to remove a segment of each vas to prove that it has been successfully divided. Burying the cut ends or turning them back on themselves helps to prevent them rejoining.

Reversal of vasectomy may not restore fertility even if technically successful because of damage to the testis secondary to the vasectomy. Although patency rates of 80 per cent or more are commonly reported, successful fertility rates are much lower and diminish with increasing delay from the time of vasectomy (Summary box 79.13).

### Summary box 79.12

**Male infertility**
- Atrophy of the testis is associated with raised levels of FSH in the blood
- Testicular biopsy will show whether azoospermia is a result of obstruction or failure of sperm production
- If spermatozoa can be harvested they can be used in ICSI with a fertility rate of around 30 per cent

### Summary box 79.13

**Vasectomy**

Counselling before vasectomy should include mention that:
- The operation is not immediately effective and that contraceptive precautions should be continued until there have been two negative semen analyses
- The procedure should be considered irreversible
- Spontaneous recanalisation is rare, but can occur
- There is a risk of chronic scrotal pain postoperatively

PART 12 | GENITOUREINARY

CHAPTER 80

Gynaecology

LEARNING OBJECTIVES

To understand:

- Pelvic anatomy and reproductive physiology
- The common causes of vaginal bleeding and acute pain in early pregnancy
- The surgical management of acute pelvic inflammatory disease, endometriosis, uterine fibroids and ovarian tumours

ANATOMY

The female external genitalia are described as the vulva, which is bordered by the mons veneris anteriorly and the labiocrural folds posterolaterally. The introitus tends to be open in parous women, but otherwise appears closed by the apposing labia majora. The labia minora are folds of skin that fuse anteriorly to form the clitoris, which contains erectile tissue similar to the penis. The fourchette is the posterior part of the introitus, which must stretch considerably to allow the delivery of a baby.

The vagina is an elastic, distensible tube, approximately 10 cm long, passing upwards and backwards from the introitus. The cervix protrudes into the vault of the vagina, dividing it into anterior, posterior and lateral fornices. Pelvic structures can be felt in the posterior and lateral fornices on bimanual examination, as the vaginal vault sits just below the pouch of Douglas (the area at the bottom of the pelvic cavity bordered by the uterus anteriorly and rectum posteriorly). The urethra and bladder neck sit above the anterior wall of the vagina; the perineal body and rectum behind the posterior wall (Figure 80.1).

The uterus, consisting of a body and a cervix, is a pear-shaped structure that is flattened anteroposteriorly giving its cavity a flat, triangular shape. The uterus is supported partly by ligaments attached to the cervix (transverse cervical, pubocervical and uterosacral) consisting of condensed connective tissue. The cervix is a canal, approximately 2 cm long, connecting the external os, which can be seen on speculum examination, to the internal os, where the cervix enters the uterine cavity. The length of the uterine cavity, including the cervical canal, is approximately 6 cm in nulliparous women and approximately 8 cm in parous women. The walls of the uterus are 1–2 cm thick and composed of muscular tissue (myometrium). The uterine cavity is lined with endometrium, a tissue that undergoes cyclical changes in response to ovarian hormones (see below under Reproductive physiology).

At the uterine fundus, on either side, are the cornua by which the uterus is connected to each Fallopian tube. These are thin, muscular tubes, approximately 10 cm long, which connect the peritoneal and uterine cavities. They are divided into four parts: intramural, isthmus, ampulla and fimbriated opening, which pick up the oocyte following its release at the time of ovulation. The tubes are very narrow in the isthmic and intramural parts but they widen in the ampullary region. Each tube is contained within the upper part of the broad ligament, a fold of peritoneum on either side of the uterus, which also contains blood vessels and the round and ovarian ligaments. The fimbriated opening and part of the ampulla, however, are free and closely associated with the ovary on either side. The ovaries are flattened, ovoid structures, approximately 3–4 cm long, suspended from the back of the broad ligament on either side of the pelvis. The ovarian blood vessels are contained within the infundibulopelvic ligaments, which are continuations of the broad ligaments to the pelvic brim on either side.
The cervix is located in the centre of the bony cavity of the pelvis and the uterus can be pivoted around this point. It is usually angled forwards (anteverted) at approximately 90° relative to the vagina. It is usually freely mobile but filling of the bladder or changes in position may rotate it backwards. In some women, the uterus is retroverted, either because of weak ligaments or because the uterus becomes adherent as the result of a disease process such as endometriosis. The uterus may also be angled forward (anteverted) or backwards (retroverted) when retroverted, in which case it can usually be felt in the pouch of Douglas on vaginal examination.

The most common cause of an enlarged uterus, aside from pregnancy, is the presence of fibroids (benign tumours of the myometrium) growing inside or outside the uterus. When fibroids are present, the overall size of the uterus is described in terms of weeks of pregnancy as it expands forwards and upwards into the abdominal cavity with increasing gestational age.

**REPRODUCTIVE PHYSIOLOGY**

The menstrual cycle is under the control of circulating hormones produced within the hypothalamic–pituitary–ovarian axis. Thus, gonadotrophin-releasing hormone (GnRH) produced in the hypothalamus stimulates the pituitary to produce follicle-stimulating hormone (FSH) and luteinising hormone (LH), which in turn control how the ovary produces an oocyte on a monthly basis and also the hormones oestrogen and progesterone. These hormones have an effect on many structures in the body, but principally on the endometrium, which prepares itself to receive a fertilised egg during the course of the menstrual cycle. In the first half (proliferative or follicular phase) of the cycle, following menstruation, the endometrium starts to regrow or proliferate in response to oestrogen produced by the growing ovarian follicle. The endometrium becomes thick and spongy during this phase of the cycle, associated with considerable angiogenesis.

Ovulation occurs at mid-cycle, on approximately day 14 (day 1 of the cycle is defined as the first day of menstruation), following which the follicle is transformed into the corpus luteum. In the second half (secretory or luteal phase) of the cycle, the endometrium thickens even more in response to the hormone progesterone, produced by the corpus luteum (Figure 80.2).

If fertilisation occurs, the fertilised egg is transported along a Fallopian tube into the uterine cavity and then implants in the endometrium. If fertilisation does not occur or if the fertilised egg fails to implant, the endometrium is shed and menstruation occurs. Bleeding (a ‘period’) tends to last for 4 days, but can range from 2–6 days. Typically, about 40 mL of blood is lost during each period; if the bleeding is heavy (i.e. greater than 80 mL), blood clots may form. The whole process then starts again in the next menstrual cycle.

If fertilisation does occur, the duration of the pregnancy (gestational age) is traditionally calculated from the first day of the last menstrual period (LMP); however, ovulation may occur earlier or considerably later than day 14 or the woman’s recollection of the date of the LMP may be incorrect, which means that calculating gestational age on the basis of the LMP alone may be inaccurate. This explains the alternative practice of calculating gestational age using ultrasound measurements of fetal size.

**VAGINAL BLEEDING IN EARLY PREGNANCY**

A miscarriage is defined as the spontaneous loss of an intrauterine pregnancy at less than 24 weeks’ gestation. A miscarriage usually starts with painless vaginal bleeding, at which point it is defined as a threatened miscarriage. The bleeding may then become heavier with associated uterine cramps, at which point it becomes an inevitable miscarriage. Blood clots and products of conception (i.e. fetal and placental tissue) are passed through the cervical os until the uterus is emptied (defined as a complete miscarriage). Sometimes, not all the products of conception are passed spontaneously (defined as an incomplete miscarriage) and the woman may require an evacuation of retained products of conception (ERPC) to remove what is left of the pregnancy.

The operation involves passing a plastic suction curette through the cervix into the uterine cavity. The current (2006) Royal College of Obstetricians and Gynaecologists (RCOG) recommendations are for ERPC to be considered if there is persistent excessive bleeding, haemodynamic instability, evidence of infected retained tissue or suspected gestational trophoblastic disease. Serious operative complications, which are fortunately rare, include uterine perforation with, possibly, intra-abdominal trauma (e.g. bowel damage), cervical tears and haemorrhage.

In the case of a miscarriage, on vaginal examination there is typically no cervical excitation (pain on moving the cervix) or tenderness in the vaginal fornices, which are signs associated with an ectopic pregnancy. The uterus feels the right size or smaller for the gestational age. The internal cervical os, by definition, is closed if the miscarriage is threatened or complete and open if the miscarriage is inevitable or incomplete. If the fetus has not developed (defined as a missed abortion) the uterus will feel small for the gestational age and there may have been no bleeding, in which case the os will be closed. In such circumstances, the os will need to be dilated before performing the ERPC.

An ultrasound scan is usually performed to determine whether there is a viable intrauterine pregnancy present. It may not be possible to determine the precise location of the pregnancy because the woman has had a complete miscarriage, the pregnancy is not sufficiently advanced or she has an ectopic pregnancy that is not visible on ultrasound. For these reasons, it is important to establish the gestational age as accurately as possible, on the basis of the LMP and the length/regularity of the menstrual cycle, as well as with any other relevant information, e.g. fertility treatment. It is still not uncommon, especially in

![Figure 80.2 Endocrine cycle. E₂, oestrogen; FSH, follicle-stimulating hormone; LH, luteinising hormone; P, progesterone.](image-url)
Vaginal bleeding in early pregnancy may also result from a local cause such as a cervical lesion (which may first manifest as bleeding after intercourse) or, rarely, trauma.

VAGINAL BLEEDING IN THE NON-PREGNANT STATE

Bleeding in the non-pregnant state may occur at the time of an expected menstrual period, between periods (intermenstrual bleeding) or after intercourse (post-coital bleeding). It may also occur after surgical instrumentation of the uterus and/or cervix, including insertion of an intrauterine contraceptive device (IUCD). The principal causes of these types of bleeding are shown in Table 80.1.

The mainstay of management is to identify and treat pathology (except in women <40 years old with heavy, menstrual periods in whom pathology is very rarely found; these women tend to be treated symptomatically). This usually involves ultrasound examination and an endometrial biopsy, either under direct vision at hysteroscopy or blindly with a Pipelle. The indications for endometrial biopsy are shown in Summary box 80.1.

**Summary box 80.1**

**Indications for endometrial biopsy**

Endometrial biopsy should be considered in the following women:

- All women >40 years old with excessively heavy, irregular or frequent bleeding
- Younger women with major risk factors for endometrial hyperplasia/cancer:
  - Polycystic ovarian syndrome
  - Obesity
  - Tamoxifen treatment
- Unopposed oestrogen therapy
- Family history of endometrial/colon cancer, especially hereditary non-polyposis colorectal cancer (Lynch syndrome)
- Younger women who fail to respond to conventional treatment

Women taking tamoxifen – the selective oestrogen receptor modulator used in breast cancer treatment – represent a special group because the drug can induce endometrial polyps, hyperplasia, cancer and, rarely, uterine sarcomas, which are much more aggressive. Tamoxifen treatment results in a doubling of the risk of endometrial cancer after one to two years of treatment and a quadrupling after five years. The relationship is time-dependent and dose-independent and the risk does not decrease after stopping treatment. There is no clear consensus regarding the need for screening and which method to use; the alternative, more common, approach is to investigate only those women who develop post-menopausal bleeding with tamoxifen use. Aromatase inhibitors such as anastrozole, letrozole and exemestane, which are also used in the treatment of breast cancer but whose effects are not mediated via the oestrogen receptor, are associated with less endometrial pathology than tamoxifen and it has even been suggested that aromatase inhibitors may reverse abnormalities induced by tamoxifen.

Women with hereditary non-polyposis colorectal cancer (HNPPC) (Lynch syndrome) and those who are at high risk of developing HNPPC are another special group, as the lifetime risk of developing endometrial cancer is as high as 60 per cent. Unlike sporadic cases of endometrial cancer, which are usually diagnosed during the sixth and seventh decades, the mean age at diagnosis in HNPPC patients is the fifth decade. However, it appears that five-year survival rates in HNPPC patients with endometrial cancer are similar to those in women with sporadic disease. International guidelines suggest that these women should be screened annually from the age of 35 years with transvaginal ultrasound, to measure endometrial thickness and look for polyps, and with endometrial biopsy.

Menstrual bleeding may be excessively heavy, irregular or frequent in the absence of pathology; this is known as dysfunctional uterine bleeding. Medical treatments used to reduce the amount of menstrual loss include tranexamic acid, mefenamic acid and the combined oral contraceptive (COC). It may be necessary to stop the bleeding completely using high-dose progestagens, the COC taken continuously or a GnRH agonist, which induces a menopause-like state. Increasingly, an intrauterine system (IUS) similar to a conventional coil, which releases levonorgestrel, is offered to patients as an alternative; it has the added advantage of being a reliable contraceptive.

The surgical treatments for excessive bleeding and their principal operative complications are described in Table 80.2; they are divided into those procedures that retain the uterus and those that do not. The ovaries may or may not be removed at the same time depending upon the woman’s age and any coexisting pathology. The aim of all of the ablation methods is to reduce menstrual bleeding by ablating the endometrial layer and some of the underlying myometrium using electrical, thermal or laser energy. Amenorrhoea is not guaranteed, but the procedures are less invasive and costly than hysterectomy. Clearly, none of these surgical treatments is suitable for women who wish to conceive.

Abnormal bleeding can also be caused by invasive carcinoma of the cervix, the incidence of which has been reduced by screening programmes that aim to detect the precancerous state – cervical intraepithelial neoplasia (CIN) – using cervical cytology. In the UK, this is carried out every three to five years in women.
Aged between 25 and 65 years. Infection with certain human papillomavirus (HPV) serotypes (16, 18, 31 and 33) is associated with an increased risk of invasive disease. Abnormalities in cervical cytology are followed up by microscopic examination of the cervix (colposcopy). CIN may be treated with local ablation (cryoablation, cold coagulation, electrodiathermy or laser) or excision (large loop excision of the transformation zone (LLETZ)). However, it is very likely that the incidence of CIN will decrease steadily in the future as a result of vaccination against HPV in young girls and HPV testing.

**ACUTE PELVIC PAIN IN EARLY PREGNANCY**

**Ectopic pregnancy**

An ectopic pregnancy is one that grows outside the uterine cavity, almost always in a Fallopian tube (rare sites include the ovary, cervix and broad ligament). As the ectopic grows, the placenta infiltrates blood vessels within the Fallopian tube, which can cause bleeding within the tube and bleeding into the peritoneal cavity. Further growth of the ectopic pregnancy can rupture the Fallopian tube causing substantial intraperitoneal blood loss. It is the most common cause of maternal death in the first trimester and accounts for 9 per cent of maternal deaths in the UK. The major risk factors for ectopic pregnancy are shown in Summary box 80.2.

**Summary box 80.2**

**Risk factors for ectopic pregnancy**

- Previous pelvic inflammatory disease
- Smoking
- Older age
- Previous spontaneous miscarriage
- Previous medical termination
- History of infertility
- Previous use of an intrauterine contraceptive device

An ectopic pregnancy may be suspected on clinical grounds, but making the diagnosis can be difficult because the presentation is so variable and can mimic that of a miscarriage (Summary box 80.3).

**Summary box 80.3**

**Differential diagnoses for acute pain in early pregnancy**

- Ectopic pregnancy
- Miscarriage
- Urinary tract infection
- Ovarian accident
- Pain unrelated to pregnancy, e.g. acute appendicitis

There may be a history of lower abdominal pain with a small amount of vaginal bleeding at 4–6 weeks’ gestation. On vaginal examination, there may be cervical excitation and tenderness in

Figure 80.3 Laparoscopy showing an ectopic pregnancy.

the vaginal fornices; the cervical os is closed. Alternatively, the woman may not have any symptoms or physical findings. The urinary pregnancy test is usually positive. Modern monoclonal antibody-based urine tests can detect the beta subunit of human chorionic gonadotropin ($\beta$-hCG) at levels of 25 IU/L, which are reached 9 days post-conception, i.e. on day 23 of the menstrual cycle assuming ovulation occurred on day 14.

A transvaginal ultrasound scan should be performed if the diagnosis is suspected. The complete absence of an intrauterine gestational sac with a positive pregnancy test increases the probability of an ectopic pregnancy unless the pregnancy is not sufficiently advanced for the sac to be seen on ultrasound in the uterus. An ectopic pregnancy is more likely if fluid is seen in the pelvis or an adnexal mass is seen on ultrasound.

In equivocal cases, measuring serum levels of $\beta$-hCG can help to establish the diagnosis. $\beta$-hCG levels double every 48 hours if the pregnancy is viable and intrauterine. Levels tend to be static or the rise is less than double over a 48-hour period if the pregnancy is ectopic. A single level above approximately 1500 IU/L in association with an empty uterus on ultrasound is highly suggestive of an ectopic pregnancy. The best diagnostic test is laparoscopy (Figure 80.3); occasionally, however, if the pregnancy is not sufficiently advanced, the ectopic pregnancy is too small to be seen in the Fallopian tube. There is also a view that a laparoscopy should only be performed once a miscarriage has been excluded because of the surgical and anaesthetic risks associated with the procedure.

Once an ectopic pregnancy has been diagnosed at laparoscopy, a salpingectomy is usually performed. A salpingostomy may be performed instead as some gynaecologists maintain that subsequent intrauterine pregnancy rates are higher and recurrent ectopic rates lower following conservative surgery. Laparoscopy is the preferred approach because it is associated with shorter operation times, less intraoperative blood loss, shorter hospital stays and similar subsequent intrauterine pregnancy rates.

In practice, the type of operation chosen depends on factors such as the following:

- **The amount of bleeding.** An immediate laparotomy may be required if the woman has lost a great deal of blood.
### INFECTION

The overwhelming majority of cases of acute PID are caused by ascending infection, which is usually sexually transmitted. Rarer causes include spread from other pelvic organs, e.g. the appendix. *Chlamydia trachomatis* is the most common organism responsible for PID; the prevalence of *Neisseria gonorrhoeae* varies depending upon the locality. Infection involves the upper genital tract, particularly the endometrium and Fallopian tubes. Risk factors include young age at first sexual activity, a high number of sexual partners and current use of an IUCD; infection may also follow a surgical procedure, e.g. termination of pregnancy.

There are no definitive criteria for the diagnosis of acute PID. Most clinicians rely instead upon the presence of one or more of the following features, which are suggestive of the diagnosis:

- lower abdominal pain and tenderness;
- deep dyspareunia (pain on intercourse);
- abnormal vaginal or cervical discharge;
- cervical excitation and adnexal tenderness;
- fever >38°C.

The differential diagnoses include endometriosis, urinary tract infection, appendicitis and gastrointestinal dysfunction. A raised neutrophil count and an elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) level support the diagnosis. Ultrasound may be useful if there appear to be hydrocele present and/or tubo-ovarian abscesses. All women with suspected PID should be screened for *N. gonorrhoeae* and *C. trachomatis* by taking endocervical with or without urethral swabs. *C. trachomatis* is an intracellular organism; therefore, samples obtained for diagnostic purposes should contain cellular material. It is important to wipe off any discharge before inserting the swab inside the cervical os and firmly rotating it against the endocervix.

The current RCOG (2008) guidelines recommend a low threshold for empirical treatment because the consequences of failing to treat acute PID effectively are so significant. Treatment should commence as soon as samples have been obtained for culture even though the results are unavailable; it should include a broad-spectrum antibiotic against coliforms and anaerobic bacteria.
species, which are responsible for secondary infection. Contact tracing and treatment, if possible, are essential (Summary box 80.4).

Inadequate or inappropriate treatment is associated with a significant risk of developing infertility, ectopic pregnancy, Fitz-Hugh–Curtis syndrome (an extrapelvic manifestation of PID associated with right upper quadrant pain, which probably results from inflammation of the liver capsule and diaphragm) and chronic pelvic pain in the future. The risk of infertility is obviously of great concern. Approximately 20 per cent of women treated for PID will become infertile because of tubal damage; >50 per cent of tubal infertility cases are due to C. trachomatis although, interestingly, many of these women do not report a history of PID (Summary box 80.5). In total, 6 per cent of women will have an ectopic in the first pregnancy following an episode of acute PID, a figure that is approximately ten times greater than the rate in the general population.

### Treatment of pelvic inflammatory disease

- Because of the lack of definitive clinical diagnostic criteria, a low threshold for the empirical treatment of pelvic inflammatory disease (PID) is recommended.
- Women with suspected PID should be screened for gonorrhoea and Chlamydia. Testing for gonorrhoea should be with an endocervical specimen, tested via culture (direct inoculation on to a culture plate or transport of the swab to the laboratory within 24 hours) or using a nucleic acid amplification test (NAAT). Screening for Chlamydia should also be from the endocervix, preferably using a NAAT. Taking an additional sample from the urethra increases the diagnostic yield for gonorrhoea and Chlamydia. A first-catch urine sample provides an alternative sample.
- Outpatient antibiotic treatment should be commenced as soon as the diagnosis is suspected. Treatment should be based on one of the following regimens:
  - 400 mg oral ofloxacin twice a day plus 400 mg oral metronidazole twice a day for 14 days; or
  - 250 mg intramuscular ceftriaxone immediately or 2 g intramuscular cefotaxime immediately with 1 g oral probenecid, followed by 100 mg oral doxycycline twice a day plus 400 mg metronidazole twice a day for 14 days.
- Admission to hospital is appropriate in the following circumstances:
  - Surgical emergency cannot be excluded
  - Clinically severe disease
  - Tubo-ovarian abscess
  - PID in pregnancy
  - Lack of response to oral therapy
  - Intolerance to oral therapy
- In more severe cases, inpatient antibiotic treatment should be based on intravenous therapy, which should be continued until 24 hours after clinical improvement and followed by oral therapy. Recommended regimens are:
  - 2 g intravenous ceftriaxone three times a day plus 100 mg intravenous doxycycline twice a day (oral doxycycline may be used if tolerated), followed by 100 mg oral doxycycline twice a day plus 400 mg oral metronidazole twice a day for a total of 14 days; or
  - 900 mg intravenous clindamycin three times a day, plus intravenous gentamicin: 2 mg/kg loading dose followed by 1.5 mg/kg three times a day (a single daily dose of 7 mg/kg may be substituted), followed by 450 mg oral clindamycin four times a day to complete 14 days or 100 mg oral doxycycline twice a day plus 400 mg oral metronidazole twice a day to complete 14 days or 400 mg intravenous ofloxacin twice a day plus 500 mg intravenous metronidazole three times a day for 14 days.

### Chlamydia and gonorrhoea testing

The majority of suspected cases are treated in the community, but hospital admission is advisable if there is doubt about the diagnosis or symptoms/signs are severe. In hospital, antibiotics should be given intravenously until 24 hours after clinical improvement. If there is an IUCD in situ, it should be removed with adequate counselling regarding pregnancy risk (if intercourse has occurred recently) and future contraception.

Severe PID manifests as a tubo-ovarian abscess, so named because the Fallopian tube and ovary become blended into a single, pus-filled, inflammatory mass, which is usually adherent to the uterus and surrounding bowel. The infection may have

</table>
progressed from a milder form of PID or, increasingly, it may result from the introduction of infection or bowel damage at transvaginal oocyte aspiration in a patient undergoing in vitro fertilisation (IVF). Modern medical practice is to manage tubo-ovarian abscesses (Figure 80.4) conservatively unless the patient fails to respond to intravenous antibiotics and systemic support. The response is judged to be inadequate if the woman remains systemically unwell, her symptoms do not improve, fever is not reduced, the white blood cell count does not fall and there is no evidence on ultrasound of the abscess becoming smaller. In such circumstances, surgical treatment is necessary, i.e. adhesiolysis and drainage of the abscess, at laparotomy or laparoscopy. As most women with a tubo-ovarian abscess are in the reproductive years, the intention is always to be as conservative as possible at surgery. Rarely, however, if the abscess has ruptured (Figure 80.5) and the patient is extremely ill, then hysterectomy and bilateral salpingo-oophorectomy may be necessary.

Abscess drainage under radiological guidance, e.g. a transgluteal approach via the greater sciatic foramen under computed tomography (CT) guidance, is sometimes performed. Transvaginal ultrasound-guided aspiration has also been advocated. It is clearly less invasive and there are claims that the method is as effective as surgery; however, it carries additional risks such as bowel damage.

**UTEROVAGINAL PROLAPSE**

Congenital weakness of the pelvic floor ligaments and fascia may be found in conditions such as spina bifida and bladder extrophy. Far more common, however, are the acquired forms of pelvic floor damage caused by prolonged or difficult labour and multiparity. A gradual increase in denervation of the striated muscle of the pelvic floor with age and oestrogen deficiency at the menopause can also occur in nulliparous women (Figure 80.6).

A minor degree of prolapse may be asymptomatic but with more significant degrees the patient complains of ‘something coming down’. A cystocoele (bladder prolapse) and a cystourethrocoele lead to the sensation of a lump in the vagina and may also be associated with incontinence and recurrent urinary infections. Uterine descent can lead to backache; with complete prolapse of the uterus (procidentia) there may be vaginal discharge, ulceration of the vaginal skin and bleeding. A rectocoele (prolapse of the rectum into the vagina) may cause difficulties with defaecation or a sensation of incomplete defaecation, which is relieved by digital reduction of the prolapse.

Non-surgical management of uterovaginal prolapse is with physiotherapy, hormone replacement therapy (HRT) and the use of vaginal rings and pessaries. The vinyl ring is inserted between the posterior fornix and the pubic bone. The main complication is vaginal ulceration and infection leading to discharge and bleeding; it is advisable, therefore, to replace the ring frequently. The aims of surgical management are usually to correct the prolapse, treat any associated incontinence and preserve coital function if appropriate. The surgical procedures are intended to restore the uterovaginal anatomy and position. They may be carried out using a vaginal or abdominal approach or increasingly by a laparoscopic or minimal access approach with the use of vaginal slings and tapes (Table 80.3).

The *Manchester repair* was introduced at St Mary’s Hospital for Women and Children, Manchester, UK.

**Figure 80.5 Pelvic inflammatory disease with rupture of a pelvic abscess.**
TUMOURS

Uterine fibroids (leiomyomas)

Fibroids are benign, well-circumscribed, smooth muscle tumours of the uterus. Most women will have more than one fibroid, varying in diameter from 1–10 cm, which are typically found in the following locations (Figure 80.7):

- **Subserosal** may cause pressure symptoms (see below); if pedunculated, they can be difficult to distinguish from an ovarian tumour.
- **Intramural** may similarly cause pressure symptoms; associated with infertility and heavy periods.
- **Submucosal** associated with infertility, recurrent pregnancy loss and heavy periods; if pedunculated, may occasionally extrude through the cervical os.
- **Rare** sites include the broad ligament and cervix.

Women with uterine fibroids will present with heavy and/or irregular menstrual bleeding, pressure symptoms or problems conceiving, especially if there is a fibroid in the uterine cavity. The pressure symptoms include pelvic discomfort, urinary incontinence, frequency and retention, constipation and backache. When large fibroids are present, back pressure may cause or exacerbate varicosities. Although these symptoms are common, it is important to note that some women with fibroids are asymptomatic. Rarely, women may present acutely with pain arising from torsion of a pedunculated fibroid or red degeneration, especially in pregnancy.

The diagnosis is usually apparent on bimanual and/or abdominal examination, on the basis of finding an enlarged uterus with attached swellings. The principal differential diagnosis is an ovarian tumour; as a general rule, the uterus is felt separately on vaginal examination if an ovarian tumour is present, although not if the structures are adherent to each other. Ultrasound can
usually distinguish fibroids from ovarian tumours; if not, magnetic resonance imaging (MRI) is clinically useful (Figure 80.8) but, sometimes, it may be necessary to perform a laparoscopy to distinguish between the two pathologies (Figure 80.9).

Emergency surgical treatment is only required if there is substantial menstrual bleeding or uncontrollable pain; these are rare events. Otherwise, the woman has time to consider her treatment options, which include shrinkage of the fibroids by inducing a hypo-oestrogenic state with a GnRH agonist, uterine artery embolisation (UAE), myomectomy (removal of the individual fibroids) and hysterectomy. The choice depends upon the woman's age and fertility intentions, the size and number of fibroids and their location. It is also important to know whether there are fibroids in the uterine cavity, especially if the woman is trying to conceive.

A GnRH agonist will usually shrink fibroids, but this class of drug has the disadvantage that treatment cannot be continued indefinitely because of the associated loss in bone mineral density; in addition, the fibroids tend to regrow to their original size when treatment is discontinued. UAE is becoming increasingly popular as an alternative to surgery. It involves blocking the blood supply to the fibroids using a technique in which particles are embolised into each uterine artery via an angiographic catheter in a similar manner to the well-established technique for treating massive post-partum haemorrhage (Figure 80.10). Following embolisation, the fibroids usually shrink, bringing symptomatic relief, i.e. decreased menstrual bleeding and fewer pressure symptoms. Complications include arterial injury at the site of catheter insertion, severe pain as a result of uterine ischaemia, infection, and ovarian damage and thromboembolism (a small number of deaths have been reported from uterine infection and pulmonary embolism). There is no consensus regarding the suitability of the technique for women who wish to conceive. Numerous pregnancies have been reported in women who have had UAE, but concern still exists regarding the possible adverse effects on myometrial strength and ovarian function, which

Figure 80.7 Uterine fibroids.
might affect a woman’s chances of conceiving, carrying the pregnancy and delivering normally.

Myomectomy (performed at laparotomy or increasingly at laparoscopy) involves the removal of pedunculated, subserosal and/or intramural fibroids and closure of any defects left in the uterine wall. Surgical complications are unusual; in exceptional circumstances, however, a hysterectomy may be necessary because of uncontrollable blood loss. Fibroids in the uterine cavity should be removed hysteroscopically; the risks of the procedure are similar to those for transcervical resection of the endometrium (TCRE) (see Table 80.2).

Endometriosis

Endometriosis – defined as the presence of endometrial-like tissue in extrauterine sites – is a complex genetic trait that affects up to 10 per cent of women in the reproductive years. The symptoms associated with the disease include severe dysmenorrhoea, chronic pelvic pain, ovulation pain, deep dyspareunia, cyclical symptoms related to the involvement of other organs (e.g. bowel or bladder) with or without abnormal bleeding, infertility and chronic fatigue. However, the predictive value of any one symptom or set of symptoms remains uncertain as each can have other causes (e.g. irritable bowel syndrome or interstitial cystitis) and a significant proportion of affected women are asymptomatic.

The most commonly affected sites are the pelvic organs and peritoneum, although distant sites such as the lungs are occasionally affected (resulting in symptoms such as recurrent haemoptysis at the time of menstruation). The extent of the disease varies from a few, small lesions on otherwise normal pelvic organs to large, ovarian, endometriotic cysts (endometriomas). There can be extensive fibrosis in structures such as the uterosacral ligaments (Figure 80.11) and adhesion formation causing marked distortion of pelvic anatomy (Figure 80.12). Disease severity can be assessed simply by describing the operative findings or, quantitatively, using various classification systems, but there is little correlation between such systems and the type or severity of pain symptoms.

Endometriosis typically appears as superficial ‘powder-burn’ or ‘gunshot’ lesions on the ovaries, serosal surfaces and peritoneum – black, dark-brown or bluish puckered lesions, nodules or small cysts containing old haemorrhage surrounded by a variable extent of fibrosis (Figure 80.13). Atypical or ‘subtle’ lesions are also common, including red implants (petechial, vesicular, polypoid, haemorrhagic, red flame-like) and serous or clear vesicles. Other appearances include white plaques or scarring and yellow-brown peritoneal discolouration of the peritoneum. Ovarian endometriomas usually contain thick fluid like tar. They are distinguishable from simple haemorrhagic ovarian cysts because, typically, they are densely adherent to the peritoneum of the ovarian fossa. The surrounding fibrosis may involve the bowel. Deeply infiltrating endometriotic nodules represent another disease type. They extend more than 5 mm beneath the peritoneum and may grow into the uterosacral ligaments, vagina, bowel, bladder or ureters; when such lesions grow into the vagina, they may be visible on speculum examination as ‘blue-domed’ cystic lesions in the posterior fornix. Lesions infiltrating the bowel may mimic cancer in their presentation.

The diagnosis of endometriosis is usually made on visual inspection of the pelvis at laparoscopy; non-invasive diagnostic tools, such as ultrasound scanning, can reliably detect only severe forms of the disease, i.e. endometriomas. The treatment options are limited because the cause is uncertain; these include hormonal drugs to suppress ovarian function, the levonorgestrel-IUS and surgical ablation of endometriotic lesions. Women may require multiple admissions for surgery and/or prolonged treatment with costly drugs that have problematic side effects. Lastly, patients with endometriosis may be at increased risk of ovarian cancer (especially endometrioid and clear-cell types) and non-Hodgkin’s lymphoma, which adds to the burden of the disease.

Finding pelvic tenderness, a fixed retroverted uterus, tender uterosacral ligaments or enlarged ovaries on examination is suggestive of endometriosis. The diagnosis is more certain if deeply infiltrating nodules are found on the uterosacral ligaments or in the pouch of Douglas and/or visible lesions are seen in the vagina or on the cervix. The findings may, however, be normal.

For a woman who has completed her family, hysterectomy plus bilateral salpingo-oophorectomy and removal of all the

Figure 80.11 Endometriosis seen on the uterosacral ligament.

Figure 80.12 Bilateral ovarian endometriosis with pelvic adhesions.
endometriosis present offers a good chance of cure. However, surgical treatment in a woman who wishes to conceive in the future aims to be as conservative as possible, ensuring in particular that ovarian function is preserved. The aim is to remove all of the endometriotic tissue and restore anatomy to normal by lysing adhesions. The standard (preferably laparoscopic) methods used are ovarian cystectomy and tissue excision or ablation with electrodiathermy, thermal coagulation or laser. The surgical risks include those for any laparoscopic procedure, as well as damage to the ureters and bowel; the risks are increased if deeply infiltrating disease is present, particularly if there is bowel wall involvement. Rarely, infection in an endometrioma will result in the formation of a tubo-ovarian abscess.

**Benign ovarian tumour and cysts**

Overall, 90 per cent of ovarian tumours are benign, although there is an increased risk of malignancy in older women. Ovarian tumours are subdivided into five main categories according to the World Health Organization’s classification system (Table 80.4).

<table>
<thead>
<tr>

</tbody>
</table>

The most common solid tumours in young women are cystic teratomas (known more commonly as dermoid cysts), which typically contain a variety of tissues including hair, teeth and bone. Benign ovarian tumours are often asymptomatic and may present coincidentally, for example when an abdominal radiograph reveals the appearance of a tooth in the abdomen or pelvis. Conversely, they may present with pain, abdominal swelling and pressure effects. The pain may be the result of torsion or bleeding inside the cysts. Management will depend, to some extent, on the age of the woman and the characteristics of the cyst. In older women, a conservative approach is reasonable only if the risks of malignancy are low (see Ovarian cancer). In younger women (<35 years), the cyst can be followed by serial ultrasound scanning as many will regress – haemorrhagic corpus luteal cysts, for example, will often shrink after three to four months’ treatment with a COC. If there is uncontrollable pain, haemodynamic collapse or a suspicion of torsion, or the cyst does not regress, then laparoscopic ovarian cystectomy with conservation of ovarian tissue is the treatment of choice. As the vast majority of oocytes lie within 5 mm of the surface of the ovary, a carefully carried out cystectomy can leave a normally functioning ovary (Figure 80.14) (Summary box 80.6).

### Summary box 80.6

**Management of benign ovarian cysts**

- Masses are usually detected incidentally but may be suggested by symptoms and signs
- A pregnancy test is done to exclude ectopic pregnancy
- Transvaginal ultrasonography can usually confirm the diagnosis. If results are indeterminate, magnetic resonance imaging or computed tomography scanning may help.
- Masses with radiographic characteristics of cancer (e.g. cystic and solid components, surface excrescences, multicellular appearance, irregular shape) require removal
- Tumour markers may help in the diagnosis of specific tumours
- In women of reproductive age, simple, thin-walled cystic adnexal masses of 5–8 cm (usually follicular) without characteristics of cancer do not require further investigation unless they persist for more than three menstrual cycles
- Many ovarian cysts resolve without treatment; serial ultrasonography is carried out to document resolution. Cyst removal (ovarian cystectomy) via laparoscopy or laparotomy may be necessary for cysts ≥8 cm, cysts that persist for more than three menstrual cycles and haemorrhagic corpus luteum cysts with signs of peritonitis
- Cystic teratomas require removal via cystectomy if possible. Oophorectomy is carried out for fibromas, cystadenomas, cystic teratomas >10 cm and cysts that cannot be surgically removed from the ovary

### Ovarian cancer

Ovarian cancer is the sixth most common malignancy among women worldwide and the leading gynaecological cause of death in the developing world. In the UK, over 6000 women die annually from ovarian cancer. Over 90 per cent of cancers arise from the surface epithelium of the ovary (which has the same embryological origins as the peritoneum); the majority are sporadic rather than inherited. The peak incidence is in the age range of 60–70 years. The overall five-year survival rate is less than 50 per
cent because approximately two-thirds of women present withadvanced disease. The usual presenting symptoms are:

- abdominal distension and/or pain;
- weight gain and increased girth (ascites);
- urinary obstruction.

However, over half of all women present initially to a speciality other than gynaecology, with often vague symptoms caused by metastatic disease, e.g. shortness of breath, gastrointestinal disturbance or a change in bowel habit. Consequently, it is important to include ovarian cancer in the differential diagnosis of any woman presenting with recent onset of persistent, non-specific, abdominal symptoms (including those whose abdomen and pelvis appears normal on clinical examination).

Ultrasound is the first-line investigation if an ovarian mass is suspected on clinical grounds. The features suggestive of malignancy on ultrasound include the presence of:

- cyst complexity (number of locules, wall structure, thickness of septa, fluid echogenicity);
- solid papillary projections into the cyst;
- bilateral lesions;
- ascites;
- intra-abdominal metastases.

The level of cancer antigen 125 (CA-125; a glycoprotein expressed on tissue derived from coelomic and Mullerian epithelia) in serum is measured; the normal cut-off value is 35 U/mL. Elevated levels are found in 50 per cent of patients with stage I disease and >90 per cent of those with advanced disease. However, CA-125 levels are also elevated in other cancers, e.g. pancreas, breast, lung and colon. Levels may even be raised during menstruation; in benign conditions such as endometriosis, PID and liver disease; if ascites or other effusions are present; and after a recent laparotomy. The value of combining the ultrasound and CA-125 measurements is such that a post-menopausal woman with a simple, unilateral, unilocular cyst of <5 cm in diameter and a normal serum CA-125 level should be managed conservatively (Summary box 80.7).

Unfortunately, there are still no effective screening methods for ovarian cancer for the general population. Hence, the preliminary results of the UK Collaborative Trial of Ovarian Cancer Screening are of great interest. The study has recruited over 200 000 women, aged 50–74 years, who have been randomised to a control arm or one of two screening strategies: primary screening using measurement of serum CA-125 levels followed by transvaginal ultrasound as a second-line test or transvaginal ultrasound alone. The two screening procedures were similar in terms of sensitivity for all primary ovarian and Fallopian tube cancers, but specificity was higher with combined screening (99.8 versus 98.2 per cent; p < 0.001).

There is also no consensus regarding how women who are at high risk because of a family history should be screened, i.e. those with a first-degree relative affected by cancer within a family that meet one of the following criteria:

- Two or more individuals with ovarian cancer, who are first-degree relatives of each other.
- One individual with ovarian cancer at any age and one with breast cancer diagnosed at <50 years, who are first-degree relatives of each other (or second-degree relatives if the transmission is paternal).
- One relative with ovarian cancer at any age and two with breast cancer diagnosed at <60 years, who are connected by first-degree relationships (or second-degree relationships if the transmission is paternal).
- Known carrier of relevant cancer gene mutations (e.g. BRCA1 or BRCA2).
- Untested first-degree relative of a predisposing gene carrier.
- Three or more family members with colon cancer or two with colon cancer and one with stomach, ovarian, endometrial, urinary tract or small bowel cancer in two generations. One of these cancers must be diagnosed at <50 years of age (Lynch syndrome).
- An individual with both breast and ovarian cancer.

</tr>
</tbody>
</table>
Some genetic mutations are known to predispose women to ovarian cancer, e.g. BRCA1 and BRCA2 and the mismatch repair genes associated with HNPCC (Lynch syndrome) families. BRCA1 mutations confer a 30 per cent lifetime risk of ovarian cancer up to the age of 60 years; the figure for BRCA2 mutations is 27 per cent up to the age of 70 years. The mismatch repair genes confer an increased lifetime risk of ovarian cancer of 9–12 per cent, in addition to the increased risk of endometrial cancer (see above under Vaginal bleeding in the non-pregnant state). Referral to a specialist cancer genetics service is advisable. Women at high risk of ovarian cancer may be offered prophylactic oophorectomy, especially as they may also be at increased risk of breast cancer and there is some evidence to suggest that oophorectomy reduces breast cancer risk in these women. Unfortunately, there is no proven role for screening in women at high risk.

Stage (Table 80.5) is performed at laparotomy via a midline incision if disease is suspected preoperatively by:

- Careful evaluation of all peritoneal surfaces.
- Four washings of the peritoneal cavity: diaphragm, right and left abdomen, pelvis.
- Infracolic omentectomy.
- Selected lymphadenectomy of the pelvic and para-aortic lymph nodes.
- Biopsy and/or resection of any suspicious lesions, masses and any adhesions.
- Random blind biopsies of normal peritoneal surfaces, including that from the undersurface of the right hemi-diaphragm, bladder reflection, cul-de-sac, right and left paracolic recesses and both pelvic side walls.
- Total abdominal hysterectomy and bilateral salpingo-oophorectomy.
- Appendicectomy for mucinous tumours; if a routine appendicectomy results in an intraoperative suspicion of a mucinous tumour, the surgeon should take washings and a biopsy from any suspicious area.

Surgery is the mainstay of treatment for ovarian cancer. The staging laparotomy and histological findings provide accurate information about prognosis and postoperative therapy. The general principle is cytoreductive surgery followed by combination chemotherapy; only a minority of patients with ovarian cancer need bowel resected during the primary procedure or surgery for recurrent disease. The only exception to this rule is a young woman with stage I disease or a borderline tumour who requests unilateral oophorectomy to conserve her fertility.

Stage I/grade 1 epithelial adenocarcinoma requires no postoperative therapy. Stage I/grade 2 or 3 cancers and stage II cancers require six courses of chemotherapy (typically, paclitaxel and carboplatin). Stage III or IV cancer requires six courses of similar chemotherapy. Intraperitoneal chemotherapy or high-dose chemotherapy with bone marrow transplantation is under study. Radiation therapy is used infrequently. Even if chemotherapy results in a complete clinical response (i.e. normal physical examination, normal serum CA-125 and negative CT scan of the abdomen and pelvis), about 50 per cent of such patients with stage III or IV cancer will have residual tumour. Of patients with persistent elevation of CA-125, 90–95 per cent have residual tumour.

Ovarian stimulation with oocyte or embryo freezing has been reported in patients with low-grade tumours who wish to preserve fertility, but the effect of this on the underlying disease is as yet unknown and it must therefore be carried out with caution.

HISTORICAL PERSPECTIVE

Since early times, the idea of tissue and organ transplantation has captured the imagination of successive generations and, over the centuries, numerous fanciful descriptions of successful transplants have been recorded. One of the most widely cited examples is that of the Christian Arab Saints Cosmas and Damian. Around AD 300, they were reputed to have successfully replaced the diseased leg of a patient with that from another man who had died several days earlier (Figure 81.1).

The modern era of transplantation began in the 1950s (Table 81.1) and relied on surgical techniques for anastomosing blood vessels that had been developed at the beginning of the twentieth century by Mathieu Jaboulay and Alexis Carrel. The first successful kidney transplant was a living-donor transplant performed between identical twins in 1954 at the Brigham Hospital in Boston by Joseph Murray and colleagues. This, and other kidney transplants between identical twins, demonstrated the technical feasibility of kidney transplantation, but attempts to perform renal transplantation when the donor and recipient were not genetically identical failed because no effective immunosuppressive therapy was available (Figure 81.2). Then, in 1959, Schwartz and Dameshek discovered that 6-mercaptopurine had immunosuppressive properties, and Calne showed that azathioprine, a derivative of 6-mercaptopurine, prevented rejection of canine kidney transplants. From the early 1960s, a combination of azathioprine and corticosteroids was used with moderate success in the clinic to prevent graft rejection after transplantation.

LEARNING OBJECTIVES

- To appreciate the immunological basis of allograft rejection
- To know the principles of immunosuppressive therapy
- To be aware of the side effects of non-specific immunosuppression
- To be familiar with the major issues concerning organ donation
- To appreciate the main indications for organ transplantation
- To know the surgical principles of organ implantation
- To be able to give an account of the causes of graft dysfunction
- To know the likely outcomes after transplantation
- To be aware of potential future developments in transplantation

Figure 81.1 Depiction of Saints Cosmas and Damian performing a miraculous transplantation of the leg. Oil painting attributed to the Master of Los Balbases (Wellcome Institute Library, London).

Alexis Carrel, 1873–1944, was a surgeon from Lyons in France, who worked at the Rockefeller Institute for Medical Research in New York, NY, USA. He received the Nobel Prize for Physiology or Medicine in 1912 'In recognition of his works on vascular suture and the transplantation of blood vessels and organs'.

Joseph E Murray, born 1919, Professor Emeritus of Plastic Surgery, The Harvard Medical School, Boston, MA, USA. He shared the 1990 Nobel Prize for Physiology or Medicine with E Donnall Thomas for his work on organ and cell transplantation.

Mathieu Jaboulay, 1860–1913, Professor of Surgery, Lyons, France.

Robert S Schwartz, Professor of Medicine, The Tufts University School of Medicine, Boston, MA, USA.

William Dameshek, 1900–1969, an American physician and haematologist.
kidney transplantation. These chemical agents were sometimes supplemented with a polyclonal antilymphocyte antibody.

The ciclosporin era began in the late 1970s following its discovery by Borel at the Sandoz laboratories in Basle and the demonstration, by Calne in Cambridge, UK, of its potent immunosuppressive properties in clinical transplantation. The introduction of ciclosporin was a major advance and ciclosporin (usually given together with azathioprine and steroids) not only improved the results of renal transplantation, but also allowed transplantation of the heart and liver to be undertaken with acceptable results. Organ transplantation is now well established as an effective treatment for selected patients with end-stage organ failure. Kidney, liver, pancreas, heart and lung transplantation are all routine procedures with good outcome, and transplantation of the small intestine is becoming more widely practised. Transplant activity is limited only by the shortage of donor organs.

Definitions of common terms in the area of organ transplantation are given in Summary box 81.1.

**Summary box 81.1**

**Definitions**

- **Allograft**: an organ or tissue transplanted from one individual to another
- **Alloantigen**: transplant antigen
- **Alloantibody**: transplant antibodies
- **HLA**: human leukocyte antigen, the main trigger to graft rejection
- **Xenograft**: a graft performed between different species
- **Orthotopic graft**: a graft placed in its normal anatomical site
- **Heterotopic graft**: a graft placed in a site different from that where the organ is normally located

**GRAFT REJECTION**

Allografts provoke a powerful immune response that results in rapid graft rejection unless immunosuppressive therapy is given. The pioneering studies of Medawar in the 1940s and 1950s firmly established that allograft rejection was due to an immune response and not a non-specific inflammatory response and subsequent studies demonstrated that T lymphocytes play an essential role in mediating rejection.

Allografts trigger a graft rejection response because of allelic differences at polymorphic genes that give rise to histocompatibility antigens (transplant antigens) of which ABO blood group antigens and human leukocyte antigens (HLA) are the most important.

**ABO blood group antigens**

The ABO blood group antigens are expressed not only by red blood cells, but by most other cell types as well. It is vitally

important, for all types of organ allograft, to ensure that recipients do not unintentionally receive a graft that is ABO blood group compatible otherwise naturally occurring anti-A or anti-B antibodies will likely cause hyperacute graft rejection.

Permissible transplants are:
- group O donor to group O, A, B or AB recipient;
- group A donor to group A or AB recipient;
- group B donor to group B or AB recipient;
- group AB donor to group AB recipient.

There is no need to take account of rhesus antigen compatibility in organ transplantation.

**HLA antigens**
Allograft rejection (in blood group-compatible grafts) is directed predominantly against HLA – a group of highly polymorphic cell-surface molecules. HLA are strong transplant antigens by virtue of their special physiological role as antigen recognition units for display of antigens from foreign pathogens for recognition by T lymphocytes. It was through their role in stimulating graft rejection responses that their existence was first demonstrated by Dausset in 1958, hence their description as major histocompatibility antigens (Summary box 81.2).

### Summary box 81.2

- **HLA antigens**
  - Are the most common cause of graft rejection
  - Their physiological function is to act as antigen recognition units
  - Are highly polymorphic (amino acid sequence differs widely between individuals)
  - HLA-A, -B (class I) and -DR (class II) are most important in organ transplantation

There are two types of HLA molecule: HLA class I and HLA class II (Table 81.2). They are broadly similar in structure (Figure 81.3) but have different cell expression profiles. HLA class I antigens are present on all nucleated cells, whereas HLA class II antigens have a more restricted distribution and are expressed most strongly on antigen-presenting cells, such as dendritic cells, macrophages and B lymphocytes. T cells recognize HLA molecules via their T-cell receptor but full T-cell activation also requires the delivery of an additional or second signal delivered by the interaction of costimulatory molecules on the surface of the antigen-presenting cell and T cell (Figure 81.4).

### Effector mechanisms of rejection
HLA antigens expressed by graft cells activate T cells and stimulate them to proliferate in response to interleukin-2 (IL-2) and other T-cell growth factors. Activated CD4 T cells, through release of cytokines, play a central role in orchestrating the various effector mechanisms responsible for graft rejection (Figure 81.5). The cellular effectors of graft rejection include cytotoxic CD8 T cells, that recognise donor HLA class I antigens expressed by the graft and cause target cell death by releasing lytic molecules such as perforin and granzyme. Graft-infiltrating CD4 T cells, which recognise donor HLA class II antigens, mediate direct target cell damage and are also able, by releasing proinflammatory cytokines such as interferon-γ, to recruit and activate macrophages that act as non-specific effector cells. Finally, CD4 T cells provide essential T-cell help for B lymphocytes that differentiate into plasma cells and produce

alloantibodies that bind to graft antigen and induce target cell injury directly or through antibody-dependent, cell-mediated cytotoxicity.

**Types of allograft rejection**

Allograft rejection can be divided into three distinct types (Summary box 81.3):

1. Hyperacute rejection (occurs immediately);
2. Acute rejection (usually occurs in the first six months);
3. Chronic rejection (occurs months and years after transplantation).

Hyperacute rejection

Immediate graft destruction due to ABO or preformed anti-HLA antibodies

Characterised by intravascular thrombosis and interstitial haemorrhage

Acute rejection

Usually occurs during first six months

T cell dependent

May be cell-mediated, antibody-mediated or both

Usually reversible

Chronic rejection

Occurs after first six months

Most common cause of graft failure

Antibodies play an important role

Non-immune factors contribute to pathogenesis

Characterised by myointimal proliferation in graft arteries leading to ischaemia and fibrosis

A standardised histological grading system, termed the Banff classification (named after the Canadian town where the initial scientific workshop was held), defines the presence and severity of allograft rejection after organ transplantation.

**Summary box 81.3**

**Types of graft rejection**

- **Hyperacute rejection**
  - Immediate graft destruction due to ABO or preformed anti-HLA antibodies
  - Characterised by intravascular thrombosis and interstitial haemorrhage

- **Acute rejection**
  - Usually occurs during first six months
  - T cell dependent
  - May be cell-mediated, antibody-mediated or both
  - Usually reversible

- **Chronic rejection**
  - Occurs after first six months
  - Most common cause of graft failure
  - Antibodies play an important role
  - Non-immune factors contribute to pathogenesis
  - Characterised by myointimal proliferation in graft arteries leading to ischaemia and fibrosis
the hepatic blood supply is derived from the portal vein and 40 per cent from the hepatic artery.

Hyperacute rejection can be avoided by ensuring ABO blood group compatibility and by performing a cross-match test on recipient serum to ensure that there are no clinically relevant antibodies directed against HLA antigens expressed by a prospective kidney donor.

**Acute rejection**

This usually occurs during the first six months of transplantation but may occur later. It is mediated predominantly by T lymphocytes, but alloantibodies may also play an important role. Acute rejection is characterised by mononuclear cell infiltration of the graft (Figure 81.6). The mononuclear cell infiltrate is heterogeneous and includes cytotoxic T cells, B cells, NK cells and activated macrophages. Antibody-mediated damage may also be present as evidenced by the deposition of the complement component C4d within the graft microvasculature (Figure 81.7). All types of organ allograft are susceptible to acute rejection, and although relatively common (typically occurring in around 20–30 per cent of grafts), most episodes of acute rejection can be reversed by additional immunosuppressive therapy.

**Chronic rejection**

This usually occurs after the first six months. All types of transplant are susceptible to chronic rejection, and it is the major cause of allograft failure. Interestingly, the liver is more resistant than other organs to the destructive effects of chronic rejection. The pathophysiology of chronic rejection is not well understood. The underlying mechanisms are immunological, and alloantibodies are thought to be a major cause although cellular effector mechanisms may also contribute. Alloantigen-independent factors also contribute. The risk factors for chronic rejection of a kidney transplant are:

- previous episodes of acute rejection;
- poor HLA match;
- long cold ischaemia time;
- cytomegalovirus (CMV) infection;
- raised blood lipids;
- inadequate immunosuppression (including poor compliance).

The single most important risk factor for chronic rejection after kidney transplantation is acute rejection (with vascular inflammation) and recurrent episodes of acute rejection. Because non-immune factors often contribute significantly to the long-term failure of a kidney transplant, the term ‘chronic allograft nephropathy’ is sometimes used.

The histological picture of chronic rejection after organ transplantation is dominated by vascular changes, with the development of myointimal proliferation in arteries, which results in ischaemia and fibrosis (Figure 81.8). In addition to vasculopathy, there are organ-specific features of chronic graft rejection. These are:

- kidney: glomerular sclerosis and tubular atrophy;
- pancreas: acinar loss and islet destruction;
- heart: accelerated coronary artery disease (cardiac allograft vasculopathy);
- liver: vanishing bile duct syndrome;
- lungs: obliterative bronchiolitis.
Chronic rejection causes functional deterioration in the graft, resulting after months or years in complete graft failure. Unfortunately, currently available immunosuppressive therapy has had little effect in preventing chronic rejection.

**Graft-versus-host disease**

Although the main immunological problem after transplantation is graft rejection, the reciprocal problem of graft-versus-host reaction is occasionally seen following certain types of organ transplantation. Some donor organs (particularly liver and small bowel) contain large numbers of lymphocytes, and these may react against HLA antigens expressed by recipient tissues, leading to graft-versus-host disease (GVHD). GVHD frequently involves the skin, causing a characteristic rash on the palms and soles. It may also involve the liver (after small bowel transplantation) and the gastrointestinal tract (after liver transplantation). GVHD is a serious and sometimes fatal complication.

**HLA Matching**

HLA molecules are encoded by the major histocompatibility complex (MHC), a cluster of genes situated on the short arm of chromosome 6 (Figure 81.9). The HLA class I antigens comprise HLA-A, -B and -C, and the HLA class II antigens comprise HLA-DR, -DP and -DQ. Expression of MHC genes is co-dominant, i.e. the genes on both the maternally derived and the paternally derived chromosomes are expressed. Consequently, an individual may express between 6 and 12 different HLA antigens, depending on the degree of homozygosity (shared genes) at individual loci.

The HLA haplotype inherited from each parent is usually inherited as a complete haplotype, according to simple Mendelian genetics (Figure 81.10). In deceased donor renal transplantation (but not other types of organ transplantation), attempts are usually made to match the donor and recipient for as many of the relevant HLA antigens as possible. In addition to reducing the risk of graft loss from rejection, a well-matched kidney allograft that subsequently fails is less likely to cause sensitisation to the HLA antigens that it expresses. It is particularly important in children and young adults to avoid, where possible, grafts that are mismatched for common HLA antigens because, if retransplantation is required subsequently, it may be difficult to find an organ donor who does not express the antigens to which the recipient has become sensitised. In terms of organ transplantation, HLA-A, -B and -DR are the most important antigens to take into account when matching donor and recipient in an attempt to reduce the risk of graft rejection (Figure 81.11).

HLA matching has a relatively small but definite beneficial effect on renal allograft survival (HLA-DR > HLA-B > HLA-A). Recipients who receive well-matched renal allografts may require less intensive immunosuppression and also are troubled less by rejection episodes. It is common practice to express the degree of HLA matching between the donor and recipient in terms of whether or not there are mismatches at each locus for HLA-A, -B and -DR. A ‘000 mismatch’ is a ‘full-house’ or complete match, whereas a ‘012 mismatch’ is matched at

**Figure 81.9** The human leukocyte antigen (HLA) system on the short arm of chromosome 6.

Gregor Johann Mendel, 1822–1884, an Austrian monk and naturalist who became Abbot of the Augustinian Monastery at Brunn, the Czech Republic and discovered the laws of inheritance by studying the edible pea. In 1865 he described ‘dominant’ and ‘recessive’ traits in hybrids. His work passed unnoticed for 35 years.

**Figure 81.10** Human leukocyte antigen (HLA) inheritance. Children acquire one HLA haplotype (depicted as A–D) from each parent. As shown, child 1 shares one HLA haplotype (haploidentical) with child 2 and child 3, but does not share either haplotype with child 4. The chances that two siblings will share the same parental haplotypes, or that they will share neither HLA haplotype, is one in four. The chance that they will share one HLA haplotype is one in two.

**Figure 81.11** Beneficial effect of human leukocyte antigen (HLA) matching (HLA-A, -B and -DR) on first deceased donor renal allograft survival (courtesy of Gerhard Opelz, Collaborative Transplant Study, CTC-K21101-0211). MM, antigen mismatch.
HLA-A loci, has one mismatched HLA-B antigen and is mismatched for both DR antigens. Deceased donor kidneys are allocated in some countries, including the UK, by a points system that optimises HLA matching but also takes into account other factors, such as time on the waiting list, sensitisation to HLA antigens and the age relationship between the donor and recipient. Allocation of organs for transplantation must also take into account the relative size of donor and recipient. This is not an issue in renal transplantation, and adult kidneys can be readily used for paediatric recipients (and vice versa). However, in the case of heart, lung, liver and small bowel transplantation, it is important to consider size compatibility between the donor and recipient. In the case of liver transplants, HLA matching does not confer an advantage and, although it is beneficial in cardiac transplantation, it is not practicable because of the relatively small size of the recipient pool and the short permissible cold ischaemic time.

THE TISSUE-TYPING LABORATORY

Successful organ transplantation requires a close-working relationship between the tissue-typing laboratory and the clinical transplant team. The tissue-typing laboratory carries out three key tasks. First, they determine the HLA type (‘tissue type’) of all potential organ transplant recipients and organ donors. This is achieved by applying polymerase chain reaction-based DNA-typing techniques to samples of peripheral blood. Second, they perform a cross-match test to exclude the presence in a recipient of clinically significant circulating antibodies to HLA antigens expressed by a potential organ donor that would result in rapid or hyperacute graft rejection. This involves incubating recipient sera with donor lymphocytes prepared from either blood or lymphoid tissue. The presence of antidonor antibodies is detected in a conventional cytotoxic cross-match assay by adding rabbit complement along with indicator dyes and visualising target cell death. More often now a flow cytometric cross-match is performed as well as, or instead of, a cytotoxic cross-match. Third, the tissue-typing laboratory determines the HLA specificity of circulating anti-HLA antibodies in recipients before and after organ transplantation to guide organ allocation and immunosuppressive therapy. This task has been revolutionised by the availability of solid phase assays, particularly Luminex technology, where patient sera are incubated with a panel of latex beads coated with purified HLA molecules and antibody binding detected by flow cytometric analysis.

Patients on the renal transplant waiting list should be screened for the development of HLA antibodies on a regular basis and especially after potential priming to HLA antigens by blood transfusion.

If, when considering renal transplantation the cross-match test is strongly positive, transplantation should not proceed, otherwise hyperacute rejection is likely. Antibodies directed against HLA class II antigens, unlike those to HLA class I, do not usually cause hyperacute rejection but are associated with acute rejection and a poor clinical outcome. Patients awaiting heart transplantation are also screened for the presence of HLA antibodies and those with preformed antibodies are subjected to a prospective cross-match test. Although heart allografts rarely undergo hyperacute rejection, transplantation in the presence of a positive cross-match is associated with graft loss from accelerated acute rejection. Even in the presence of a strongly positive cross-match test, liver transplants rarely undergo hyperacute rejection, although long-term survival is reduced.

IMMUNOSUPPRESSIVE THERAPY

A range of different agents are available that act at different sites during T-cell activation to prevent rejection (Table 81.3 and Figure 81.12). They can be classified according to their principal mode of action.

Calcineurin inhibitors (ciclosporin and tacrolimus)

Ciclosporin and tacrolimus are the mainstay of most modern immunosuppressive protocols for organ transplantation. Although structurally distinct, they exert their principal immunosuppressive effect through the same intracellular pathway. Each of the two agents binds within the T cell to a cytoplasmic protein or immunophilin (ciclosporin binds to cyclophilin and tacrolimus to FK-binding protein). The resulting immunophilin–drug complex then blocks the activity of calcineurin (a phosphatase) within the cytoplasm of the T cell. Calcineurin plays a critical role in facilitating the transcription of IL-2, the main T-cell growth factor, and other cytokines after T-cell activation. By blocking cytokine synthesis, ciclosporin and tacrolimus exert a potent immunosuppressive effect. The two agents share a number of side effects, the most notable of which is nephrotoxicity (Table 81.4). Ciclosporin sometimes causes cosmetic side effects (hirsutism and gingival hypertrophy) that may be distressing, particularly in younger female recipients. The calcineurin inhibitors (CNIs) have a relatively small therapeutic window. Their immunosuppressive action, as well as their side effects, is dependent on their blood concentration, and monitoring of whole-blood drug levels is an important guide to optimal therapy. Ciclosporin and tacrolimus are broadly equivalent in terms of long-term graft survival but increasing evidence suggests tacrolimus is more effective in reducing acute rejection. The choice between the two agents depends on the preference of the transplant unit and on individual patient tolerance to the different side effects of the two agents.

Table 81.4  Agent-specific side effects of immunosuppressive agents used in organ transplantation (all immunosuppressive agents increase the risk of infection).

Notes: ALG, antilymphocyte globulin; mTOR, mammalian target of rapamycin; PTLD, post-transplant lymphoproliferative disease.

Antiproliferative agents (azathioprine and mycophenolate)

Lymphocytes are among the most rapidly proliferating cells in the body, and lymphocyte proliferation and clonal expansion is an integral part of the immune response to an allograft. The antiproliferative agents available for immunosuppression are azathioprine and mycophenolic acid preparations (mycophenolate mofetil (MMF) and mycophenolic acid sodium (MPAS)). Azathioprine is converted in the liver to its active metabolite, 6-mercaptopurine, which blocks purine metabolism and thereby inhibits cellular proliferation. Mycophenolic acid (MPA) preparations are more expensive than azathioprine but have largely replaced it as the agents of choice. After ingestion, MMF is converted to its active metabolite MPA. It inhibits the enzyme inosine monophosphate dehydrogenase, which is the rate-limiting enzyme in the de novo pathway of purine nucleotide synthesis. Because lymphocytes do not have a salvage pathway for purine synthesis, their ability to proliferate is selectively impaired. The main side effects of azathioprine and MPA are bone marrow suppression and gastrointestinal symptoms.

Steroids

Steroids are an important component of many immunosuppressive regimens. Glucocorticoids are potent anti-inflammatory agents and have wide-ranging effects on the immune response. Because of their numerous and well-known side effects, some centres attempt to gradually withdraw steroids from patients who have stable graft function after transplantation, but this sometimes precipitates a rejection episode and necessitates recommencement of steroids.

Antibody therapies

Monoclonal antibodies directed against the IL-2 receptor on T lymphocytes (CD25) are commonly given at the time of transplantation to temporarily augment the effects of calcineurin blockade during the early post-transplant period. Their effect lasts for a few weeks only and they lack any significant agent-specific side effects. Polyclonal antibody (antithymocyte globulin (ATG)) and monoclonal antibody preparations (alemtuzumab (anti-CD52 expressed on T cells and dendritic cells) are also quite widely used as more potent and alternative induction agents. They cause a temporary depletion of circulating lymphocytes that reduces rejection but may lead to an increase in infection and malignancy. In addition to their use as induction agents, antibody preparations may be used to treat acute rejection episodes that fail to respond to steroid therapy.

The monoclonal anti-CD20 antibody (rituximab) depletes B lymphocytes and is widely used as a component of desensitisation protocols to enable ABO and HLA antibody-incompatible renal transplantation. It may also be helpful for the treatment of antibody-mediated acute rejection although its efficacy here is limited because it does not deplete antibody-producing plasma cells.

Mammalian target of rapamycin inhibitors (sirolimus and everolimus)

Sirolimus and its structural analogue everolimus are, like tacrolimus, macrolides that bind within T lymphocytes to FK-binding protein. However, their mode of action is completely different to that of both ciclosporin and tacrolimus.
They act by inhibiting an intracellular kinase called mammalian target of rapamycin (mTOR) and interfere with intracellular signalling from the IL-2 receptor, arresting T-cell division in the G1 phase. In contrast to CNIs they are not nephrotoxic. However, their side effect profile includes lymphocele formation, impaired wound healing, an adverse effect on the blood lipid profile, thrombocytopenia and very occasionally pneumonitis. mTOR inhibitors may have antitumour activity and the potential value of this effect in transplant patients is under investigation. Although the negative effect on wound healing and lymphocele formation limits the immediate use of mTOR inhibitors after transplantation, switching from CNIs to mTOR inhibitors is being used increasingly as a strategy to minimise CNI-induced nephrotoxicity.

**T-cell costimulatory blockers**

CTLA-4Ig (belatacept, LEA29Y) is a fusion protein comprising the extracellular domain of CTLA-4 fused to human IgFc. It binds to the costimulatory ligands CD80 and CD86 expressed on antigen-presenting cells and as a result prevents them from delivering the costimulatory signals to the T cells that are required for full T-cell activation. It has recently been shown in renal transplantation to provide an effective alternative to CNIs when given by regular i.v. injection, thereby avoiding the metabolic, cardiovascular and nephrotoxic effects of CNIs. Although its future looks very promising, a potential concern is that it may be associated with an increased risk of post-transplant lymphoproliferative disease (PTLD).

**Immunosuppressive regimens**

When selecting an immunosuppressive regimen, the challenge is to provide levels of immunosuppression that are sufficient to protect the graft from rejection without exposing the recipient to excessive risk from infection and malignancy as a result of non-specific immunosuppression (Summary box 81.4). Immunosuppressive therapy is started at the time of transplantation and is continued indefinitely (as maintenance therapy), although the requirement for immunosuppression is highest in the first few weeks after transplantation when the risk of acute rejection is greatest. Immunosuppressive protocols vary, but all use a combination of immunosuppressive agents acting at different points in the pathway of lymphocyte activation. Most currently include a CNI (ciclosporin or tacrolimus) as the main agent and often this is supplemented with anti-CD25 monoclonal antibody induction therapy. CNIs are usually combined with an antiproliferative agent (most often MMF) and steroids, so-called triple therapy. Less often, a CNI is used with an antiproliferative agent alone or with steroids alone (dual therapy). When there is particular concern about acute rejection, polyclonal or monoclonal antibody preparations are administered followed by a CNI, an antiproliferative agent and steroids.

The principles of immunoprophylaxis are similar for all types of organ transplantation. Interestingly, liver grafts seem to be less susceptible to rejection for reasons that are still unclear. The mTOR inhibitors have been shown to be effective immunosuppressive agents for preventing acute rejection following kidney transplantation and they provide a non-nephrotoxic alternative to CNIs for maintenance therapy. They have a similar safety profile to CNIs in terms of post-transplant infection but some of their agent-specific side effects are of potential concern and their clinical niche is still to be fully determined. Similarly, the potential role that CTLA-4Ig will find as an alternative to CNIs remains to be seen.

Acute rejection occurs in up to around 30 per cent of transplant recipients but usually responds to a short course of high-dose steroid therapy. If the response to steroids is inadequate or if acute rejection recurs, acute rejection can often be treated successfully by recourse to antilymphocyte globulin (ALG) therapy.

**COMPPLICATIONS OF IMMUNOSUPPRESSION**

As well as the agent-specific side effects already mentioned, the immunosuppressive agents used in organ transplantation cause non-specific immunosuppression and increase the risk of both infection and malignancy (Summary box 81.5).

### Summary box 81.5

**Side effects of non-specific immunosuppression**

- **Infection**
  - Transplant recipients are at high risk of opportunistic infection, especially by viruses
  - Bacterial and fungal infections are also common
  - Risk of infection is greatest during first six months
  - Chemoprophylaxis is important for high-risk patients
  - Viral infection may result from reactivation of latent virus or from primary infection
  - Cytomegalovirus is a major problem
  - Pretransplant vaccination against community-acquired infection should be considered

- **Malignancy**
  - Most types of cancer are more common after transplantation
  - Recipients, especially children, are at risk of post-transplant lymphoproliferative disease (PTLD)
  - There is a very high risk of squamous cancer of the skin and recipients should have regular skin review

**Infection**

Transplant recipients receiving immunosuppressive therapy are at high risk from opportunistic infection, especially by viruses. Opportunistic infection is a potential problem in all transplant recipients, but those receiving aggressive immunosuppressive...
therapy are most at risk. Chemoprophylaxis is important in high-risk recipients, and early recognition followed by prompt and aggressive treatment of infection is essential in all transplant recipients. Pretransplant vaccination against community-acquired infections should be considered.

**Bacterial infection**

The risk of bacterial infection is highest during the first month after transplantation. Transplant recipients are, like any patient undergoing major surgery, at risk of bacterial infections in the wound, respiratory tract and urinary tract. It is standard practice to give a broad-spectrum antibiotic to cover the perioperative period as prophylaxis against wound infection and possible bacterial contamination of the donor organ. The risk of bacterial infection is greatest in transplant recipients who are critically ill before or after surgery and are in the intensive care unit with indwelling catheters and lines. After recovery from surgery, the risk of bacterial infection is much reduced. Tuberculosis is a concern in patients who have previously had mycobacterial infection and in patients from the Indian subcontinent, and it is usual to give them chemoprophylaxis for a period of 6–12 months after transplantation.

**Viral infection**

The risk of viral infection is highest during the first six months after transplantation and the most common problem is CMV infection. CMV disease may arise because of reactivation of latent infection or because of primary infection that can be transmitted by an organ from a CMV-positive donor. Recipients at most risk from CMV infection are those who are CMV seronegative (i.e. those who have not been infected previously with CMV) and receive an organ from a CMV-seropositive donor (about half of all UK donors are CMV seropositive). Unfortunately, matching seronegative donors with seronegative recipients is not practicable. Without prophylaxis, CMV disease typically presents at 4–8 weeks with a high swinging fever, lethargy and leukopenia. The severity of the disease is variable and the clinical picture depends on the organ system most affected. It may present as:

- pneumonia
- gastrointestinal disease
- hepatitis
- retinitis
- encephalitis.

Severe CMV disease is potentially fatal. Prophylaxis for CMV consists of administration of antiviral agents, most commonly valganciclovir; aciclovir and valaciclovir are cheaper but less effective alternatives. A diagnosis of active CMV infection is confirmed by polymerase chain reaction (PCR) to detect viral DNA in whole blood, and by histological examination of biopsy material. Treatment is with antiviral agents (either oral valganciclovir or i.v. ganciclovir) and is more effective when given pre-emptively on the basis of increased viral load detected by quantitative PCR analysis of peripheral blood.

**Fungal infection**

Pneumocystis jiroveci (previously designated Pneumocystis carinii and wrongly classified as a protozoa) is one of the more important fungal infections after transplantation. It occurs during the first few months and presents with respiratory symptoms. The diagnosis is made by examination of bronchoalveolar lavage fluid or lung biopsy material for evidence of fungal infection (Figure 81.13). Chemoprophylaxis is highly effective and usually continued for up to six months after transplantation.

Other types of invasive fungal infections are uncommon in renal transplant recipients but infection with Candida or Aspergillus is more common after other types of organ transplantation. Fungal infection usually occurs in the first three months after transplantation, and early diagnosis and aggressive treatment are essential to avoid fatal infection.

**Malignancy**

After transplantation, there is an increased risk of developing most types of malignant disease but the risk is particularly high for those types of tumour in which viral infection plays an aetiological role. The increased risk of malignancy is particularly high for skin cancer and post-transplant lymphoproliferative disorder. Most of the skin cancers seen are squamous cell car-

![Figure 81.13 Transbronchial lung biopsy from a renal allograft recipient with *Pneumocystis jiroveci* pneumonia. The silver stain used reveals fungal cysts, each containing several intracystic bodies or spores, distributed widely within the biopsy material.](image-url)
cinomas, but basal cell carcinoma and malignant melanoma are also more common than in the general population. The risk of skin cancer after transplantation rises with age and with exposure to sunlight, and it has been predicted that 50 per cent of transplant patients will develop a skin malignancy within 20 years of transplantation. Patients must be warned of this risk before they undergo transplantation and advised to take precautions to protect their skin from excessive sunlight. They should undergo regular review of their skin to detect early malignancy, and when malignant lesions occur they must be treated promptly and aggressively.

Post-transplant lymphoproliferative disorder is an abnormal proliferation of B lymphocytes, usually in response to Epstein–Barr virus infection. The condition presents in a variety of ways including as an infectious mononucleosis-type illness, as lymphadenopathy or with involvement of extranodal sites such as the tonsils, gastrointestinal tract, lung, liver or the transplanted organ (Figure 81.14). PTLD occurs in around 1–3 per cent of kidney and liver transplant recipients and the incidence is considerably higher in children. Those patients at most risk are those who have received aggressive immunosuppression. PTLD is a serious condition with an overall mortality of up to 50 per cent. If it is identified at an early stage, reduction or cessation of immunosuppressive therapy may cause disease regression and result in a cure. Chemotherapy is often given and antiviral therapy, surgery and radiotherapy may also have a role in treating established disease. Disseminated PTLD and central nervous system (CNS) involvement have a very poor prognosis.

Transplant patients also have a 300-fold increased risk of developing Kaposi’s sarcoma, although this malignancy is still very uncommon after transplantation.

**ORGAN DONATION**

The number of organs required to satisfy the needs of transplantation far exceeds the number of donor organs available. In the case of renal transplantation in the UK there are approximately 7000 patients waiting for transplantation, but only around 3500 transplants performed annually, which has led to a median waiting time for transplantation of three years. Similar shortages exist for liver and pancreas transplantation. For cardiothoracic organs the shortage is even worse and not all patients who might benefit from transplantation are listed.

Organs may be obtained from living donors or from deceased donors (DD) and DD may be either brainstem-dead heart-beating donors (donation after brain death or DBD donors) or donation after circulatory death (DCD) donors. Living donation is limited to donation of the kidney and, to a much lesser extent, liver or lung lobe. DBD donors provide a majority of organs for transplantation for all organ types although DCD donors provide an increasing number of kidneys, livers, pancreas glands and lungs for transplantation (see Summary box 81.6). The approach to referral and consent for organ donation varies between countries. Some have ‘required request’ or ‘required referral’ systems in place where all patients dying in intensive care settings have to be referred for their potential suitability to be organ donors assessed. Some countries (e.g. Austria and Spain) have an ‘opt out’ or ‘presumed consent’ system, where the assumption is made that an individual wished to donate their organs for transplantation unless they specifically registered their objection before death. There is debate about whether such a policy alone increases organ donation and a concern expressed by some that individuals who may not have wanted to become organ donors may fail to opt out before death, and that conflict may occur with relatives and next of kin who may oppose organ donation.

**Summary box 81.6**

**Overcoming the shortage of organs for transplantation**

- Maximising donation after brain-death (DBD) donation
- Use of marginal DBD deceased donors
- Use of donation after circulatory death (DCD) donors
- Increased use of split liver transplantation
- Increased living donor kidney (and liver) transplantation

**Donation after brain death donors**

The majority of DD organs are obtained from patients in whom brainstem death has been diagnosed. Such donors were previously called ‘heart-beating deceased donors’ and in most brain death results from stroke or traumatic head injury. Brain
death occurs when severe brain injury causes irreversible loss of the capacity for consciousness combined with the irreversible loss of the capacity for breathing. In most countries, it is accepted that the condition of brain death equates in medical, legal and religious terms with death of the patient. The concept of brain death arose through necessity in the management of patients with irreversible brain damage on life support when there was no prospect for recovery. It was not in the interest of such patients, their relatives or the hospital in which they were being treated to delay their inevitable demise by continuing with futile life support. Acceptance of the concept of brain death had major implications for organ transplantation as it allowed the possibility for removal of viable organs from brain-dead patients before their circulation failed.

In the UK and many other countries, brain death is defined in terms of permanent functional death of the brainstem as neither consciousness nor spontaneous respiration is possible in the absence of a functional brainstem. A diagnosis of brainstem death should be considered only when certain preconditions have been met. The patient must have suffered major brain damage of known aetiology, be deeply unconscious and require ventilatory support. Particular care must be taken to ensure that muscle relaxant agents and drugs with known CNS depressant effects are not contributing to the clinical picture. Hypothermia, profound hypotension and metabolic or hormonal conditions that may contribute to CNS depression and confound the diagnosis of brainstem death must also be excluded. When the necessary preconditions have been satisfied, formal clinical assessment of the brainstem reflexes can be undertaken (Table 81.5). The UK guidelines state that the tests should be performed on two separate occasions by two clinicians experienced in this area. At least one of the two clinicians should be a consultant and neither should be connected with the transplant team. The time that must elapse between the two sets of brainstem tests is not specified in the guidelines and is determined on the basis of clinical judgement. In the UK, there is no requirement to perform electrophysiological or brain perfusion studies to aid the diagnosis of brainstem death. Particular care is required in the diagnosis of brainstem death in neonates and infants.

### Donation after circulatory death donors

The number of potential DBD donors has remained relatively static or even declined as a result of changes in neurosurgical practice and improved road safety. To address the rising demand for organ transplantation there has been a major trend towards increasing use of organs from DCD donors. DCD donors can be grouped according to the Maastricht classification as follows:

- **category 1**: dead on arrival at hospital;
- **category 2**: resuscitation attempted without success;
- **category 3**: ‘awaiting cardiac arrest’ after withdrawal of support;
- **category 4**: cardiac arrest while brain dead;
- **category 5**: cardiac arrest and unsuccessful resuscitation in hospital.

Maastricht categories 1, 2 and 5 donors are sometimes referred to as uncontrolled DCD donors. The warm ischaemic time of organs from these three categories of donor is usually longer and less predictable than in the case of categories 3 and 4 (controlled) donors. The majority of DCD donor organs used for transplantation in the UK, US and several other European countries are from controlled (category 3) donors who have died in intensive care after planned withdrawal of futile cardiorespiratory support.

Kidneys may be also be recovered from carefully selected patients who are dead on arrival at the hospital or who have died following unsuccessful resuscitation. In Spain and France most DCD kidneys are obtained from uncontrolled donors.

### Evaluation of the deceased donor

After a deceased donor has been referred to the transplant team with a view to organ donation, the general suitability of the potential organ donor must be carefully assessed. Particular care must be taken to assess the donor from the point of view of transmissible infectious agents and malignancy. The medical history should be carefully scrutinised and evidence sought of risk factors for human immunodeficiency virus (HIV), such as intravenous drug abuse. The presence of Creutzfeldt–Jakob disease is an absolute contraindication to organ donation. Organs from HIV-infected donors should not be used for transplantation, except sometimes in recipients who are already infected by the HIV virus. Hepatitis B infection (in most countries) and active systemic sepsis, e.g. major abdominal infection, are contraindications to donation. The presence of malignancy within the past five years is usually an absolute contraindication to organ donation with the exceptions of primary tumours of the CNS, non-melanotic tumours of the skin and carcinoma in situ of the uterine cervix. If there are no general contraindications to organ donation, consideration is then given to organ-specific selection criteria.

Because of the high demand for donor organs there has been a progressive relaxation in the organ-specific selection criteria. The chronological age of the donor is less important than the physiological function of the organs under consideration for transplantation.

**Maastricht** is a city in the province of Limburg, in The Netherlands.

**In situ** is Latin for ‘in the place’.
The liver from a deceased donor is split and the left lobe or left transplantation, which was first performed by Pichlmayr in 1988.

and there are insufficient deceased paediatric donor livers available to be transplanted into a child because of the size mismatch, and bronchial aspirates should be free from fungal and bacterial infection. Elevations of blood glucose and serum amylase are not uncommon in deceased donors and do not preclude pancreas donation. The use of organs from suboptimal or ‘marginal’ deceased donors has increased markedly in an attempt to address the demand for transplantation. The definition of a marginal donor depends on the organs being considered for transplantation and varies between countries. In the case of kidney transplantation a marginal donor is defined in the United States as a donor age >60 years or one between the ages of 50 and 60 years with two of the following: hypertension, death from stroke and a terminal creatinine of >132 mmol/L. Organs from ‘marginal donors’ generally lead to less satisfactory transplant outcomes than those from standard donors.

**Organ recovery from deceased donors**

In DBD donors, once brainstem death has been confirmed, management of the donor is aimed at preserving the functional integrity of the organs to be recovered. Brainstem death produces profound metabolic and neuroendocrine disturbances leading to cardiovascular instability. Careful monitoring and management of fluid balance is essential. Inotropic support is given and there may be a role for the use of tri-iodothyronine (T3) and argipressin.

Recovery of multiple organs from a DBD donor requires cooperation between the thoracic and abdominal surgical teams. A midline abdominal incision and median sternotomy is used to obtain access. After dissection of the organs to be recovered, they are perfused in situ. The heart is perfused with cold cardioplegia solution via a cannula in the ascending aorta and the lungs are perfused via a cannula in the pulmonary artery. The abdominal organs are perfused with chilled organ preservation solution via an aortic and portal cannula. Blood and perfusate are vented from the left atrial appendage and the inferior vena cava. This produces rapid cooling of the organs, reduces their metabolic activity and preserves their viability. Additional surface cooling of the abdominal organs may be achieved by application of saline ice slush. The heart and lungs are excised followed by the liver and pancreas and then the kidneys, either en bloc or separately. The extent to which the abdominal organs are dissected prior to cold flush depends on the preference of the surgical team. Some surgeons perform minimal dissection prior to cold perfusion to complete the dissection of the abdominal organs in situ or on the back table after the organs have been removed en bloc. During recovery of the liver, care is taken to ensure that if there is an aberrant hepatic artery arising from the superior mesenteric artery it is included in the aortic patch. An adult donor liver cannot be transplanted into a child because of the size mismatch, and there are insufficient deceased paediatric donor livers available for transplantation. One solution is to undertake split liver transplantation, which was first performed by Pichlmayr in 1988. The liver from a deceased donor is split and the left lobe or left lateral segments are used for a paediatric recipient and the right lobes are used for an adult recipient (Figure 81.15).

When removing the donor kidneys care is taken to ensure that any polar renal arteries are included on an aortic patch with the renal artery (Figure 81.16). In older kidney donors with atherosclerosis the aortic segment may be too diseased to use as an arterial patch and the donor renal artery and any polar arteries are divided shortly after their origin and if necessary reconstructed prior to implantation (Figure 81.17). In the case of the pancreas, a Y graft of donor iliac artery is excised and used to reconstruct the divided splenic and superior mesenteric arteries of the graft prior to implantation (Figure 81.18).

In DCD donors there is an inevitable period of warm ischaemia (up to 45 minutes is acceptable) between the diagnosis of death (cardiorespiratory arrest) and cold perfusion of the organs. The aim during organ recovery is to minimise the period of

---

**Figure 81.15** An adult liver may be split (according to Couinard’s segments) so that the left lateral segment (segments II and III) can be transplanted into a child and the right lobe (together with segment IV) can be transplanted into an adult. CHD, common hepatic duct; FL, falciform ligament; HA, hepatic artery (on aortic patch); IVC, inferior vena cava; LHD, left hepatic duct; LHV, left hepatic vein; LPV, left portal vein; RHA, right hepatic artery; RPV, right portal vein.

**Figure 81.16** Deceased donor kidney with multiple renal arteries on an aortic patch. The aortic patch has been shortened to limit the length of the anastomosis needed when joining the donor patch to the side of the recipient external iliac artery (Medical Photography, Addenbrooke’s Hospital).

---

Rudolph Pichlmayr, 1932–1997, surgeon of Hannover, Germany.
warm ischaemia although the approach used differs according to whether the donor is a controlled or uncontrolled DCD donor. It is important to note that only around 50 per cent of all patients considered as potential controlled DCD donors have a cardiopulmonary arrest within the period of time (usually 2 hours) considered practicable for the surgical team to stand by for organ recovery. After cardiorespiratory arrest there is an obligatory ‘hands off’ period before certification of death of at least 5 minutes before the surgical procedure for organ recovery can begin. If not already in the operating theatre, the DCD donor is transferred immediately to the operating room and the abdomen opened to allow rapid cannulation of the aorta and cold perfusion of the organs to be recovered. In the case of uncontrolled DCD donors the warm ischaemic time can be minimised by rapid insertion of a double balloon catheter introduced into the aorta via a femoral cut-down and used to cool the kidneys in situ by chilled perfusate preferably within 30 minutes of circulatory arrest (Figure 81.19). This allows time to gain consent from relatives for organ donation to proceed if it is not already available and to assemble the surgical team for organ recovery.

After removal from the donor, the organs may undergo a further flush with chilled preservation solution before they are placed in double or triple sterile bags and stored at 4°C by immersion in ice while they are transported to the recipient centre and await implantation. Once the donor organs have been excised, samples of donor spleen and mesenteric lymph nodes are obtained for confirmation of tissue type and use in the cross-match test.

Various organ preservation solutions are available for flushing organs before cold storage. They all contain impermeants to limit cell swelling, buffers to counter acidosis and electrolytes, the composition of which reflects that of intracellular rather than extracellular fluid. Commonly used preservation solutions include University of Wisconsin (UW) solution and Euro-Collins solution, but there are many others. The use of UW solution (Table 81.6) (developed by Belzer and colleagues in Wisconsin, USA) is particularly effective for liver grafts, and after perfusion with UW the liver can be stored safely for up to 24 hours. The length of time for which an organ can be stored before transplantation varies depending on the type of organ (Table 81.7). Although minimising the duration of organ storage is important for all organs, it is essential that organs from DCD donors are transplanted with the minimum possible cold storage time. Most organs for transplantation are stored by static cold storage in an ice box. However, there is a recent trend towards storing deceased donor kidneys by pulsatile machine perfusion where the kidneys are placed inside a purpose-designed perfusion machine that pumps cold preservation solution through the renal artery in an attempt to reduce ischaemic injury. Machine perfusion can be started immediately after removal from the donor.
after kidney recovery or as soon as practicable thereafter and is usually continued until the time of implantation. The benefit of machine perfusion over simple cold storage is currently the subject of considerable debate.

**Living kidney donors**

Living-donor renal transplants account for around 30 per cent of the total renal transplant activity in the UK, but in some countries (notably the Scandinavian countries and the US) this figure is much higher (>50 per cent). The justification for living-donor renal transplantation is based on the shortage of deceased donor transplants and the superior results obtained. Traditionally most living-donor transplants were between genetically related individuals. However, living donor kidney transplants performed between genetically unrelated individuals also fare better than even well-matched deceased donor grafts, and this observation gave rise to a steady increase in living unrelated kidney transplantation activity, usually between spouses or partners. It is essential to ensure that in all cases of living donation the prospective donor is fully informed and is free from coercion to donate and that the risk to the donor is small.

In the UK, all living donor transplants (irrespective of whether they are genetically related or not) require prior approval by the Human Tissue Authority (HTA). An independent person (one not associated with the transplant team) approved by the HTA must provide confirmation to the HTA that the donor and recipient understand the implications of the proposed operation and that there is no evidence of coercion or financial inducement.

Live donation should proceed only after the prospective donor has undergone rigorous assessment to ensure that they are suitable. Before the donation, it is essential to perform imaging (usually magnetic resonance angiography or computed tomography-guided angiography), to delineate the anatomy of the arterial supply to the kidneys. If the left kidney has a single renal artery (10 per cent of kidneys have two or more renal arteries), it is usually chosen for transplantation because the longer left renal vein simplifies the transplant operation. The presence of multiple renal arteries does not necessarily preclude donation although implantation of living donor kidneys with multiple renal arteries may increase the chances of vascular complications developing after implantation.

Live donor nephrectomy was historically undertaken either through a loin incision and retroperitoneal approach or through a midline abdominal incision and transperitoneal approach. In most transplant units, nephrectomy is now undertaken laparoscopically (totally laparoscopic or hand-assisted). Laparoscopic nephrectomy is associated with less wound pain in the donor, allows more rapid mobilisation after surgery and reduces hospital stay. Initial concerns that kidneys removed by the laparoscopic technique may have more ureteric complications after implantation have proven unfounded. After removal from the donor the kidney is flushed immediately with chilled organ preservation solution (Figure 81.20). The mortality rate for live donation is less than 0.05 per cent, and around one-half of reported deaths are due to pulmonary embolic disease so it is essential to ensure prophylaxis to reduce deep-vein thrombosis (DVT). The major complication rate after live donor nephrectomy is <5 per cent: potential complications include haemorrhage requiring blood transfusion or surgery, infection (chest, abdomen, renal tract and wound), damage to an intra-abdominal viscus, adverse reaction to drugs and anaesthetic agents, and DVT and pulmonary embolus.

(Assuming zero warm ischaemic time and organs obtained from a non-marginal donor.)

The University of Wisconsin is at Madison, WI, USA.

Fokert O Belzer, 1931–1995, a surgeon of Madison, WI, USA.
In the long term, kidney donors may be at increased risk from hypertension and donors should have their blood pressure and urine checked annually.

Around 35 per cent of potential living donor transplant recipients will be ABO blood group incompatible with their intended donor and until recently this precluded transplantation. However, there are now two potential solutions to this problem. The first is ‘paired donation’ where incompatible donor/recipient pairs exchange kidneys between pairs to allow ABO-compatible transplantation (Figure 81.21). Recruitment of more than two pairs to facilitate ‘pooled donation’ increases the likelihood of matching donors with compatible recipients and while such schemes pose considerable logistic challenges they are now operating successfully in several countries. An alternative approach is to transiently deplete ABO antibodies from potential recipients by passing their blood through special absorption columns or by performing plasmapheresis along with administration of pretransplant immunosuppressive agents (Figure 81.22). Perhaps surprisingly, graft outcome following desensitisation is similar to that after paired donation. Both paired donation and antibody depletion strategies are also potentially applicable to recipients in whom HLA antibodies preclude transplantation from an intended living donor, but graft survival after depletion of HLA antibodies is lower than when the recipient receives a kidney from an HLA antibody-compatible donor.

**Living liver donors**

Living donor liver transplantation is now undertaken in a number of transplant centres worldwide and is relatively common practice in some countries where deceased donation is not practised for cultural or religious reasons, notably Japan and Korea. The concept was first pioneered to allow children to receive the left lobe or left lateral segment from an adult donor and has been very successful. It has now been extended to adult-to-adult live liver transplantation (Figure 81.23). The majority of such transplants require a right liver lobe to provide adequate hepatic function. For adult-to-adult live liver donation, the donor procedure has a reported mortality rate of around 0.5 per cent and a major complication rate of up to 15 per cent. One of the more common donor complications is bile leak.

**Living donors: other organs**

Occasionally, living donors have provided segments of pancreas, small bowel and lung for transplantation, but this is more controversial. In the United States, living donor combined kidney and segmental pancreas transplantation has been undertaken to treat insulin-dependent diabetics with end-stage renal disease. In occasional patients, living-donor small bowel transplantation has been performed using a small bowel graft, which comprises a length of around 1.5 m of ileum. Finally, a small number of living-donor segmental lung transplants have been performed. To provide sufficient pulmonary tissue without compromising the donor, it is necessary to use segments from two different donors for each recipient. The ethical issues raised by living donation for extrarenal organs are understandably complex.

**Resumption of function following organ transplantation**

It is crucial that following heart, lung or liver transplantation the transplanted organ resumes satisfactory function immediately. If primary non-function occurs, the only option is rapid retransplantation. After kidney, pancreas or small bowel transplantation, immediate graft function is desirable but not vital. The factors that determine the functional integrity of a transplanted organ are shown in Summary box 81.7. Kidneys

---

**Summary box 81.7**

**Factors determining organ function after transplantation**

- **Donor characteristics**
  - Extremes of age
  - Presence of pre-existing damage in transplanted organ
  - Haemodynamic and metabolic instability
- **Procurement-related factors**
  - Warm ischaemic time
  - Type of preservation solution
  - Cold ischaemic time
- **Recipient-related factors**
  - Technical factors relating to implantation
  - Haemodynamic and metabolic stability
  - Immunological factors
  - Presence of drugs that impair transplant function
that the right lobe can be transplanted into an adult recipient. "Figure 81.23 Living donor hepatectomy. A CUSA (cavitron ultrasonic aspirator) is being used to divide the right and left lobes of the liver so that the right lobe can be transplanted into an adult recipient.

obtained from DCD donors invariably suffer a variable degree of ischaemic damage, and delayed graft function is more common (typically 50 per cent for category 3 DCD donors) than for kidneys obtained from DBD deceased donors (typically 25 per cent). Irreversible ischaemic necrosis occasionally occurs and the graft never functions adequately (primary non-function). However, graft survival results for kidneys from controlled DCD donors are similar to those obtained from DBD deceased donors. Livers obtained from DCD donors have an increased incidence of primary non-function and of biliary complications, including biliary anastomotic strictures, bile leak and ischaemic cholangiopathy.

KIDNEY TRANSPLANTATION

Patient selection
Renal transplantation is the preferred treatment for many patients with end-stage renal disease because it provides a better quality of life for them than dialysis. Transplantation releases patients from the dietary and fluid restrictions of dialysis and the physical constraints imposed by the need to dialyse. Transplantation is also more cost-effective than dialysis and improves patient survival.

In the UK, around 100 people per million of the population develop end-stage renal disease, and the incidence increases with age. The causes of end-stage renal disease are numerous and include the following:
- glomerulonephritis;
- diabetic nephropathy;
- hypertensive nephrosclerosis;
- renal vascular disease;
- polycystic kidney disease;
- pyelonephritis;
- obstructive uropathy;
- systemic lupus erythematosus;
- analgesic nephropathy;
- metabolic disease (oxalosis, amyloid).

Frequently, the primary cause of end-stage renal disease is uncertain. For renal transplantation, as for other types of organ transplantation, careful patient selection is essential. Before acceptance as suitable candidates on the transplant waiting list, a transplant surgeon and nephrologist should formally assess all patients. A significant number of patients are likely to be considered unsuitable for renal transplantation because of major comorbid disease, especially cardiovascular disease. In the UK, around 30-40 per cent of the dialysis population are on the waiting list for renal transplantation.

The nature of the primary renal disease does not generally affect the decision to proceed to transplantation. Many of the glomerulonephritides (especially IgA, focal segmental glomerulosclerosis, and mesangiocapillary glomerulonephritis types I and II) may recur in a kidney transplant, and sometimes can lead to early graft failure (especially focal segmental glomerulosclerosis). In the case of primary oxalosis, combined kidney and hepatic transplantation is usually undertaken to eliminate the metabolic defect and thereby prevent early graft failure from the formation of further oxalate stones.

The age of patients with end-stage renal failure accepted for dialysis has gradually risen over the last two decades, and in the UK the mean age of patients starting dialysis is around 70 years. There is no absolute upper age limit to renal transplantation, but inevitably older patients (over the age of 65 years) are less likely to be considered suitable candidates because of major cardiovascular and other comorbid disease.

A careful assessment of comorbid disease that might significantly reduce the chances of successful outcome after transplantation is essential (Summary box 81.8). Rigorous evaluation of the cardiovascular system is particularly important. Cardiovascular disease is very common in the dialysis population, especially those with diabetes, and is the major cause of death after transplantation. Before listing patients for transplantation, it is important to ensure that their urinary tract is functional and that there is no need for corrective urological surgery. Only when there is intractable renal sepsis or very large polycystic kidneys that intrude into both iliac fossae is native nephrectomy required before transplantation (Figure 81.24). Finally, the prospective transplant recipient must be deemed able to cope with the psychological consequences of transplantation and likely to comply with immunosuppressive therapy.

Summary box 81.8
Evaluation of potential recipients for organ transplantation
- Evaluation undertaken by appropriate multidisciplinary team including surgeon and physician
- Determine presence of comorbid disease
- Exclude malignancy and systemic sepsis
- Evaluate against organ-specific criteria for transplantation
- Determine probable ability to cope psychologically with transplant and comply with immunosuppression
- Evaluate need for any preparative surgery needed to facilitate transplantation
- Optimise recipient condition prior to transplantation

---

PART 11 | TRANSPLANTATION

Kidney transplantation 1423

13-81-B&L_26th-P113_Ch81-cp.indd 1423
10/09/2012 12:02
Immunosuppressive therapy impairs the protective response to both malignancy and infection. Consequently, pre-existing malignancy is an absolute contraindication and, even after curative treatment, transplantation should not usually be considered for at least three years. Similarly, the presence of active infection is a contraindication to transplantation.

**Technique of renal transplantation**

The transplant kidney is placed in the iliac fossa, in the retropertitoneal position, leaving the native kidneys in situ. After induction of general anaesthesia, a central venous line and a urinary catheter are inserted. It is helpful to distend the bladder with saline containing methylene blue to allow it to be identified with certainty prior to ureteric implantation. A curved incision is made in the lower abdomen and, after dividing the muscles of the abdominal wall, the peritoneum is swept upwards and medially to expose the iliac vessels. These are dissected free so that they can be controlled with vascular clamps. The kidney is then removed from ice and the donor renal vein is anastomosed end-to-side to the external iliac vein. The donor renal artery on a Carrel patch of donor aorta is anastomosed end-to-side to the external iliac artery (Figure 81.25a). If the donor renal artery lacks an aortic patch, as in the case of a living-donor transplant, it may be preferable to anastomose the donor artery end-to-end to the recipient internal iliac artery (Figure 81.25b). While the vascular anastomoses are being undertaken, the kidney is kept cold by application of topical ice.

Following completion of the venous and arterial anastomoses, the vascular clamps are removed and the kidney is allowed to reperfuse with blood. The ureter, which is kept reasonably short to avoid the risk of distal ischaemia, is then anastomosed to the bladder (Figure 81.26). This is achieved by direct implantation of the ureter into the dome of the bladder with a mucosa-to-mucosal anastomosis followed by closure of the muscular wall of the bladder over the ureter to create a short tunnel, the Lich–Gregoir technique. A double-J ureteric stent should be left in situ, to reduce the risk of urine leak or early obstruction, and removed after several weeks by cystoscopy. If the donor ureter is too short to reach the bladder, the native ureter can be divided...
and the distal segment anastomosed to the ureter or renal pelvis of the donor kidney. The proximal segment of the native ureter can usually be ligated and the native kidney left in situ without causing a problem. Before closing the transplant wound, it is very important to ensure that the kidney is lying in a satisfactory position without kinking or torsion of the renal vessels. In small children receiving an adult donor kidney, the abdomen is opened through a midline incision and the graft is placed intra-abdominally with anastomosis of the renal vessels to the aorta and vena cava.

**Technical complications**

**Vascular complications**

The incidence of vascular complications after renal transplantation is quite low. Renal artery thrombosis occurs in approximately 1 per cent of cases. Renal vein thrombosis is more common (up to 5 per cent of cases) and, although sometimes due to technical error, the aetiology is often uncertain. It presents during the first week after transplantation with sudden pain and swelling at the site of the graft. The diagnosis is confirmed by Doppler ultrasonography. Urgent surgical exploration is indicated, and in most cases transplant nephrectomy is required. The incidence of renal vein thrombosis can be minimised by giving low-dose heparin or aspirin prophylaxis. Renal artery stenosis usually presents late (often years) after transplantation with increasing hypertension and decreasing renal function. It may occur in up to 10 per cent of grafts and is diagnosed by angiography. Renal artery stenosis is best treated by angioplasty, but if angioplasty fails or is not technically possible then the condition can be treated successfully by open surgery and vascular reconstruction.

**Urological complications**

Urological complications occur in around 5 per cent of patients in the early post-transplant period, but their incidence can be reduced markedly by leaving a temporary ureteric stent in situ. Urinary leaks result from technical errors at the ureteric anastomosis or because of ureteric ischaemia. They present with discomfort and leakage of urine from the wound and usually require surgical intervention and reimplantation of the ureter into the bladder or anastomosis of the transplant ureter to the ipsilateral native ureter. Obstruction of the transplant ureter may occur early or late. Causes of obstruction include technical error, external pressure from a haematoma or lymphocele and ischaemic stricture. Ureteric obstruction presents with painless deterioration in graft function and is confirmed by demonstrating hydronephrosis and ureteric dilatation on ultrasound examination. Initial treatment is by percutaneous antegrade nephrostomy and insertion of a stent. Some ureteric strictures may be amenable to treatment by balloon dilatation but most are best treated by surgical intervention, reimplanting the donor ureter into the bladder or anastomosing it to the native ureter.

**Lymphocele**

Peritransplant lymphoceles are usually asymptomatic, but occasionally they become large enough to cause ureteric obstruction or oedema of the ipsilateral leg. Initial treatment is usually by ultrasound-guided percutaneous drainage. In the case of large or recurrent lymphoceles, surgical intervention may be needed to drain a persistent lymphocele into the peritoneal cavity, and this can often be achieved by an ultrasound-guided laparoscopic approach.

**Investigation of graft dysfunction**

Graft dysfunction (Summary box 81.9) during the early postoperative period is a common problem. Possible causes are:

- acute tubular necrosis;
- arterial/venous thrombosis;
- urinary leak/obstruction;
- CNI toxicity;
- hyperacute/accelerated acute rejection.

### Summary box 81.9

**Causes of allograft dysfunction**

**Early**

- Primary non-function (irreversible ischaemic damage)
- Delayed function (reversible ischaemic injury)
- Hyperacute and acute rejection
- Arterial or venous thrombosis of the graft vessels
- Drug toxicity (e.g. CNI toxicity)
- Infection (e.g. CMV disease in graft)
- Mechanical obstruction (ureter/common bile duct)

**Late**

- Chronic rejection
- Arterial stenosis
- Recurrence of original disease in graft (glomerulonephritis, hepatitis C)
- Mechanical obstruction (ureter, common bile duct)

Delayed graft function (defined as the need for dialysis post-transplantation) as a result of acute tubular necrosis occurs in around 25 per cent of kidneys from DBD and up to 50 per cent of kidneys from DCD donors, but is uncommon (<5 per cent) following living-donor transplantation. Often, recipients produce significant volumes of urine from their native kidneys, making the diagnosis of delayed graft function more difficult. The incidence of delayed function can be minimised by optimising donor management before kidney procurement and reducing the cold ischaemia time by avoiding unnecessary delay before implantation. As a first step in the management of early graft dysfunction, the urinary catheter should be irrigated in case it is occluded by a blood clot. Hypovolaemia, if present, should be corrected with the aid of central venous pressure (CVP) monitoring. A Doppler ultrasound examination of the graft is the single most important investigation as it allows exclusion of vascular thrombosis and urinary obstruction as causes of graft dysfunction. Renal radionuclide scanning provides information on renal perfusion and excretion and may be helpful but is used infrequently. If graft dysfunction is still present after several days, it is usual to perform an ultrasound-guided needle biopsy of the kidney to ensure that graft rejection is not present and then to repeat the investigation every week or so until graft function occurs. CNI toxicity may cause graft dysfunction and it is important to monitor CNI blood levels to avoid nephrotoxicity. Acute tubular necrosis usually resolves within the first 4 weeks of transplantation, but a small number of grafts (<5 per cent) suffer primary non-function (i.e. never function).
Allograft dysfunction developing late (>1 month after transplant) may be due to:

- acute/chronic rejection;
- drug toxicity;
- ureteric obstruction (lymphocele/ureteric stricture);
- recurrent disease;
- urinary tract infection.

Blood levels of cyclosporine or tacrolimus are assessed to ensure that they are not unduly elevated, and ultrasound examination of the graft is performed to determine whether ureteric obstruction is present. If obstruction is detected, it is further investigated by percutaneous antegrade pyelography and treated as outlined above. If there is uncertainty about the cause of graft dysfunction, transplant biopsy should be performed to establish whether allograft rejection is present.

Outcome after transplantation
The results of organ transplantation (Summary box 81.10) are generally defined in terms of patient and graft survival. Patient survival after deceased donor renal transplantation is >95 per cent at one year and >85 per cent at five years. Graft survival is around 90 per cent at one year and 80 per cent at five years. Graft survival after a second transplant is only marginally worse than after a first graft. After living-related kidney transplantation, overall graft survival is around 95 per cent at one year and 85 per cent at five years. Graft survival after transplantation can also be expressed in terms of the half-life of the graft. The half-life of grafts obtained from living donors is substantially longer than that of DD grafts:

- deceased donor grafts, 13 years;
- living-unrelated grafts, 15 years;
- living-haploidentical grafts, 16 years;
- living-identical sibling grafts, 27 years.

Summary box 81.10

Outcome after transplantation
- Transplantation improves the quality and duration of life in most recipients
- Transplant outcome has improved progressively over the last two decades and continues to improve
- Improved outcome is due to better immunosuppression, organ preservation, chemotherapy and technical advances
- Graft survival after kidney, liver and heart transplantation is >90 per cent at one year and >80 per cent at five years
- The results of lung and small bowel transplantation are less good
- Chronic rejection is the most common cause of graft failure after all types of solid-organ transplant
- Recurrence of the original disease necessitating transplantation may also lead to graft failure
- Death with a functioning transplant from cardiovascular disease is relatively common
- Up-to-date transplant outcomes for the different organs can be found at the online national and international transplant databases (see end of chapter for website addresses)

If a kidney transplant fails late after transplantation, the graft can often be left in situ and immunosuppression stopped, but transplant nephrectomy may be indicated if the graft is causing symptoms. The operation is undertaken via the original wound, but the kidney is dissected free from the renal capsule and delivered into the wound. The renal vessels are then ligated and divided, leaving behind the original vascular anastomosis.

In addition to graft survival, it is important to consider the extent to which transplantation improves the physical and mental well-being of the patient and allows them to lead a satisfactory social life. In the case of kidney, as in other types of solid organ transplant, successful transplantation undoubtedly leads to a substantial improvement in quality of life. However, although some recipients return to a normal or near-normal life, others fare much less well and, for the group overall, the quality of life after transplantation falls short of that seen in normal healthy individuals. Renal transplantation is best regarded, therefore, as an effective form of therapy rather than a complete cure.

Pancreas transplantation
Successful pancreas transplantation restores normal control of glucose metabolism and obviates the need for insulin therapy in patients with diabetes mellitus. Improved control of blood glucose levels in diabetes reduces the progression of secondary complications such as retinopathy, peripheral vascular disease and nephropathy. However, in considering the indications for pancreas transplantation, these advantages have to be weighed carefully against the risks posed by both the transplant procedure itself and the immunosuppressive therapy required to prevent graft rejection. For most patients with diabetes, the additional risks associated with pancreas transplantation and immunosuppressive therapy are such that the operation can be justified only when kidney transplantation for diabetic nephropathy is also being undertaken. The only additional risks of pancreas transplantation in such patients relate to the transplant operation itself. In the United States, around one-half of all diabetic patients undergoing kidney transplantation also receive a pancreas transplant. In most cases, the kidney and pancreas are obtained from the same donor, so-called simultaneous pancreas and kidney (SPK) transplantation. Pancreas transplantation is sometimes performed in patients who have already undergone successful kidney transplantation, pancreas after kidney (PAK) transplantation. Occasionally, pancreas transplantation alone (PTA) can be justified to treat life-threatening diabetic complications such as hypoglycaemia unawareness.

Careful patient selection is essential to avoid excessive mortality and morbidity. The procedure is usually reserved for those patients with type I diabetes who are relatively young (under the age of 55 years) and do not have advanced coronary artery disease or peripheral vascular disease. Investigation of the heart’s response to stress, either using echocardiography or nuclear medicine imaging is mandatory.

Surgical technique
The whole pancreas gland together with a segment of duodenum is transplanted, essentially as pioneered by Lillehei in 1966. Segmentsal pancreas transplantation is performed only occasionally. SPK transplantation is usually performed through a midline incision (Figure 81.27). The pancreas graft is placed intraperitoneally in the pelvis, usually on the right, and the
is one cause. Urinary drainage has the advantage, after PTA graft rejection. Serum lipase and amylase levels are useful indicators of conversion to enteric drainage. Most centres now prefer bladder drainage, urinary complications are common, and in around 20 per cent of cases their severity necessitates conversion to enteric drainage. Most centres now prefer primary enteric drainage after SPK transplantation. Acute rejection after SPK transplantation is relatively common (10–20 per cent) and if detected early responds to treatment with steroids. Since it usually involves both the kidney and pancreas graft, serum creatinine can be used as a surrogate marker for pancreas graft rejection. Serum lipase and amylase levels are useful indicators of pancreas graft inflammation of which acute rejection is one cause. Urinary drainage has the advantage, after PTA and PAK transplantation, of allowing pancreas graft rejection to be monitored by serial measurement of urinary amylase. A fall in urinary amylase is indicative of acute rejection. Elevation of blood glucose level is a late feature of acute rejection and often indicates the process is beyond reversal.

**Results of pancreas transplantation**

The principal aim of pancreas transplantation is to prolong life in diabetic patients who otherwise have a high mortality at ten years after receiving a kidney transplant alone. It also provides freedom from insulin treatment and improves quality of life.

The results of pancreas transplantation have improved significantly over the last decade. After SPK transplantation, the one-year patient survival rate is greater than 95 per cent and the one-year graft survival rates for pancreas and kidney grafts are 85 and 95 per cent, respectively. Most deaths are due to cardiovascular complications or overwhelming infection. Patient and kidney graft survival after SPK transplantation in patients with diabetic nephropathy is at least as good as after kidney transplant alone in this group. The results of PTA are not as good as after SPK transplantation (one-year pancreas graft survival 75 per cent) because acute rejection is more difficult to monitor in the absence of a kidney allograft.

**Transplantation of isolated pancreatic islets**

Treatment of diabetes by transplantation of isolated islets of Langerhans is a more attractive concept than vascularised pancreas transplantation because major surgery and the potential complications of transplanting exocrine pancreas are avoided. Pancreatic islets for transplantation are obtained by mechanical dispersing the pancreas after injection of collagenase into the pancreatic duct. The islets are then purified from the dispersed tissue by density-gradient centrifugation and can be delivered into the recipient liver (the preferred site for transplantation) by injection into the portal vein. Until recently, human islet transplantation had been performed intermittently and with very disappointing results. However, in 2000, Shapiro and colleagues in Edmonton, Canada, reported success with islet transplantation in seven patients with type 1 diabetes. Sequential islet transplantation from two or three donor pancreas glands was required to produce insulin independence, and although the long-term success is less than initially hoped for, some patients remained free from exogenous insulin and other units are now undertaking islet transplantation with variable results.

As an alternative to preventing islet rejection through immunosuppressive therapy, attempts have been made to protect isolated islet cells from rejection by encapsulating them inside semipermeable membranes. The protective membranes are designed with a pore size that allows insulin to pass through but prevents antibodies and leukocytes from reaching the islets, thereby avoiding the need for immunosuppressive therapy. A major attraction of this approach is that islets isolated from animals can be used and biosynthetic pancreas grafts containing xenogenic islets are currently under evaluation.

**LIVER TRANSPLANTATION**

Starzl first attempted liver transplantation in 1963 and, by 1967, had achieved prolonged survival. The first liver transplant...
performed outside the US was performed in Cambridge, UK by Calne in 1968. Throughout the 1970s, liver transplantation remained a hazardous procedure that frequently failed. However, since then, the results have progressively improved as a result of better patient selection, improved immunosuppression and chemoprophylaxis, better organ preservation, refinements in the operative technique, and advances in per- and postoperative management.

**Indications and patient selection**

The indications for liver transplantation fall into four groups:

1. Cirrhosis;
2. Acute fulminant liver failure;
3. Metabolic liver disease;
4. Primary hepatic malignancy.

The most common indication for transplantation is chronic liver failure. In adults, the most common causes are alcoholic liver disease, viral liver disease (hepatitis C in Europe and the US and hepatitis B in some other countries), non-alcoholic steatohepatitis, primary biliary cirrhosis and sclerosing cholangitis. In children, who account for around 10–15 per cent of all liver transplants, biliary atresia is the most common indication for transplantation. Acute fulminant liver failure requiring transplantation on an urgent basis accounts for approximately 10 per cent of liver transplant activity and is usually viral or drug induced (e.g., paracetamol overdose in the UK). There are a variety of metabolic diseases for which transplantation offers the prospect of cure. These include Wilson’s disease, oxalosis and familial amyloid polyneuropathy. Primary hepatic malignancy is more common in patients with cirrhosis, especially virally induced disease, and may be best treated by transplantation because the field changes in the cirrhotic liver predispose to further primary malignancies. Cholangiocarcinoma has a high recurrence rate and is seldom an indication for liver transplantation.

**Technique of liver transplantation**

A transverse abdominal incision with a midline extension is usually made and the diseased liver is mobilised (Figure 81.28). Because of portal hypertension, the recipient hepatectomy is often the most difficult part of the operation, especially if there has been previous upper abdominal surgery. The common bile duct is divided, as is the hepatic artery. The inferior vena cava is clamped and divided above and below the liver, and the portal vein is clamped and divided, allowing the recipient liver to be removed. Occlusion of the vena cava and portal vein results in a reduction in cardiac output and may necessitate the use of venovenous bypass. The bypass circuit delivers blood from the inferior vena cava and/or portal vein and back to the heart via a cannula inserted into the internal jugular vein. After placing the donor liver in position, the supra- and infrahepatic caval anastomoses are performed. The portal vein and the hepatic arterial anastomoses are then completed and the graft is reperfused. Finally, biliary drainage is re-established usually by a duct-to-duct anastomosis (without the use of a T-tube). It may be necessary, for example in recipients with biliary atresia or sclerosing cholangitis, to reconstruct the biliary drainage by a bile duct to Roux loop anastomosis. An alternative caval preservation technique of liver transplantation allows the recipient liver to be removed without cross-clamping the vena cava and the donor liver to be implanted using a ‘piggyback’ technique onto the recipient hepatic veins or using a side-to-side cavocavoplasty.

Many patients undergoing liver transplantation are extremely ill, and the surgery involved can be very technically demanding. Optimal perioperative management is crucial to a successful outcome and presents a major challenge. Blood loss during and after the transplant procedure can be very considerable, and management of coagulopathy is particularly important. Coagulation is assessed repeatedly throughout the transplant period and corrected with appropriate clotting factors. Many centres routinely use a thromboelastography to perform dynamic assessment of coagulation (Figure 81.29). In the most widely used system (rotational thromboelastography) this involves placing a blood sample in a small cuvette and then inserting a sensor pin that is subjected to rotational torsion and as clot between the cuvette and the pin forms, the resulting signal is displayed graphically and indicates the speed and strength of clot. Various modifications can be made to the test conditions to maximise the information provided.

---

**Figure 81.28** (a) Incision used for liver transplantation. (b) Completed implantation. The anastomoses, in order of performance, are: (1) suprahepatic cava; (2) infrahepatic cava; (3) portal vein; (4) hepatic artery; (5) bile duct.

**Figure 81.29** Thromboelastogram situated in the operating theatre and used to measure coagulation serially throughout the liver transplant procedure and guide administration of blood products.

---

Thomas Earl Starzl, Professor of Surgery, Pittsburgh, PA, USA.
Samuel Alexander Kinner Wilson, 1878–1936, Professor of Neurology, King’s College Hospital, London, UK, described this condition in 1912.
Technical complications

Haemorrhage

Meticulous haemostasis during the transplant operation is important in order to minimise the risk of early haemorrhage. It may be necessary, occasionally, to pack the peritranplant area for 2–3 days to achieve adequate haemostasis when there is diffuse oozing despite correction of coagulopathy. Evacuation of extensive perihepatic haematoma may be required to avoid secondary infection.

Vascular complications

Heaptic artery thrombosis may occur spontaneously or as a result of acute rejection and is more common in paediatric recipients and in adults with primary sclerosing cholangitis. It may present as a rise in serum transaminase levels, unexplained fever or bile leak. Doppler ultrasonography or angiography is used to confirm the diagnosis, and urgent retransplantation is usually required. Portal vein thrombosis is rare and presents with the features of portal hypertension.

Biliary complications

Biliary leaks are now relatively uncommon and biliary stenosis is the more common problem. It usually occurs within the first few months of transplantation and is managed by endoscopic dilatation and stenting or by surgical correction.

Outcome after liver transplantation

The outcome after liver transplantation depends on the underlying liver disease and the best results are seen in patients with chronic liver disease (Figure 81.30). Patients undergoing transplantation as a result of acute liver failure have a higher mortality in the early post-transplant period because of multiorgan failure, but those who make a satisfactory recovery have very good long-term liver allograft survival. Conversely, patients transplanted for tumour have a very good early outcome but ultimately fare much less well because of recurrent malignancy. Patients receiving a liver transplantation following hepatitis B or hepatitis C infection may develop graft failure as a result of recurrent viral disease. However, the availability of improved antiviral therapy has largely eliminated this problem in recipients with hepatitis B infection.

SMALL BOWEL TRANSPLANTATION

Progress in small bowel transplantation has lagged behind that of other types of organ transplantation but it is now a well-established therapy for highly selected recipients. Intestinal transplants stimulate a particularly strong graft rejection response, probably because the small intestine contains very large amounts of lymphoid tissue. Moreover, ischaemia and rejection increase intestinal permeability and allow translocation of bacteria from the lumen of the bowel. Added to this, the operation is often complex and is made technically difficult because of repeated previous abdominal surgery. Consequently, graft rejection and infection remain major problems after small bowel transplantation and the results obtained are inferior to those seen after other types of organ transplantation. Small bowel transplantation is a treatment option for patients with intestinal failure to an extent that long-term parenteral nutrition is required. Intestinal failure may result from short bowel syndrome after resection of the intestine or from intestinal dysfunction. Conditions that may give rise to intestinal failure include the following:

- intestinal atresia;
- necrotising enterocolitis;
- volvulus;
- disorders of motility;
- mesenteric infarction;
- Crohn’s disease;
- trauma;
- desmoids tumours.

Because of the substantial risks associated with small bowel transplantation, the procedure is only considered for those patients in whom long-term total parenteral nutrition (TPN) has failed, usually because venous access has become impracticable or because of frequent life-threatening line sepsis. The need for small bowel transplantation is estimated at around 0.5–1.0 patients per million of the population, and around 50 per cent of cases are children.

Small bowel transplantation may be carried out as an isolated procedure, performed together with a liver transplant or undertaken as a component of a multivisceral transplant. When possible, isolated small bowel transplantation is undertaken because patient survival is higher.

A small bowel transplant from a deceased donor comprises the entire small bowel, and may include the ascending colon in the graft. The superior mesenteric artery of the graft (with an aortic patch) is anastomosed to the recipient aorta, and the superior mesenteric vein is anastomosed to the inferior vena cava or to the side of the portal vein. The proximal end of the small bowel graft is anastomosed to the recipient jejunum or duodenum. The distal end of the graft is anastomosed to the side of the colon (with a loop ileostomy) or is fashioned as an

Figure 81.30 Outcome after liver transplantation according to the initial liver disease. Patients transplanted for acute liver disease have a higher early mortality but good long-term outcome. Patients transplanted because of liver tumour have a good initial outcome but survival continues to decline progressively [courtesy of Gerhard Opelz, Collaborative Transplant Study, L-75101-0211].
end ileostomy. A gastrostomy tube (to overcome delayed gastric emptying) and a feeding jejunostomy tube are inserted.

About one-half of all patients who require small bowel transplantation have cholestatic liver disease secondary to TPN and require combined liver and small bowel transplantation. Cholestatic liver disease due to TPN is especially common in children. When combined liver and small bowel transplantation is carried out, the two grafts are transplanted en bloc. The donor aorta is fashioned into a conduit including the superior mesenteric and coeliac arteries and anastomosed to the recipient aorta. The portal vein anastomosis is as for isolated liver transplantation (Figure 81.31).

Multivisceral or ‘cluster’ transplants may be necessary in the case of large desmoid tumours when excision of both the small bowel and adjacent organs is required, where there has been extensive thrombosis of the splanchnic vessels and for generalised disorders of gastrointestinal motility.

The one-year graft survival rate after small bowel transplantation is about 70 per cent for both isolated small bowel transplantation and for combined liver and small bowel transplantation. After three years, the graft survival rate is around 50 per cent. As already noted, however, patient survival is better after isolated small bowel transplantation than after combined liver and small bowel transplantation, when loss of the graft usually equates with death of the recipient. Most of the mortality after small bowel transplantation is due to sepsis and multiorgan failure. The risk of infection after small bowel transplantation is heightened by the additional requirements for immunosuppression in order to control graft rejection. This accounts for the relatively high incidence of lymphoproliferative disease (around 10 per cent) observed in patients who have undergone small bowel transplantation. Because of the large amount of donor lymphoid tissue transplanted, GVHD may be an added complication. Despite the hazards, small bowel transplantation offers patients with intestinal failure a chance to lead an active life free from the constraints of long-term nutritional support.

**THORACIC ORGAN TRANSPLANTATION**

**Heart transplantation**

Dr Christian Barnard performed the first human heart transplant in Cape Town, South Africa, in 1967. The operation was based on the experimental work of Lower and Shumway in Stanford, and Shumway subsequently went on to pioneer successful cardiac transplantation in the clinic. Heart transplantation is now considered an effective treatment for selected patients with end-stage cardiac failure. The most common indications for heart transplantation are ischaemic heart disease and idiopathic cardiomyopathy, but other indications include valvular heart disease, myocarditis and congenital heart disease.

Transplantation is considered only in patients with end-stage heart disease that has failed to respond to all other conventional therapy and when predicted survival without transplantation is only 6–12 months. Transplantation is usually limited to patients under the age of 65 years who do not have irreversible damage to other organ systems. The preoperative assessment is rigorous, and measurement of pulmonary vascular resistance is mandatory because when it is raised the perioperative mortality is high.

**Technique of heart transplantation**

A median sternotomy is performed and the patient is given systemic heparin, placed on cardiopulmonary bypass and cooled to 29°C. After cross-clamping the aorta, the recipient heart is excised at the mid-atrial level. The donor heart is then prepared and the left atrium is opened by making incisions (Figure 81.32) in the posterior wall, between the orifices of the pulmonary veins, to create an atrial cuff. The left and then right atrial

![Figure 81.32 Recipient cardiectomy. After median sternotomy, the recipient is placed on cardiopulmonary bypass. Venous cannulae for bypass are sited in the superior vena cava (SVC) and inferior vena cava (IVC) via punctures in the right atrium (RA), and oxygenated blood is returned via a cannula in the ascending aorta (Ao). The diseased recipient heart is excised, leaving behind cuffs of right and left atria. PA, pulmonary artery; IPV/SPV, inferior/superior pulmonary veins; LA, left atrium (courtesy of J Dunning).](image-url)
anastomoses are performed and the pulmonary and aortic arterial anastomoses are then completed (Figure 81.33). The patient is then rewarmed and weaned from cardiopulmonary bypass. Occasionally, heterotopic cardiac transplantation is undertaken, when the donor heart is placed adjacent to and augments the recipient’s own heart.

**Heart-lung, single-lung and double-lung transplantations**

Pulmonary transplantation became a clinical reality when Dr Bruce Reitz performed the first successful combined heart–lung transplant in 1981. Combined heart–lung transplantation is still sometimes performed, usually in patients with pulmonary vascular disease in whom there is cardiac dysfunction due to congenital (e.g. Eisenmenger syndrome, in which the left-to-right shunt is reversed owing to pulmonary hypertension) or acquired cardiac dysfunction. For most patients with end-stage pulmonary disease, however, single- or double-lung transplantation has now replaced heart–lung transplantation. Lung transplantation is more economical in terms of organ use, although if heart–lung transplantation is undertaken for isolated respiratory disease, the healthy native heart can be used for transplantation, the so-called ‘domino procedure’. Heart–lung transplantation is performed through a median sternotomy, taking particular care to avoid injury to the phrenic, vagus and recurrent laryngeal nerves during excision of the recipient heart and lungs. The recipient right atrium and aorta are divided as for orthotopic cardiac transplantation and the donor heart–lung block ready for implantation, incising the right atrium from the divided inferior vena cava. An end-to-end tracheal anastomosis is performed and the right atrial and aortic anastomoses are performed as for cardiac transplantation.

Single- and double-lung transplantation are effective therapies for selected patients with end-stage chronic lung disease, in whom declining lung function limits life expectancy despite optimal medical therapy. Common indications are pulmonary fibrosis, pulmonary hypertension, emphysema and cystic fibrosis. Single-lung transplantation can be performed for pulmonary fibrosis. Single-lung transplantation is performed through a posterolateral thoracotomy and double-lung transplantation through a bilateral thoracotomy or median sternotomy. During lung transplantation, the donor pulmonary veins on a left atrial cuff are anastomosed to the recipient left atrium. Next, the bronchial anastomosis and the pulmonary arterial anastomosis are completed. Cardiopulmonary bypass is usually required if pulmonary hypertension is present. Dehiscence of the airway anastomosis used to be common after heart–lung and lung transplantation, but improvements in organ preservation and surgical technique have dramatically reduced the incidence of this often fatal complication to <5 per cent. Late airway stenosis at the bronchial anastomosis due to ischaemia occurs in around 10 per cent of bronchial anastomoses and is treated by dilatation.

**Outcome after thoracic organ transplantation**

The one- and five-year graft survival rates after heart transplantation are around 85 and 70 per cent, respectively. The results after heart–lung and lung transplantation are less good, with one-year graft survival rates of around 75 per cent and five-year survival rates of around 50 per cent.

**FUTURE PROSPECTS**

The two major problems in organ transplantation are:

1. chronic graft rejection and the side effects of non-specific immunosuppression;
2. the shortage of organs for transplantation.

New immunosuppressive agents that have fewer or different agent-specific side effects than existing therapy are likely to enter clinical practice and there is continuing research into the development of non-invasive biomarkers (in urine or blood) that will allow early diagnosis of graft rejection. A long-standing goal in organ transplantation has been the development of strategies for inducing specific immunological tolerance (Summary box 81.11). Transplantation tolerance would eliminate the need for long-term non-specific immunosuppressive agents, leaving the immune system intact for defence against infection. It has long been possible to induce transplant tolerance in experimental animals with a variety of preconditioning regimens that often involve pretreatment schedules using donor bone marrow cells or donor antigen. So far, however, there is no clinically applicable strategy for inducing transplant tolerance.

**Summary box 81.11**

**Future developments in transplantation**

- Novel immunosuppressive agents
- Non-invasive biomarkers for early diagnosis of graft rejection
- Donor-specific immunological tolerance
- Xenotransplantation
- Stem cell medicine and tissue engineering

---

Bruce Arnold Reitz, thoracic surgeon, Stanford University School of Medicine, Palo Alto, CA, USA.
Norman Edward Shumway, 1923–2006, cardiothoracic surgeon, Stanford University School of Medicine, Palo Alto, CA, USA.
Victor Eisenmenger, 1864–1932, German physician.
The demand for human organs for transplantation is so great that deceased donors cannot ever satisfy it. Many consider that the solution is to perfect xenotransplantation, and there is general agreement that the pig is the most suitable source of xenogeneic organs. However, all humans have preformed antibodies directed against carbohydrate antigens expressed by pig organs, and these cause hyperacute rejection. The dominant carbohydrate antigen responsible is gal-1, 3-α-gal. Progress has been made towards circumventing hyperacute xenograft rejection and pigs that have been genetically engineered not to express the gal-1, 3-α-gal antigen have been produced. However, organs from genetically modified pigs are still rejected within a few weeks by primates, despite the use of potent immunosuppressive agents. In addition to the complex immunological problems posed by xenotransplantation, there is a risk that pig organs may transmit infectious agents, and there is particular concern about the risks posed by porcine endogenous retrovirus (PERV). Lastly, there are unanswered questions regarding the extent to which pig organs are able to fulfil the physiological demands required of them after transplantation into a human.

Finally, looking to the future, there is optimism that human pluripotent stem cells may ultimately provide a source of tissue transplants for treating a wide range of diseases. Attempts are now under way to define the cell signals needed to guide human embryonic and adult-induced pluripotent stem cells to differentiate in vitro into functional tissue of the desired cell type. These include insulin-producing cells, cardiac myocytes and neuronal tissue. Although cell transplantation is the initial goal, by combining the developments in stem cell medicine with those taking place in tissue engineering and biomaterials it may one day be possible to engineer more complex vascularised grafts for transplantation.

*In vitro* is Latin for ‘in the glass’.
Common instruments used in general surgery

This is a list of some of the instruments used in open (as opposed to minimal access surgery) ‘general surgery’ with information on how they are used and about the people associated with them. It is hoped that this information will help the general surgical trainee answer questions on operative surgery in postgraduate examinations.

**Langenbeck retractor.** This small general purpose retractor is useful for holding open wounds, as in an open appendicectomy. They are often used in pairs (one in each of the assistant’s hands). They stay in position best if the handles are lifted slightly so that the tips lock in under the fascia. The width of the lip of the retractors varies. Bernhard Rudolf Konrad von Langenbeck (1810–1887) was Professor of Surgery successively at Kiel and Berlin, Germany. He performed the first internal fixation of a femoral neck fracture in 1850.

**Morris retractor.** This is a big retractor which is useful for giving maximum exposure in large incisions such as those used in the abdomen. It can be used to improve visibility on one side of an incision (by pulling firmly in that direction); so is valuable during the initial phase of a laparotomy. Sir Henry Morris (1844–1926) was a surgeon at the Middlesex Hospital, London, UK.

**Deaver retractor.** This retractor is specifically designed for holding the liver up out of the way during a cholecystectomy. It needs to be used carefully to avoid damaging the liver. Some surgeons protect the liver with an abdominal pack before placing the blade on top. John Blair Deaver (1855–1931) was Professor of Surgery at the University of Pennsylvania Medical School, Philadelphia, PA, USA. He also described a paramedian incision for appendicectomy.

**Dyball retractor.** Used in major abdominal surgery to retract deeper parts of the abdominal wall or the bladder or the uterus while operating on the rectum and entering the rectovesical or rectouterine pouch. It has a lip at the bottom of the blade to prevent slippage. Care should be taken if it is used to retract the liver in operations in the region of the right upper quadrant as it may damage the liver parenchyma. Brennan Dyball was a distinguished West Country surgeon from Exeter. He also excelled as a carpenter and motor mechanic. He died in 1934 at the age of 62 leaving a great professional legacy to the Royal Devon and Exeter Hospital.

**Joll retractor.** This is a self-retaining retractor used in thyroid surgery. After making the collar incision and raising the lower and upper flaps fully, this retractor is then inserted. The two clips on the upper and lower edges are attached to the skin preferably with a swab over the skin edge. The central segment is then unscrewed to separate the two edges to obtain full exposure. Cecil Augustus Joll was a surgeon in London who first qualified as a dentist. He was regarded as ‘a brilliant technician and an extraordinarily versatile surgeon’ who operated on conditions ‘from knees to necks and stomach to perineum’. A keen ornithologist, he was a connoisseur of all things good – furniture, pottery, food, wines and cigars. He died in 1945 at the age of 59.
**APPENDIX 1**

**COMMON INSTRUMENTS USED IN GENERAL SURGERY**

**Goligher retractor.** This is a self-retaining retractor used in operations on the sigmoid colon and rectum, such as anterior resection and upper end of abdominoperineal resection. Once the abdomen has been opened and laparotomy performed, the patient is placed head down and all the small bowel is packed to the upper end of the abdomen. The retractor is then inserted with the side blades to separate the edges of the abdominal wall. The central blade is then inserted to keep the small bowel well tucked away from the operation site. All three blades come in different widths to fit in with the patient’s build. John Cedric Goligher (1912–1998), Ulsterman by birth, Professor of Surgery at Leeds, his contributions to colorectal surgery in the world have been legendary. His operating theatres at Leeds General Infirmary ‘have been the Mecca for surgeons from all over the world’. His book, *Surgery of the Anus, Rectum and Colon*, was regarded as the ultimate authority on the subject and had five editions.

**St Mark’s perineal retractor.** This is used for the perineal part of an abdominoperineal resection. After making the perineal incision and adequate dissection of the perineal wound, the retractor is inserted. As the dissection proceeds, the retractor has to be repositioned. The pointed ends are directed towards the front. St Mark’s Hospital, Harrow, UK, is recognised as a national and international referral centre for intestinal and colorectal disorders. It was founded in a small room in No. 11 Aldersgate Street. Established in 1854 on City Road in Hackney as St Mark’s Hospital for Fistula and other Diseases of the Rectum. It was so named as it was opened on St Mark’s Day, 25 April. In 1994, it moved to its present site in Harrow.

**Travers retractor.** This is a self-retaining retractor used for intermediate-type operations, such as herniorrhaphy, groin dissection for varicose veins and femoral embolectomy. It retracts skin and subcutaneous tissues; as the incision is deepened, the retractor has to be repositioned. If used incorrectly, it can traumatis the skin. For longer incisions, two such retractors may be used, one at each end of the incision for good exposure. Benjamin Travers (1783–1858) was a surgeon to the London Infirmary for Disease of the Eye (now Moorfields Ophthalmic Hospital). He is regarded as the first general hospital surgeon in England to devote himself especially to disease of the eye. He later became surgeon to St Thomas’s Hospital and Vice-President and President of Royal College of Surgeons of England and a Fellow of the Royal Society. As an operator, he was regarded as clumsy and nervous. He had ‘exquisite polish of manners, took off his hat and acknowledged salutes more elegantly than any contemporary dandy’.

**West retractor.** Used in a similar manner to the Travers retractor, this is ideal for minor procedures under local anaesthetic where the surgeon is operating without an assistant, e.g. lymph node biopsy, temporal artery biopsy. After making the incision and undermining the edges, the retractor is then inserted and the jaws are prised open gently. Charles Ernest West (1873–1951) ‘aural surgeon’ of St Bartholomew’s Hospital is credited with devising this retractor. It is possible that he got the idea from Franz Weitlaner, an Austrian physician who published the first description of his retractor in the *Vienna Clinical Review* in 1903. He became known as ‘the great spreader of surgery’. It would be safe to presume that the present retractor is West’s modification of Weitlaner’s spreader.

**Czerny retractor.** This is a double-ended retractor used to retract wound edges for intermediate-type procedures. One end has a blade with a lip which helps to retract without the edge slipping. The other end has two prongs and helps to retract the ends of an incision. When using it, a slight upward tilt gives a better exposure. It is used where a Langenbeck retractor can also be used, but the lip here is broader making it more versatile. Vincenz Czerny (1842–1915) was Professor of Surgery at Freiberg and Heidelberg in Germany. He was a disciple of Theodor Billroth. He was the originator of the concept of multidisciplinary management in cancer.

**McIndoe scissors** are used by surgeons to perform dissection respecting anatomical planes. The closed blades are inserted into a fascial plane, and then gently opened. The tissue to be divided can then be seen clearly and divided without risk of damage to vital structures. Sir Archibald Hector McIndoe (1900–1960) was a plastic surgeon at St Bartholomew’s Hospital, London, and the Queen Victoria Hospital, East Grinstead, UK. He was born in New Zealand (cousin of Harold Gillies) and became a consultant plastic surgeon to the RAF during the Second World War. He supervised the rehabilitation of badly disfigured airmen who later formed the Guinea Pig Club.
DeBakey forceps allow the surgeon to grasp tissues firmly while minimising damage to the tissue held in the jaws of the forceps. They are useful for holding vessel walls in vascular surgery. Michael Ellis DeBakey (1908–2008) was Professor of Surgery at Baylor University College of Medicine, Houston, TX, USA. He was the first to successfully implant an artificial heart; he also performed the first successful carotid endarterectomy.

Gillies forceps have teeth and are ideal for holding tough tissues, such as skin. Sir Harold Gillies (1882–1960) was a plastic surgeon at St Bartholomew’s Hospital, London, UK. He was born in New Zealand (cousin of Archibald McIndoe) and became one of the founders of British plastic surgery. He originated the tubed pedicle flap.

Adson forceps are non-toothed, and so are ideal for holding delicate tissues, such as bowel. Alfred Washington Adson (1887–1951) was Professor of Neurosurgery at the Mayo Clinic, Rochester, MN, USA. He was one of the first to use sympathectomy for the treatment of hypertension, and cervical sympathectomy for Raynaud’s syndrome.

Allis forceps are used to hold soft tissues for a long period while minimising tissue damage. Using the ratchet they can be locked on to tissue, such as bowel, and can be used to provide gentle traction. Oscar Huntington Allis (1836–1921) was a surgeon at the Presbyterian Hospital, Philadelphia, PA, USA.

Babcock forceps. This is used to grasp any part of the bowel. The jaws are atraumatic and cause minimal tissue damage. Used commonly in appendicectomy to grasp the appendix and deliver it out of the wound. Care is taken when using it not to perforate the inflamed appendix. William Wayne Babcock (1872–1963), Professor and Head of the Department of Surgery at the Temple University School of Medicine, Philadelphia for 40 years. ‘He was the inventor of the acorn-shaped vein stripper, introduced the alloy steel wire sutures, wire mesh in hernia repairs, and zinc chloride in the treatment of osteomyelitic sinus’.

Spencer Wells forceps. These were one of the first ratchet forceps ever designed and are still very useful. They are often used in pairs for clamping an artery before dividing it. The cut ends of the artery are then tied off, and the forceps removed (carefully!). Sir Thomas Spencer Wells (1818–1897) was a surgeon at the Samaritan Free Hospital for Women and Children, London, UK. He was one of the earliest surgeons to make use of anaesthetics in operation.

Kocher dissector. This is used during a thyroidectomy to dissect the upper pole of the thyroid. The instrument is blunt and therefore the surgeon is highly unlikely to inadvertently damage the superior thyroid artery or the external laryngeal nerve. It is used to dissect the superior pedicle, the superior thyroid artery. Once it has been isolated, the dissector is pushed under the pedicle. A tie is then put through the eye of the dissector which at this stage doubles up as an aneurysm needle. The pedicle is thus tied three times as close to the gland as possible. With the dissector under the tied pedicle, a fine knife is now used to cut leaving two ties in the patient. The presence of the dissector under the pedicle prevents any damage to the underlying structures. Emil Theodor Kocher (1841–1917), Professor of Surgery at Berne, Switzerland, was awarded the Nobel Prize for Physiology or Medicine in 1909 for his work on the thyroid. The first surgeon to be a Nobel Laureate.

ACKNOWLEDGEMENTS

With thanks to Steven Kerr, Assistant Librarian, Royal College of Surgeons of Edinburgh.
Bailey & Love’s Short Practice of Surgery remains one of the world’s pre-eminent medical textbooks, beloved by generations of surgeons, with lifetime sales in excess of one million copies. Under the guidance of the eminent editors, the expert team of contributors have revised and updated the material throughout while retaining those features praised in previous editions.

The content is sub-divided into parts for ease of reference. Sections devoted to the underlying principles of surgical practice, investigation and diagnosis, and pre-operative care are followed by chapters covering all aspects of surgical trauma. The remainder of the book considers each of the surgical specialties in turn, from elective orthopaedics through skin, head and neck, breast and endocrine, cardiothoracic and vascular, abdominal and genitourinary to transplantation.

Key features:
■ Authoritative – emphasises the importance of effective clinical examination and soundly based surgical principles while taking account throughout of the latest developments in surgical practice
■ Current – text and illustrations fully revised with brand new chapters on patient safety, day care surgery and bariatric surgery
■ Readable – preserves the clear, direct writing style, uncluttered by technical jargon, that has proved so popular in previous editions
■ User-friendly – numerous photographs, explanatory line diagrams, learning objectives, summary boxes, biographical footnotes and memorable anecdotes support and enhance the textual descriptions

The 26th edition of Bailey & Love retains a wide appeal among all those studying surgery, from undergraduate medical students to those in preparation for their postgraduate surgical examinations. In addition, its high standing and reputation for unambiguous advice continue to make it the first point of reference for many practising surgeons.

About the editors:
Norman S. Williams MS FRCS FMedSci is Professor of Surgery and Director of Surgical Innovation, Barts and the London School of Medicine and Dentistry, Queen Mary, University of London and President, The Royal College of Surgeons of England, London, UK

Christopher J.K. Bulstrode MCh FRCS(T&O) is Emeritus Professor, University of Oxford, Oxford, UK

P. Ronan O’Connell MD FRCSI FRCPS Glas is Head, Surgery and Surgical Specialties, UCD School of Medicine and Medical Sciences; Consultant Surgeon, St Vincent’s University Hospital, Dublin, Ireland

This is a specially priced edition, published exclusively for the benefit of students living in newly industrialized countries and those with a developing economy. If you have made your purchase in North America, Europe (excluding Eastern Europe), Japan, Australia or New Zealand, this book is being made available in an unlawful way, without the approval of the Publisher or Authors.
